# Using Your Sybex Electronic Book

To realize the full potential of this Sybex electronic book, you must have Adobe Acrobat Reader with Search installed on your computer. To find out if you have the correct version of Acrobat Reader, click on the Edit menu—Search should be an option within this menu file. If Search is not an option in the Edit menu, please exit this application and install Adobe Acrobat Reader with Search from this CD (double-click on AcroReader51.exe in the Adobe folder).

## Navigation

Navigate through the book by clicking on the headings that appear in the left panel; the corresponding page from the book displays in the right panel.

## Find and Search

To find and search, click  on the toolbar or choose Edit > Find to open the "Find" window. Enter the word or phrase in the "Find What" field and click "Find." The result will be displayed as highlighted in document. Click "Find Again" to search for the next consecutive entry. The Find command also provides search parameters such as "Match Whole Word Only" and "Match Case." For more information on these features, please refer to the Acrobat Help file in the application menu.

Click here to begin using  
your Sybex Electronic Book!

## Software License Agreement: Terms and Conditions

The media and/or any online materials accompanying this book that are available now or in the future contain programs and/or text files (the “Software”) to be used in connection with the book. SYBEX hereby grants to you a license to use the Software, subject to the terms that follow. Your purchase, acceptance, or use of the Software will constitute your acceptance of such terms.

The Software compilation is the property of SYBEX unless otherwise indicated and is protected by copyright to SYBEX or other copyright owner(s) as indicated in the media files (the “Owner(s)”). You are hereby granted a single-user license to use the Software for your personal, noncommercial use only. You may not reproduce, sell, distribute, publish, circulate, or commercially exploit the Software, or any portion thereof, without the written consent of SYBEX and the specific copyright owner(s) of any component software included on this media.

In the event that the Software or components include specific license requirements or end-user agreements, statements of condition, disclaimers, limitations or warranties (“End-User License”), those End-User Licenses supersede the terms and conditions herein as to that particular Software component. Your purchase, acceptance, or use of the Software will constitute your acceptance of such End-User Licenses.

By purchase, use, or acceptance of the Software you further agree to comply with all export laws and regulations of the United States as such laws and regulations may exist from time to time.

### REUSABLE CODE IN THIS BOOK

The author(s) created reusable code in this publication expressly for reuse by readers. Sybex grants readers limited permission to reuse the code found in this publication, its accompanying CD-ROM or available for download from our Web site so long as the author(s) are attributed in any application containing the reusable code and the code itself is never distributed, posted online by electronic transmission, sold, or commercially exploited as a stand-alone product.

### SOFTWARE SUPPORT

Components of the supplemental Software and any offers associated with them may be supported by the specific Owner(s) of that material, but they are not supported by SYBEX. Information regarding any available support may be obtained from the Owner(s) using the information provided in the appropriate read.me files or listed elsewhere on the media.

Should the manufacturer(s) or other Owner(s) cease to offer support or decline to honor any offer, SYBEX bears no responsibility. This notice concerning support for the Software is provided for your information only. SYBEX is not the agent or principal of the Owner(s), and SYBEX is in no way responsible for providing any support for the Software, nor is it liable or responsible for any support provided, or not provided, by the Owner(s).

### WARRANTY

SYBEX warrants the enclosed media to be free of physical defects for a period of ninety (90) days after purchase. The Software is not available from SYBEX in any other form or media than that enclosed herein or posted to [www.sybex.com](http://www.sybex.com). If you discover a defect in the media during this warranty period, you may obtain a replacement of identical format at no charge by sending the defective media, postage prepaid, with proof of purchase to:

SYBEX Inc.  
Product Support Department  
1151 Marina Village Parkway  
Alameda, CA 94501  
Web: [www.sybex.com](http://www.sybex.com)

After the 90-day period, you can obtain replacement media of identical format by sending us the defective disk, proof of purchase, and a check or money order for \$10, payable to SYBEX.

### DISCLAIMER

SYBEX makes no warranty or representation, either expressed or implied, with respect to the Software or its contents, quality, performance, merchantability, or fitness for a particular purpose. In no event will SYBEX, its distributors, or dealers be liable to you or any other party for direct, indirect, special, incidental, consequential, or other damages arising out of the use of or inability to use the Software or its contents even if advised of the possibility of such damage. In the event that the Software includes an online update feature, SYBEX further disclaims any obligation to provide this feature for any specific duration other than the initial posting.

The exclusion of implied warranties is not permitted by some states. Therefore, the above exclusion may not apply to you. This warranty provides you with specific legal rights; there may be other rights that you may have that vary from state to state. The pricing of the book with the Software by SYBEX reflects the allocation of risk and limitations on liability contained in this agreement of Terms and Conditions.

### SHAREWARE DISTRIBUTION

This Software may contain various programs that are distributed as shareware. Copyright laws apply to both shareware and ordinary commercial software, and the copyright Owner(s) retains all rights. If you try a shareware program and continue using it, you are expected to register it. Individual programs differ on details of trial periods, registration, and payment. Please observe the requirements stated in appropriate files.

### COPY PROTECTION

The Software in whole or in part may or may not be copy-protected or encrypted. However, in all cases, reselling or redistributing these files without authorization is expressly forbidden except as specifically provided for by the Owner(s) therein.

Dedicated to the memory of Scott Anderson (1964–2002). Christa's husband was, for lack of better words, a great guy. I (Mark) met him in 1992 and thus was fortunate enough to enjoy his company for a decade. He was a smart, funny, capable-at-nearly-everything person who told good stories, played games masterfully, and brewed good beer. It has to be one of life's great ironies that a man with so much heart was betrayed by that very organ, and far too soon.

As a computer type, I'm used to a world of reversible catastrophes; there are always backups. It is daunting to be reminded that some things *can't* be restored.

Even precious things.

# Acknowledgments

THIS BOOK WAS A *lot* of work, so I'm sure glad I didn't have to do most of it!

This is essentially the twelfth edition of the *Mastering NT Server* book that debuted in 1994. In every other edition, we always had contributors who only worked on a chapter or a less, and so did not get co-author credit. This time, I wanted everyone who worked on it to get their name on the cover, and turned to two old tried-and-true contributors. Christa Anderson has contributed in a major way to every version of this book, and this one is no exception. Lisa Justice's work also appeared in the past six editions and she is a welcome addition to this one as well.

This book also introduces two newcomers to book writing, but not to networking. Michele Beveridge, the University of Georgia's Active Directory architect, and veteran tech teacher C.A. Callahan come from solid backgrounds in both working with technology and communicating it, and I think you'll agree that their first outing as geek book co-authors is a successful one. They dug into every chapter, forsaking family and friends in order to get this done. I owe all four co-authors quite a bit, and am quite thankful for their efforts. (Additionally, Michele tells me that a techie friend of hers, Martijn Middleplaats, helped her with some of the heavy lifting by researching some of her chapter material. She thanks him and so do I.)

While this *should* have been an easy book to write, it wasn't, as I'll explain in the Introduction—that's my fault. That made life horrendous for the Sybexers involved, and I can't thank them enough for their help in getting this volume out.

Chris Denny and Neil Edde got the ball rolling, and Sally Engelfried edited the chapters. Many thanks also to technical editor Jim Kelly for his painstaking checking and verifying.

There is, of course, the whole production crew to thank as well. Without them, all we'd have is a collection of electronic files. Kylie Johnston steered the project smoothly through the production channels, as she did with previous editions; Rozi Harris at Interactive Composition Corporation transformed the manuscripts into the handsome book before you; and the proofreaders—Laurie O'Connell, Yariv Rabinovitch, Nancy Riddiough, and Monique van den Berg—scrutinized the many pages to ensure that no stone was left unturned. Thanks also to Ted Laux, the indexer, and Dan Mummert and Kevin Ly of the CD team.

Finally, we could not have done this without the assistance of Microsoft, who not only created the product but also allowed us to see it before it was finished.

# Introduction

I SAID IT IN the Acknowledgments, and I'll say it again: *man*, was this book a lot of work! But trust me, I don't say that to complain; rather, it lets me explain—to explain what is probably the question in most prospective readers' minds:

“Is this a book only for people who use Windows Server 2003?”

The answer is, *definitely not*. Yes, it's a Server 2003 book—but it's *also* basically *Mastering Windows 2000 Server*, FIFTH edition. Here's what I mean.

When planning this book, I decided early on that it had to have *two* major goals. First, it had to cover the new features in Server 2003, or the title would be downright wrong. But the differences between 2000 and 2003 are, while not insignificant, not huge either. And that led me to the second goal. I'm guessing that almost no one reading this will have thrown away all of their “old” Windows 2000 Server systems when adopting Server 2003; as a matter of fact, many of you tell me that you're still running Windows NT 4 Servers! Nor is that a bad thing—NT 4 and Win2K are both *really* good tools, in my opinion. Yes, in some ways Server 2003 is better—and you'll learn those ways in this book—but not so much better that many can justify tossing out the Win2K systems to make room for Server 2003. No, I'm guessing that Server 2003 will move into your network gradually, and so you'll be living in a server environment that includes *both* Windows 2000 Server and Windows Server 2003 for quite a while. That's why I asked my co-authors to “think of this as the Fifth!”

Instead of taking the *Mastering Windows 2000 Server* book and looking for things that we'd have to change to make it a Server 2003 book, we started with the topics that previous editions of the Windows 2000 Server book explored and took them further, to build on the book series' growth. For example, previous editions didn't consider a lot of Active Directory maintenance issues, like checking database integrity or compacting the database, so this one did, even though it wasn't a new-to-2003 topic. A look at the Macintosh chapter will reveal that what *was* a chapter consisting of only a handful of pages in previous editions is now 50 or so pages long, with completely new information on Mac OS/X clients.

We tried, then, to make this essentially two books in one; I hope you think we succeeded.

## What's Inside

In Chapter 1, I briefly list and explain what's new in Windows Server 2003. As you'll see, Server 2003 is basically 2000 Server, version 1.1. But when you consider what a big product Windows 2000 Server is, and what a major change it was from NT 4, then you'll understand that even just a 1.1 version of 2000 would involve a lot of changes—this chapter outlines them. In Chapter 2, I offer a basic answer to the question, “Why do we network?” for those who are just joining us. Folks who have no idea what a domain is, or why they'd want one, should take a look at Chapter 2 and in no time you'll sound like a grizzled network veteran.

Lisa Justice then shows you in Chapter 3 how to navigate the Server 2003 user interface. Thank God it wasn't as large a change as the NT-to-2000 shift, and that it doesn't come out of the box configured in the XP “Playskool” user interface. But you'll find a few things have changed, and Lisa will guide you through the new stuff. She also walks you through the process of creating your *own* user interface with taskpads, a great way to build customized tools for administrators.

The user interface is *one* way to control Server 2003, and that's why Lisa covers it in Chapter 3. But the *other* way is via the Registry, 2000's place to store system settings and home to hundreds of undocumented or poorly documented switches, dials, knobs, and levers. No NT, 2000, XP, or 2003 techie can last long without a bit of Registry work, and so in Chapter 4 I introduce it.

By now, you'll be itching to load it up and try it out, so in Chapter 5 I not only show you how to shove a CD into a drive and answer questions, but I also cover scripting 2003 installs, using the Remote Installation Server, and finally, how Sysprep can make setting up systems and cloning them easier. Microsoft has made automated rollouts—scripts, RIS, and Sysprep—quite a bit easier and more powerful. Study Chapter 5 and you'll see how to deploy 2003 with style and grace...but mostly with a minimum of effort on your part!

Chapters 6 and 7 permit me to explain how TCP/IP works, both in a general sense and in the specific sense of configuring Server 2003 to use it. In Server 2003, Microsoft has taken another baby step toward making the NT platform an IP-only platform, as NetBEUI is no longer even an *option* for protocols. Chapter 6 explains the basics: how to get on an internet; how IP addresses, subnet masks, and routing work; and how to use a Server 2003 as a router. Chapter 7 then explains the three basic TCP/IP services that every Microsoft network needs: DHCP, WINS, and DNS. Server 2003 doesn't really do much that's new in DHCP and WINS, but DNS now offers several new features, all of which the chapter covers. The biggest changes in the chapter, however, are in the structure of the DNS section, which now spans almost 200 pages. It's not only a primer on DNS; in this edition I completely reoriented the discussion and the examples around building not just any DNS infrastructure, but a more secure infrastructure, using split-brain DNS techniques—and if you don't know what that means, don't worry, the chapter covers it all. You'll also see in Chapters 6 and 7 that I've worked hard to unify the step-by-step examples so that they all fit together, allowing you to follow along and build a small network that is then completely ready for Active Directory...which is the next chapter's topic.

Chapter 8 is basically a medium-sized book in itself, at 81,000 words and 110-plus figures. It takes you from the basics of "What is an Active Directory and why would you want one?" to designing an AD, implementing one, managing it, optimizing it, rearranging its structure when necessary, and fixing it when it breaks. Server 2003's changes permeate this topic, as you'll see. The migration section is much larger than in the 2000 Server book, and it and the rest of the chapter offers many step-by-step examples that allow you to build a small working AD.

Lisa returns in Chapter 9 to explain the ins and outs of creating and managing user accounts. That's a *big* topic, as it includes user profiles and group policies, which Lisa explains in detail. She also showcases and shows you how to use 2003's new Resultant Set of Policies troubleshooting tool for group policies. GP fans will love it.

Windows 2000 handles storage differently than NT did, and 2003 changes things a bit more, as you'll learn in Chapter 10. In that chapter, Michele Beveridge shows you how to connect, partition, and format drives, and she also covers Windows 2000's RAID functions. I was very fortunate to get Michele's help on this book, as she's responsible for the University of Georgia's Active Directory, both its design and implementation. Her years of real-world, in-the-trenches experience with NT in its various forms show through in her coverage of both this and the companion Chapter 11. That chapter covers shared folders, including how to secure those shares with both share and NTFS permissions, as well as coverage of Windows 2000 and Server 2003's Distributed File System and the File Replication Service. In that chapter, you'll also learn about the Encrypted File System—which

has changed in some subtle but important ways since Windows 2000—and offline folders, a modification of the network redirector that offers greater network response, laptop synchronization support, and network fault tolerance.

C.A. Callahan joins us in Chapter 12 to describe one of 2000, XP, and 2003's nicest features for desktop support folks: central software distribution. Callahan has been in the technical teaching business for many years and has a well-honed talent for digging into a topic, getting excited about it, and explaining to you so that *you'll* be excited about it as well. (She's also a Mac geek, which is why she rewrote the Mac chapter [Chapter 16] completely and made it about ten times larger than it was before.) Christa returns in Chapter 13 to describe how to network printers under Server 2003. Lisa then explains, in Chapter 14, how to connect client PCs to a Server 2003 network, whether those PCs are running DOS, Windows, or whatever. And you may be surprised to hear that it's now *impossible* to connect a DOS or Windows 9x system to a 2003-based Active Directory...unless you know the trick. (Of course, Lisa lets you in on the secret.)

Christa then warms to a favorite topic of hers in Chapter 15, where she covers the built-in Terminal Services feature of Server 2003 and remote server administration in general. And if you have no idea what Terminal Services does, check out that chapter: Terminal Services makes your Server 2003 system a multiuser computer, in many ways combining the best of the PC and the mainframe! Then, in Chapter 16, Callahan “cracks the Mac,” as I've already mentioned.

Once your organization is connected to the Internet, you'll probably want to get a Web server up and running. Server 2003 includes a Web server, as did NT 4 and Windows 2000, but 2003's IIS 6 is built to be both more secure and more reliable, so you won't want to miss Lisa's coverage of it, including not only the Web piece but also the FTP server piece, the SMTP mail server, *and* 2003's new POP server. Yes, that's right, Server 2003 now comes with a complete e-mail server service built in, and you can read about it in Chapter 17.

Then, in Chapter 18, Christa offers some advice and instruction on tuning and monitoring a Server 2003-based network, and in Chapter 19, she looks at disaster recovery—never a happy topic, but a necessary one.

Michele returns for a lengthy and quite complete look at dial-up, ISDN, and frame relay support in Routing and Remote Access Service (RRAS) in Chapter 20. Callahan then finishes the book with coverage of NetWare coexistence in Chapter 21.

## Conventions Used in This Book

As you know, when discussing any network technology, things can get quite complex quite quickly, so I've followed some conventions to make them clearer and easier to understand.

### Referring to Windows NT, 2000, XP, and 2003

Throughout this book, you'll see me refer to *Server 2003*, *Windows 2000*, *NT 4*, and just plain *NT*. I don't want to confuse, so let me clarify what I mean when I use those terms.

When I say “Server 2003,” “Windows 2000” or “NT 4,” then of course I mean those particular products. But when I say “NT,” I'm referring to the various versions of the NT operating system that have come out, including NT 4, Windows 2000, Windows XP, and Windows Server 2003. Despite the name change from NT-version-something to Windows-model-year, under the hood, NT 4, 2000, XP, and 2003 are quite similar. The underlying kernel, the piece of the operating system that

manages memory, handles multitasking, and loads and unloads drivers, changes with every revision, but not in any earthshaking way. For example, from NT 4 to 2000 the *look* of NT changed, but under the hood the main *kernel* difference we saw as administrator types was Plug and Play. Basically, you can think of it this way:

- ◆ Windows 2000 = NT 5.0, in both Workstation and Server flavors.
- ◆ Windows XP Professional = NT 5.1 Workstation. (XP Home is also NT 5.1 Workstation, but crippled. Don't use it.)
- ◆ Windows Server 2002 = NT 5.2 Server, no Workstation version. (The next version of Workstation probably won't appear until 2005, code-named "Longhorn.")

I wish they'd just kept calling things "NT version *something*," because then simply saying "NT" would obviously refer generically to all versions of the OS. In this book, therefore, I'm going to use the phrase "NT networks" to mean "anything running NT 4, 2000, XP and/or 2003." When I'm talking about NT 4-based things, I'll include the "4."

### Call It "Server 2003"

And speaking of names...Microsoft is working so hard to "brand" the name Windows that now they've attached the name to three totally different operating systems. The first of the "original" Windows—versions 1.0, 2.0, 2.1, 3.0, 3.1, 3.11, Windows for Workgroups 3.1 and 3.11, Windows 95 and 98—is an ever-evolving operating system built to extend the life of Microsoft's cash cow, MS-DOS. The second was NT, a project intended originally to extend an older operating system named OS/2. And the third is Windows CE, an OS designed for smaller, diskless computers, including the of-dubious-value "AutoPC," a computer designed for your car's dashboard. (Oh great, now I get to worry that the bozo in front of me in traffic will be distracted playing Warcraft; good call, Bill.)

Now, of course, what should have been called "NT Server 5.2" has the much-longer name "Windows Server 2003, Standard Edition." If I stopped to write that every time I needed to identify the product, I wouldn't get the book done until about 2009, so permit me to just shorten it to "Server 2003."

I can't wait until Microsoft sends Pella and Andersen cease and desist letters enjoining them from using the word "Windows" in their corporate name and product-line descriptions.

### Directory Names: `\windows`, `system32`

In a change from previous versions of Server, Windows Server 2003 installs by default into a directory named `\windows` on some drive. Upgrades from previous versions stay in whatever directory you installed the previous version in—probably `\winnt`. You can decide at installation time to put the operating system somewhere else, but almost no one does.

As a result, I have a bit of a problem: I often need to refer to the directory that Server 2003 is installed into, and I need a phrase less cumbersome than "whatever directory you installed your server into" or the brief and technically accurate but nonintuitive `%systemroot%`. So you'll see references to the `\windows` directory, which you should read as "whatever directory you've installed Windows Server 2003 into."

Similarly, both Server 2003 and every other version of NT includes a directory inside `\winnt` or `\windows` or whatever called `system32`—`\winnt\system32` on older OSes and upgrades, `\windows\system32` on fresh installs. I'll refer to that directory as `system32`. But let me stress this: *If you see a reference in this book to `\windows` or `\windows\system32` and you do not have a `\windows` or `\windows\system32`, don't panic—just substitute `\winnt` and it'll work.*

## Stay Up-to-Date with Our Free Newsletter

With the first version of this book, I tried out a way to keep you folks informed about book errata, changes to the NT family, or just plain new stuff that I've learned. No matter how long 2003 stays around, we'll *never* know everything about it—there will always be new things to learn. And certainly I'll include the things that I learn into new editions of the book—but why wait for the next edition? I'd rather get you at least *some* of that new information immediately!

So I'm extending the following offer to my readers. Visit my Web site at [www.minasi.com](http://www.minasi.com) and register to receive my free Windows Networking newsletter. It covers everything from NT 4 to 2000 to XP to 2003 and even a little Linux. Every month that I can, I send you a short update on tips and things that I've learned, as well as any significant errata that appear in the book (which I'm praying don't appear). It won't be spam—as the saying goes, “Spammers must die!”—just a short heads-up on whatever I've come across that's new (to me) and interesting about NT, 2000, XP, or 2003. Past newsletters have also included lengthy articles on DNS troubleshooting, Indexing Service, and IPSec, so I think you'll find it a worthwhile newsletter for the price.

Well, okay, about the spam part: there will be *one* bit of naked marketing—when the next edition of the book comes out, I'll announce it in the newsletter.

## For Help and Suggestions: Check the Newsletter and [www.minasi.com/gethelp](http://www.minasi.com/gethelp)

As always, if I can help, I'm available on e-mail. Got a question the book didn't answer? Visit my FAQ page at [www.minasi.com/gethelp](http://www.minasi.com/gethelp) and, if that doesn't help, there are instructions on how to e-mail me. I can't promise that I'll have the answer, but I'll sure try! I'm often traveling, sometimes for weeks at a time, and I don't pick up e-mail when I'm on the road, so if I take a week or few to respond, don't worry, I'll get back to you as soon as I can. It's easiest to help with questions which are specific but brief—please understand that I sometimes open my e-mail to find more than a hundred questions waiting for me!

In addition to offering help, I'd appreciate *your* help and feedback. Sybex and I have been able to get a new edition of this book out roughly annually since NT Server first appeared in 1993. I don't know everything about Microsoft networking—I'm not certain *anyone* does—and through the years, reader suggestions and “book bug reports” have been a tremendous source of assistance in making the NT books better and better. (“Gasp! An *error*? In *my* book? No, say it isn't so!”) Got a tip, something you want to share with the world? Pass it along to me, and I'll include it in the next edition and acknowledge your contribution.

And by the way, to all of you reading this book: thank you so much, and I hope you enjoy our coverage of Microsoft's flagship networking platform!

## Chapter 1

# Windows Server 2003 Overview

IF YOU LIVED THROUGH the change from NT 4 Server to Windows 2000 Server, then you might be a bit gun-shy about Windows Server 2003; how much more will you have to learn, and how hard will it be? If so, then I have good news: while Server 2003 offers a lot of new stuff, there's not nearly as *much* new stuff—if 2000 was a tsunami, 2003 is just a heavy storm. (If, however, you're an NT 4 guy getting ready to move to 2003, then yes, there's a whole *lot* of new stuff to learn. But don't worry, this is the right book, and I'll make it as easy as is possible!)

Clearly explaining what Server 2003 does is the job of the entire book, but in this chapter I'll give you a quick overview of what's new. I'm mainly writing this chapter for those who already know Windows 2000 Server and are looking for a quick overview of what's new in 2003, so if you're just joining the Microsoft networking family then don't worry if some of this doesn't make sense. I promise, in the rest of the book I'll make it all clear.

### Four Types of Server

Once, there was just one kind of NT Server. Under 3.1 it was called NT Advanced Server 3.1, which confused people—was there a cheaper “basic” server available?—and so Microsoft just renamed it NT Server 3.5 for its second outing, and it stayed that way through NT Server 3.51. But with NT 4 came a slightly more powerful (and expensive) version called Enterprise Edition, which offered a different memory model and clustering but not much else, so not many chose it.

### Pre-Server 2003 Varieties

Under Windows 2000, the basic server was just called Windows 2000 Server, and Enterprise became Windows 2000 Advanced Server. It offered a bit more incentive to buy it than Enterprise had, but not much; its most enticing feature was a new tool called Network Load Balancing Module, something that Microsoft had purchased and decided to deny to the buyers of basic Server. (But it's now shipped in the basic Server, thankfully.)

Microsoft also started releasing a third version of Server called Datacenter Server, but you couldn't just go to the store and buy it—they only “OEMed” it, which means that they allowed vendors to buy Datacenter and tune it very specifically for their particular hardware. The only way that you're going to get a copy of Datacenter is if you spend a whole lot of money on a high-end server computer, and then you get Datacenter with it.

Should you feel left out because you can't buy a copy of Datacenter 2000 and slap it on your TurboClone3000 no-name Web server? Probably not. Yes, there are a few things that Datacenter 2000 can do that the others can't: eight-computer clusters is the main one, but for most of us the loss isn't great. Unfortunately, that changes with Windows Server 2003.

## **Windows Server 2003 Flavors: Web Edition Makes Four**

As you'd expect, Microsoft introduced a number of new features with Windows Server 2003 but didn't make them available in all of the versions. It also added a new low-cost version, Web Edition, and reshuffled the features among the four versions. There are actually a whole pile of different versions of Server 2003 if you include the 64-bit versions, the embedded versions, and so on, but the main product grouping is the four “product editions”:

- ◆ Windows Server 2003, Standard Edition
- ◆ Windows Server 2003, Enterprise Edition
- ◆ Windows Server 2003, Datacenter Edition
- ◆ Windows Server 2003, Web Edition

I'm going to focus on Standard Edition in this book, but let's take a very quick look at each edition.

### **“REGULAR OLD SERVER” GETS A NAME**

For the first time since 1983, the basic variety of server has a name; it is now Windows Server 2003, Standard Edition. (I suspect I may have to sue Microsoft for the extra carpal tunnel damage that I'm getting writing this book—where I could once just say “NT 4,” now I'm typing half a sentence just to identify the product.) In general, it has just about all of the features that it did back when it didn't have a name.

Standard Edition comes with a bunch of new features that are new to all of 2003's editions, as you'd expect, but it also comes with a bit of quite welcome news: Standard Edition includes Network Load Balancing (NLB). NLB's not new, as it was included in Windows 2000 Advanced Server, the more expensive version of Windows 2000 Server. But where Microsoft once required you to buy the pricier version of 2000 Server to get this very useful feature, it's now included in all four editions of Windows Server 2003. (You'll learn how to set it up in Chapter 6.) But that's not all that's new in Standard Edition—for instance, how does, “You finally get a complete e-mail server free in the box” sound? But I'm getting ahead of myself.

### **WEB EDITION DEBUTS**

The newest and fourth option for Server is Web Edition. The idea is that Microsoft really wants their Web server, IIS, to completely crush, overtake, and overwhelm the competition: Apache and Sun Web servers. So they ripped a bunch of things out of Server and offered it to hardware vendors as an

OEM-only copy of Windows Server 2003. It can only address 2GB of RAM (NT has always been able to access 4 or more GB) and cannot

- ◆ Be a domain controller, although it can join a domain
- ◆ Support Macintosh clients, save as a Web server
- ◆ Be accessed remotely via Terminal Services, although it has Remote Desktop, like XP
- ◆ Provide Internet Connection Sharing or Net Bridging
- ◆ Be a DHCP or fax server

So it's unlikely that you'll actually see a copy of Web Edition, but if you do, then don't imagine that you'll be able to build a whole network around it. As its name suggests, it's pretty much intended as a platform for cheap Web servers.

#### **WHAT YOU'RE MISSING: ENTERPRISE AND DATACENTER FEATURES**

Back in the NT 4 days, Microsoft introduced a more expensive version of Server called NT 4 Server, Enterprise Edition. It supported clusters and a larger memory model. When Windows 2000 Server came around, Microsoft renamed it Windows 2000 Advanced Server. With Server 2003, Microsoft still offers this higher-end version of Server, but with yet another name change. Now it's called Windows Server 2003, Enterprise Edition. Yes, you read that right: once it was Enterprise Edition, then it became Advanced Server, and now it's back to Enterprise Edition. (Don't shoot me, I just report this stuff.)

Enterprise Edition still does clusters—four-PC clusters now. It also lets you boot a server from a Storage Area Network (SAN), hot-install memory like Datacenter can, and run with four processors.

With Windows Server 2003, Microsoft has finally made me covetous of Datacenter. It has this incredibly cool tool called Windows Resource Manager that basically lets you do the kind of system management that you could do on the mainframe years and years ago. How'd you like to say to your system, "Don't let SQL Server ever use more than 50 percent of the CPU power or 70 percent of the RAM?" WRM lets you do that, and it only ships with Datacenter. Datacenter also now supports eight-PC clusters as well as hot-installing RAM—yup, that's right, you just open the top of the server *while it is running* and insert a new memory module, wait a second or two and poof! the system now recognizes the new RAM, no reboot required.

## **XP Support Comes to Server**

For the first time in a long time, Microsoft shipped NT in two parts, delivering NT Workstation version 5.1—that is, Windows XP Professional and its sadly eviscerated sibling, XP Home—over a year earlier than its NT Server counterpart, Windows Server 2003. I don't think that Microsoft originally intended for there to be a year and a half interregnum, but that unintended extra time let Microsoft make Windows Server 2003 much more than "XP Server"—it's NT Server version 5.2.

XP was a nice upgrade from 2000 Professional but not a great one, not a must-upgrade for current Windows 2000 Professional systems, but a very attractive step up for those running NT 4 or Windows 9x/Me on their desktops. Okay, I might have understated things a bit there—let's go back and italicize that "very." And for people running—auggh—Wintendo (9x and Me) put that "very"

in double-sized bold text. (This assumes, of course, that you have the minimum reasonable hardware to run XP—128MB RAM and a 600MHz processor.) But, again, if you're already running 2000 Pro and you want some you-are-a-fool-if-your-company-doesn't-upgrade-to-XP reasons, then I can't help.

But that doesn't mean that XP didn't introduce some neat features, and now with the introduction of Windows Server 2003, the server side of the NT house has them as well.

## XP Integration

Windows 2000 Server came with a file named `adminpak.msi`, which would let you install all of the administrative tools for a 2000 network on a 2000 Pro desktop. I *loved* that, as NT Workstation never really did a great job as an administrator's desktop and I always ended up running Server as my desktop OS. But 2000 Pro was a different story; get `adminpak.msi` on the Win2K Pro box and you could do all the server administration that you wanted.

But then XP arrived.

I was perfectly happy with my Win2K desktop, but it's kind of my job to use the latest version of NT, so I upgraded to XP, only to immediately find that none of the server administration tools worked anymore—the only way to control my DNS server, AD domain controllers, DHCP server, and the like was by either keeping a Win2K machine around somewhere, walking over to the server to work on it, or just using Terminal Services to remotely control the server. It was irritating. Microsoft soon shipped a beta version of administrative tools that worked on XP, but I'm kind of leery of running my actual commercial network with beta tools, if you know what I mean.

So it's good news that Server 2003 brings a welcome addition: a new set of administrative tools that run fine on XP.

## Server Understands XP Group Policies

To my mind, XP's two absolute best features from an administrator's point of view were its remote control/support and software restriction capabilities. Both of those capabilities either absolutely require or considerably benefit from group policies, but Server 2000 knew nothing about them, and so required some tweaking to support XP-specific policies on a Windows 2000–based Active Directory. That's all taken care of now.

## New Free Servers: An E-Mail Server and SQL Server “Lite”

Thank you, Microsoft.

Not too many people remember this, but back when Server first came out, it wasn't all that impressive in terms of performance. But over time, it took market share away from network OSes that were, in many ways, faster, more flexible, or more reliable. How'd they do it? Many reasons, but I've always thought that there were two biggies. First, NT used the Windows interface, which meant that once you'd mastered Solitaire you were well on the way to administering an NT Server.

The second reason was that NT came with a lot of stuff free in the box. From the very beginning, NT contained software that most vendors charged for. At one time, most server OS vendors charged for the TCP/IP protocol, but NT always had it. Ditto remote access tools, or Macintosh support, or a Web server, FTP, and a dozen other things. In terms of features, Microsoft made NT an attractive proposition.

So I could never understand why they didn't include an e-mail server. Well, okay, I understood it—they wanted to sell you MS-Mail (you in the back there, stop laughing) or Exchange, and didn't want to offer a free alternative. But I've never understood that. Exchange is a mail server that, while powerful, is complex, difficult to set up, and expensive. Why not offer an e-mail server that is nothing more than an SMTP and POP3-based system? It would serve that five-person office well, and they're probably not about to buy Exchange. Nor would it keep the 100-person (or 100,000-person) enterprise from buying Exchange, as they're probably large enough that they want support of shared calendars, IMAP, mailbox forwarding, antivirus add-ons, and so on, and a super-basic POP3 service wouldn't do it.

I got my wish. Windows Server 2003 in all flavors includes a POP3 service. The other part, SMTP, has always existed, so between the two of them, you've got a complete low-end mail server. Again, there are no hooks for antivirus software, no way to set a mailbox to automatically forward somewhere else, and no way to create an autoresponder message for a mailbox ala, "Jack doesn't work here anymore, please don't send anymore mail here to his address," but it may still do the job for you.

The next goodie wasn't on my wish list, but I'll bet it was on a lot of other peoples': a free database engine. Even better, it's a free database engine that is a copy of SQL Server 2000, although with a "governor" and no administrative tools.

For years, Microsoft has offered a thing called Microsoft Database Engine or MSDE. It was never generally available to NT users, but it was available to various groups of developers. The idea with MSDE was that Microsoft took SQL Server 2000—a fairly expensive piece of software—and crippled it in three ways:

- ◆ First, they limited the database size to 2GB. That may not sound like much, but a "real" application of any size could grow beyond that in not too much time. But it's a great size for testing and developing database-driven apps, or for managing a database that will never get very big.
- ◆ Second, they put a "throttle" (Microsoft's word) on it so that if more than five people access it, it slows down. Again, it's a barrier to using this for member registration on a thousand-member Web site, but fine for testing and small networks.
- ◆ Finally, they do not ship any administrative tools for MSDE. If you want to do something as simple as changing the password on the default "sa" account, you'll have to do some scripting.

None of that is intended to sound negative, even though it's true the MSDE is a severely cut-down version of SQL Server 2000. The price is right and once you get past the basic lack of admin interface—the hard part—then you'll find that it's a pretty nice add-on.

## General Networking Pluses

XP's new networking features made it to Windows Server 2003, with some extras as well.

### NAT Traversal

First, XP introduced NAT Traversal. For those who don't know what that is, NAT Traversal tries to solve the problem of "how do I communicate from inside one NAT network to another?"

More specifically: suppose you've got a cable modem or DSL connection with a connection sharing device of some kind, like a DSL router. The DSL router has two IP addresses. First, there's the honest-to-God, fully routable IP address that it got from your Internet provider, connected to the DSL or cable modem connection. Then there's the connection to a switch that you've got all of your internal machines connected to—the old Windows 9x boxes, NT machines, 2000 systems, Macintoshes, or whatever. The DSL router's job is to share the one “legal” Internet address among several devices. But every device needs a unique IP address. Lots of devices, but just one IP address—what to do?

As you may know, DSL routers solve this problem by giving all of the internal systems—those Windows, NT, 2000, and Mac machines—IP addresses from a block of addresses set aside to be nonroutable. Anyone can use them.

**NOTE** *By the way, if you've never worked with IP, don't worry too much about this—read Chapter 6 on the basics of TCP/IP on Server 2003.*

There are several of these nonroutable blocks, but most DSL routers seem to use the 192.168.1.x or 192.168.0.x subnets. The DSL routers then use something called network address translation or, more correctly, port address translation (again, see Chapter 6 if this isn't familiar) to share the one routable address with all of the internal systems. How it does it is pretty simple: whenever an internal system wants to access the Internet, perhaps to browse some Web site, then that system just says to the DSL router, “Please forward this request to Internet address so-and-so,” as routers normally do. But the DSL router knows perfectly well that it *can't* do that: if it says to the Internet, “Hey, someone at 192.168.1.3 has a request,” then the first Internet router to see the message will simply refuse to route it, as the address is in a range of addresses that are, by definition, NONroutable. So the DSL router *doesn't* say “192.168.1.3 wants something”; instead, the DSL router substitutes *its* routable address. Then, when the answer to 192.168.1.3's question comes back, the DSL router remembers which machine asked the question in the first place and routes the answer to 192.168.1.3. The result is that to the general Internet, that DSL router sure seems like a demanding system, when in fact it is simply busy because it is impersonating a bunch of systems.

In any case, notice that it's possible for an internal system (one with one of those 192.168.x.x addresses) to initiate a communication with a device on the public, routable Internet, but it's NOT possible for a device on the public, routable Internet to initiate a conversation with an internal 192.168.x.x system.

Here, then, is the problem. Suppose I'm sitting at a Windows 2000 Pro box in my home that has a 192.168.x.x address, accessing the Internet via my DSL router or cable modem sharing device. You're sitting in *your* house, also using some kind of DSL router or cable modem sharing device to access the Internet. We meet on-line and decide to play some networkable game and start to set up our connection. One of us acts as the server and one as the client. The client then initiates communication with the server. That's where the problem appears. I could initiate a communication to a routable address, or YOU could initiate a communication to a routable address, but neither of us has a routable address... and so we can't communicate.

(Note that some of you might be scratching your heads saying, “Mark, I don't have that problem.” In that case, I'm guessing that you use your Windows 98 SE, Windows Me, or 2000-based system as the DSL or cable modem-sharing device. As you know if you read Chapter 6 of *Mastering Windows 2000 Server*, you can easily activate something called Internet Connection Sharing to

make your 98 SE/Me/2000 device into a simple NAT router. But if you do your gaming while sitting at that box, then NAT isn't a problem, as that particular computer has a legal IP address, recall, as *it's* the device connected to the Internet.)

How, then, to create a meeting of the minds in PC-land? With NAT Traversal. The idea is that if your DSL router (or other sharing device), your opponent's sharing device, and your game software understand NAT Traversal, then the two sharing devices work out the details to allow 192.168.x.x-to-192.168.x.x communications with no muss, fuss, or greasy aftertaste. And XP Pro's version of Internet Connection Sharing supports NAT Traversal, so if you replaced your DSL router with an XP Pro (or Home) box, you'd have all the more online gaming options. (And of course it's good for more than just gaming; you could use this for any peer-to-peer communications that must go through a NAT-type router, like Webcam-type videoconferencing—once there's videoconferencing software that understands NAT Traversal.)

NAT Traversal's migration to Windows Server 2003 is, then, pretty good news.

## IPSec NAT Traversal

I discussed NAT Traversal as if it were mainly of interest to gamers, and I suppose that at first it was. But you could just as easily imagine 192-to-192 type network communications in business as well. Consider a business with two offices in different cities and about 50 employees in each location. They'd like to connect the offices but don't want to have to buy a dedicated leased line or frame relay between the offices, so they get DSL in each location.

In each location they end up with network addresses that look like 192.168.0. something, but they'd like to communicate from location to location. Their problem is, as you can see, exactly the same problem that the gamers in my earlier example face. So they could just put in NAT Traversal hardware and software and be done with it.

But then they'd be transmitting office-to-office data in cleartext over the Internet. An OK thing in 1993, I suppose, but a definite no-no in these modern times. Running sensitive data over the Internet is exactly what IPSec (Internet Protocol Security) was built for. IPSec (also covered in Chapter 6) converts an IP connection into an *encrypted* IP communication.

The only trouble is that IPSec and NAT don't mix. Or didn't, until Windows Server 2003.

Windows Server 2003 includes a new kind of IPSec that is NAT Traversal-aware. So you can have as many 192 networks as you like, and they can all talk to one another, and securely. Of course, this isn't free—you need firewalls and routers that are NAT Traversal-aware—which is probably one reason Microsoft has started selling network hardware, including some interesting wireless devices.

## RRAS's NBT Proxy Eliminates Network Neighborhood Problems

Routing and Remote Access Service (RRAS) has always been a source of troubles, largely due to the fact that one of its main jobs is to allow networking over dial-up lines, and dial-up lines are noise-ridden, unreliable things. Another RRAS problem stems from the fact that you normally use it to connect some remote computer, like a home PC, to a distant larger network, such as your company's network, meaning that your home PC is now a network segment all by itself, and in effect the RRAS server has to act as router, authentication server, and a host of other things.

A side effect of your home system being a network segment all its own is that Network Neighborhood or My Network Places doesn't have much to show, as it normally displays the systems on the local segment. (I'm simplifying but that's basically right.) That doesn't mean that users cannot access

servers on the corporate network; unless configured otherwise, a remote user can connect to any server at the office. But people aren't comfortable using Find Computer or some other way to connect to a server, and unfortunately Network Neighborhood is the tool of choice for many when looking for a server—so an empty NetHood is disconcerting to many users.

Seeing tons of computers in NetHood while in the office and none while at home troubles some users, but Windows Server 2003 can fix that. Server 2003's RRAS server includes a feature called the NetBIOS over TCP/IP proxy or NBT proxy. This basically takes the Network Neighborhood that any system inside the office sees and ships it over to the dial-in system.

Of course, in the long run users are going to have to get used to finding servers and resources by searching the Active Directory rather than browsing NetHood, but this provides a useful interim tool.

## **DNS Conditional Forwarding Supports Multidomain AD-Integrated DNS**

As you learned when creating your Windows 2000-based AD, or as you'll learn when you create your Windows Server 2003-based AD, AD needs a sturdy and secure DNS infrastructure. A big part of the "secure" aspect of DNS comes from a DNS design called split-brain DNS where you essentially keep two sets of books, DNS-wise—a DNS server that the outside Internet sees, which holds the address information for your Web, mail, and FTP servers, and a separate DNS server (or a set of DNS servers) inside your intranet that serves AD's needs.

Split-brain DNS works by bypassing the normal process whereby a DNS server converts DNS names like `www.bigfirm.biz` to an IP address. And it works fine, except when joined with a very useful feature of Windows called Active Directory-integrated zones. You'll learn more about this in Chapter 7, but basically AD-integrated zones let you secure a zone for a DNS domain (like `bigfirm.biz`) with one limitation: the DNS servers for `bigfirm.biz` must be domain controllers (DCs) for an Active Directory domain whose name is *also* `bigfirm.biz`.

Where that presents a problem is the case wherein you want to run more than one Active Directory domain in your intranet. Each AD requires a DNS zone to back it up (and, again, if you're not sure about what these things are, don't worry, I'll cover them in detail in Chapter 7, starting from the basics). If you want to use AD-integrated zones, however, then you'll have to have a separate set of DNS servers for each domain... and that's where the problem lies. It's easy to keep a separate set of books on just one DNS domain, as you divide the world up into two areas: folks on the outside of your network, who only see your external DNS server's information, and folks on your intranet, who see your internal server's DNS information and incidentally can also see DNS information on the outside world—so even though the folks inside your intranet are being deceived, so to speak, about the contents of your internal Active Directory's associated DNS data (`bigfirm.biz` in my example), they get the unfiltered DNS information about other DNS, like `microsoft.com`, `whitehouse.gov`, and the like.

Now add that second internal domain; let's call it `acme.com`. To make the `bigfirm.biz` folks see the correct separate set of books, you point all of their servers and workstations to the internal DNS servers that contain the internal-only version of the `bigfirm.biz` information. Recall that these servers must be Active Directory domain controllers for the `bigfirm.biz` AD domain. To support the people in `acme.com`, you'd set up a different set of DNS servers for your internal-only information for `acme.com` and point all of `acme.com`'s servers and workstations to those `acme.com` DNS servers.

People in `bigfirm.biz` can, then, get the internal-only DNS information about `bigfirm.biz`, as well as the public DNS information for any other domain. People in `acme.com` can get the internal-only DNS information about `acme.com`, as well as the public DNS information for any other domain.

*Here's the problem:* if a bigfirm.biz member wants to log onto some resource on acme.com, then that bigfirm.biz-ite will have to find a domain controller for acme.com, as DCs handle logons. But you find DCs in Active Directory via DNS. A bigfirm.biz user, however, uses DNS servers that know the internal-only information about bigfirm.biz, not acme.com. So if someone in bigfirm.biz tries to look up a DC in his local DNS server, that local DNS server will end up asking the public DNS server for acme.com, "Where are your DCs?" The answer will be a puzzled look from the public DNS server for acme.com, as it has no clue what a DC is.

There are workarounds for this, but Windows Server 2003 offers a terrific one: conditional DNS forwarding. It lets me set up the bigfirm.biz DNS servers by saying, "OK, you already know the internal-only information about bigfirm.biz. And you know that if you have to find out DNS information for someone else, like www.google.com or www.cnn.com, or the like, then you go search the public Internet. But here's a new bit of information: on the off-chance that you ever need to find out information about a zone called acme.com, then go straight over to that server over there (pointing to the internal-only acme.com DNS servers) and it'll have the answer." A great new feature for folks rolling out Active Directory forests with more than one domain. You'll see it at work in Chapters 7 and 8.

## Active Directory Improvements

For a first try, Windows 2000's Active Directory was pretty good... not bad for a 1.0, Microsoft. (Of course, they *did* have Banyan and Novell's directory services to learn from, but let's ignore that for this discussion.) In Windows Server 2003, Microsoft dishes up a 1.1 version of AD that solves several irritating problems, makes running branch offices easier, and expands AD's flexibility.

While I don't want this to sound negative, it's a fact that Active Directory still suffers from most of its inflexibility—there is no simple way to rearrange the structure of an existing forest, to merge forests into one forest, or to break off a piece of a forest and make it a forest of its own. Don't think that those scenarios are marginal or unusual ones—they're not. The reorganizations that most organizations undergo every year or so will often require rearranging a forest. Two firms merging need to be able to merge their forests as well. And a firm divesting itself of a subsidiary would want to be able to detach one or more domains or trees from a forest. But perhaps that will appear in a future version of Server; let's hope so.

Meanwhile, the 2003 edition of AD has, again, some very good news. Here's a look at its high points.

### Forest-to-Forest Trusts

Combining a bunch of AD domains into a forest offers two main benefits: first, those domains all automatically trust each other, and, second, the domains share a set of "super" domain controllers called global catalog (GC) servers, which are domain controllers that contain a subset of information not just about their own domains but about every single domain in the forest. Doing away with the unreliability of NT 4 trusts for the convenience and dependability of AD's automatic trusts is a big win for AD users.

But, as I suggested a few paragraphs back, AD forests were and are still pretty inflexible. So suppose you're an organization that finds itself with more than one forest, and you need to get those forests to share things? Well, there's always been the hard way—get a migration tool and copy all of the user accounts, machine accounts, and other objects from Forest 1 to Forest 2, then just plain delete Forest 1. The problem with that answer is that while migration tools are pretty nice, they don't do the whole job and they're a lot of work to get working.

With a Windows Server 2003–based forest, however, you have a new answer: forest root trusts. With these, you just build one new trust relationship between Forest 1 and Forest 2 and instantly every domain in Forest 1 trusts every domain in Forest 2 and vice versa. Cool; thank you, Redmond.

But I said that forests had two main features—complete trust and a centralized database of forest information called the global catalog. A forest-to-forest trust gives us back the first benefits of a single forest; what about the second? Unfortunately, two forests that trust each other do not share a global catalog. That means that forest trusts will not let applications that are GC-dependent see the trusting forests as one single overall directory. What apps are GC-dependent? Well, the most prominent one is Exchange 2000: it really wants to see your organization as one big forest. Forest trusts don't solve that problem.

I was surprised to learn of another limitation to forest trusts: they're not transitive. Interestingly enough, if Forest 1 trusts Forest 2 and Forest 2 trusts Forest 3, then Forest 1 does not trust Forest 3. Bummer. And *none* of this forest trust stuff works at all until you've upgraded every single DC in every single domain of both forests. So, overall the forest trusts are a good step forward... but not the whole story.

## Group Replication Problem Solved

It's always been ironic that while Active Directory can support a far larger user list than could NT 4 domains, AD couldn't support *groups* as large as NT 4. You can create literally millions of users in an AD, but because of a quirk in AD's method of keeping domain controllers' information consistent ("AD replication") in combination with the way that group membership is stored in AD, you can't put more than about 5,000 users into a group.

In 2003's AD, Microsoft restructured the way they store group membership, and now the sky's the limit. It also solves another problem wherein it is possible in 2000's AD that you and I work in the same world-wide company and you change a group's membership while sitting in the Edenton office while I change that same group's membership while sitting in the Port Angeles office, and one of our changes overwrites the other person's changes. With 2003, that's fixed.

To get this benefit, you must upgrade all of the DCs in all of the domains in your forest.

## Good News for Branch Offices

Branch offices have always presented a problem for IT folks. Many firms have one or two large centralized locations and dozens (or hundreds!) of small offices housing a dozen or two employees. These small branch offices are important but expensive to run, as a firm typically has to install some kind of persistent connectivity—frame relay, DSL, T1, cable modem, or the like—to the branch office so that the employees there have access to the corporate intranet and potentially the Internet.

As branch offices are typically served by only one WAN link and WAN links aren't always so reliable, companies have to make some tough choices: do we put a domain controller on every site? Does each site need a DNS, WINS, DHCP, etc. server? If we put servers on a branch office site, will they do so much chattering over the WAN link with the servers in the central office that they'll chew up a significant proportion of that link's bandwidth? And most importantly, when the WAN link is down, how do we ensure that the employees in the branch office can still get logged in and remain productive?

Server 2003 can't solve all of those problems because, well, unreliable WAN connections aren't Microsoft's fault. But 2003 offers some changes that will make setting up and maintaining branch offices easier.

### **SIMPLIFIED BRANCH OFFICE DC INSTALLATION**

I've helped a number of firms get AD up and running. Sometimes, however, they call me back to help out with a particularly difficult part. In one case, it was the Case of the Dial-Up Office.

This company had a branch office that did not have a persistent connection either to the Internet or to the head office; instead, they dialed up when necessary. And they were having trouble getting a domain controller set up in that branch office. Now, you see, to create a domain controller, you start from a regular old vanilla Windows Server, either vintage 2000 or 2003, and run a program called DCPROMO, a wizard that will convert a member server into a domain controller or will decommission a DC back to a member server. In order to create a new DC, you must have a live connection back to the main office, so before trying to set up the DC I dialed out to the Internet and from there established a connection to the "mothership" back at HQ.

DCPROMO started out fine, accepting my credentials and okaying the idea of promoting this member server. But a new DC needs a copy of the Active Directory, so DCPROMO's last act is to hook up with another DC and download the latest version of AD. This firm had a few thousand employees, so their AD was actually not too large—under 10MB.

Did I mention that their phone line was a bit noisy? That it only connected at about 26 kilobits? And that it tended to disconnect at inconvenient times?

Anyway, DCPROMO would try to start replicating and get partway through... and then the line would hang up. Sometimes a reboot and another DCPROMO would get us back to member server, where we could start all over again; in a couple of cases, I had to reinstall Win2K Server from scratch. After only about a day of trying, though, I found that the phone lines were quiet and clean enough around midnight to allow the initial replication to complete. Grrrr.

I really would have welcomed Windows Server 2003 in that case. With Server 2003 you can take a backup of your AD domain database with you to the remote site, and DCPROMO then lets you start a new DC out from the backup of the AD, rather than forcing a complete initial replication over the WAN. From there, you connect the new DC up to that unreliable phone line, and all the DC must do is to replicate whatever's changed in AD between when the backup occurred and now, which usually isn't much.

This feature does *not* require you to upgrade every DC in creation; in fact, this works fine if the very first Server 2003-based DC in your network is the one that you're installing in that branch office.

### **BRANCH OFFICE REPLICATION CONTROL**

Should you put a DC in a branch office or not? It's not an easy question. On the one hand, having a local DC in a branch office means that when the WAN link is down the local users can still log on. On the other hand, having a local DC means that DC must keep a complete copy of the entire domain's Active Directory database. So if there are 15 users in the branch office and 50,000 members of the domain, every time those 50,000 people change their passwords those changes must be replicated across the WAN link to your branch office's DC. (That's an example of what I meant when I said earlier that server communications can seriously burden the WAN links to branch offices.)

AD has always tried to limit its effect on branch offices in a couple of ways. First, it uses a routing algorithm that is designed to enable it to get data from a DC in one office to a DC in another office in the least-cost way. Second, it compresses the data before moving it between DCs. Those both sound like good features, but Server 2003 improves upon them.

First, there is a large body of literature about optimal routing algorithms... but the Microsoft programmers working on AD in Windows 2000 didn't employ them. Instead, they made up an algorithm all their own. (Why? I don't know. But I do know that many firms, Microsoft included, are sometimes struck by what's called the "NIH syndrome"—short for Not Invented Here. It refers to the fact that it's more fun to sit down and reinvent your own wheel than it is to merely reimplement someone else's wheel.) Microsoft found that AD bogs down when faced with more than a few hundred sites; implementing industry-standard algorithms shot that up into the multithousand-site range.

Second, odd as it sounds, apparently some branch offices found that the CPU power required to compress and uncompress data outweighed any benefits gained from bandwidth recovery. So in Server 2003, Microsoft lets you choose to shut off intersite compression.

Both of these features require that you upgrade every DC in every domain in your forest.

### **BRANCH OFFICE LOGON INFO CACHEABLE**

When the WAN goes down, does everyone get a day off? Well, that's essentially true if they need the WAN to do a logon. Windows 2000 and later systems require several ingredients in order to log on. First, of course, a workstation must be able to find a domain controller; that's always been true. Second, Active Directory member machines need to be able to find a global catalog server in order to log a user on.

It is, then, possible that you might have a local DC but not a local GC. In that case, a WAN failure means that you'd only be halfway to logon, so you're logged on with "cached credentials." One answer is to put a GC on every site, but that can be very expensive in terms of WAN bandwidth: GCs not only replicate from other DCs in their same domain, GCs also replicate from every other domain in the forest!

AD 2003 offers a nice workaround: Server 2003-based DCs will locally cache the information that they need from a GC. So if you logged on yesterday from your branch office, your local DC collected enough information over the WAN from your GC that it was satisfied to let you log on. If the WAN's down today then your local DC remembers that it logged you on yesterday, and logs you on today.

The best part of this news is that it requires no other upgrades—the DC in your branch office can be the first Windows Server 2003 introduced into your enterprise and this will still work fine.

### **Domains Can Be Renamed**

One of 2000's most annoying AD limitations was that it prevented you from renaming a domain; if Bell Atlantic had had an AD forest when it merged with GTE and was renamed Verizon, there would have been no way to rename an AD domain named bellatlantic.com to verizon.com. Now you can rename a domain, but it's not a simple matter, even now.

First, you will have to be completely Server 2003ed in the domain: every DC in the domain to be renamed (not all DCs in the forest, just the ones in the domain) must be running Windows Server 2003. And second, there are... well, I was going to write "... a few steps to perform in order to complete the domain renaming," but the truth is that Microsoft has a white paper online explaining how to do it.

The paper is *60 pages long*. So it's *possible*, just not easy, at least not yet.

### **AD Can Selectively Replicate**

Active Directory is a database, and domain controllers are database servers, just like systems running Access, Oracle, MySQL, or SQL Server and holding some other kind of database. (Well, not *just* like...

DCs do not respond to SQL queries. Instead, their query language is LDAP.) While the AD database was originally designed for storing user accounts, machine accounts, and the like, there's no reason application designers can't take advantage of AD's built-in database engine to store other information.

Microsoft's own programmers did just that when designing 2000's DNS server. As you may know, 2000 introduced you to the option to create a DNS zone that was an Active Directory–integrated zone. A zone of that type stores the DNS info for your systems in the AD itself and replicates it along with the normal domain information from DC to DC. But *only* DCs get copies of the database, so if you choose AD-integrated DNS, all of your DNS servers must be DCs.

But now consider: what if you had a lot of DCs, but only a few of them were DNS servers? Wouldn't that be a bit wasteful? You'd use precious bandwidth to replicate DNS info to every DC, whether it used it or not. Server 2003 solves that problem with the notion of an *application partition*. Partitions are subsets of the AD that only replicate to a subset of DCs. Microsoft then applied that notion to their DNS servers, so in a network using AD-integrated zones only the DCs running DNS will get the DNS info. This feature doesn't require any preparation; you get its benefit on any DC running Windows Server 2003.

## Remote Administration Upgrades

For years, remote administration and control of Microsoft operating systems drove me nuts. It seemed only Microsoft OSes required you to be physically sitting down at a computer in order to control the software running on it. Sure, there were third-party alternative tools like PCAnywhere or VNC, but remote control/admin always seemed like something that really needed to be “in the box,” integrated into the OS.

Windows 2000, then, was a great advance, incorporating remote Telnet sessions and a remote control tool called Terminal Services that was a cut-down version of a program from a company named Citrix. Terminal Services only ran on Server, though, so remote control of 2000 Pro boxes was dicey. But then came XP and now Windows Server 2003.

First, the workstation/desktop version of Windows Server 2003, Windows XP Professional, includes Microsoft's adaptation of Citrix's remote control product. It and the server version of Terminal Services are built around a tool called the Remote Desktop Protocol (RDP). Microsoft has improved RDP to make it run on slower connections, and I'm not exaggerating when I say that remote control over a 40-kilobit dial-up connection works very well, almost as well as sitting at the computer.

RDP also matures in that it automatically gives your remote control session access to your local printers and drives, something that Terminal Services for Windows 2000 couldn't do. It supports colors beyond the simple 8-bit, 256-color of Windows 2000's RDP, and transports sound as well.

Perhaps even better, Windows Server 2003 and XP repackaged RDP in two forms: *remote desktop support* and *remote assistance*. These are ways to provide remote control or offer remote assistance but are nothing more than new user interfaces placed atop Terminal Services. If you've not used them yet for XP, I think you're really going to like them on Windows Server 2003.

Finally, Windows Server 2003 offers a completely new set of remote control tools in the form of Web pages. You can install a bunch of modules on your server that will let someone do approximately 80 percent of the administrative functions you'll ever need, all through a secure Web connection. The bottom line is that we don't have to put up with those Unix guys kicking sand in our faces telling us that their OS is more manageable!

## Command-Line Heaven

Okay, I admit it, the command line is harder than the GUI. GUI-based administrative tools walk you through a process and offer tons of online help and wizards while they're at it. The command line is definitely an acquired taste. But may I offer a very heartfelt bit of advice?

*Acquire* the taste. You'll be glad you did.

Take a common problem that I hear about a lot: a private DNS root. Through a process that I'll cover in Chapter 7, it's possible to set up a DNS server that lives in its "own private Idaho," and is unable to resolve names on the rest of the Internet. It happens through a common bit of misconfiguration. And it can be fixed from the GUI, with about two paragraphs of explanation. Or you can just open up a command line and type

```
dnscmd /zonedelete /f .
```

Then press Enter and it's done. (Most of the time, but I'm keeping this simple.) Command lines let you type a few dozen characters and accomplish amazing things. Just a few keystrokes can often accomplish quite a lot.

But how's that different from saying, "Use the GUI, and in a few dozen mouse clicks you can get a lot done?" Well, that's true, you can. But the command line offers two more things:

- ◆ First, simply opening a Telnet session lets you run one of those powerful command-line commands on a remote computer, so it's a great way to do remote administration. "Wait a minute, Mark," you say, "didn't you just tell me a page or two back how well Terminal Services runs in low bandwidth?" Sure, but command-line sessions run in even *lower* bandwidth. Imagine administering your computer remotely with nothing more than your cell phone and either a wireless keyboard or a bit of patience and the phone dialing keyboard. It's possible with command lines.
- ◆ Second, suppose you have some repetitive administrative job, something that needs doing pretty regularly or, worse, regularly at some inconvenient time, like 3 A.M. daily. It's a task so simple that you could train a monkey to do it... if they'd only let you hire monkeys and give them administrator accounts. Instead, you can create an "e-monkey." Figure out how to do the task from the command line. Then type those commands into an ASCII text file with Notepad. Give the file the extension `.CMD`. And whammo: you've just written a batch file that you can schedule to run at 3 A.M. Try writing a batch file that stores *mouse clicks* and you'll see how neat the command line can be!

Windows 2000 made some great strides in offering better command-line tools, but didn't go all the way. With Windows Server 2003, it's actually possible to do about 98 percent of your administration from the command line.

## Desktop Support Improvements

Most of you don't use Server as a Desktop operating system, so you wouldn't expect much in the way of improvements to Desktop control, but recall that Windows Server 2003 incorporates all of the new things that came to XP. If keeping Desktops up and running is part of your job, then you'll like what Windows Server 2003 brings, although in most cases you need XP on the Desktop to see Server 2003's improvements.

## Profiles and Policies

When they first arrived, roaming profiles seemed like a great idea. . . but then we tried them. Slow, prone to breaking. . . auugh. But Windows 2000 made them more palatable, and so has Windows Server 2003.

First of all, there's a new group policy that you can apply to a machine (or machines) that says, "Ignore all roaming profiles." This is terrific—now I can ensure that just my laptop and desktop get my roaming profile, by setting up all of the public access/shared systems and the servers to "ignore roamers."

Another group policy makes roaming profiles better for laptop users. Sometimes I'll check into a hotel and find that it offers Ethernet connections to the Internet (yippee! I will sleep on a *stone floor* if it means I get high-speed Internet access), so I plug my laptop into the Ethernet and boot it up, only to realize that my stupid laptop is trying to suck my roaming profile over the Internet. A half-hour later, it gives up.

Or at least that's what *used* to happen. Now I just set the group policy on my laptop that stops and asks, "Do you want to download your roaming profile?" I say no and log on in seconds. (Of course, the laptop must be running XP.)

Those are just two examples of the new things you can do to control profiles; there is a ton more, as a look at the Group Policy Editor (which you'll meet in several places in the book) shows.

## Software Restriction Group Policies

Every help and support desk person has a little list of things she'd like to see. One is almost always, "I'd really like to keep users from running particular programs on the system." (If you're having trouble thinking of examples, then see if the names Morpheus or Kazaa ring any bells.) With XP desktops, you can do that.

XP and Windows Server 2003 include a whole new set of group policies called software restriction policies. With them, you can tell a Desktop, "Nothing runs except Word, Internet Explorer, Outlook, and the Palm Desktop." It's pretty neat and pretty powerful, and you can learn more about it in Chapter 9.

## The Group Policy Management Console (GPMC)

After reading the last page, you may be shaking your head saying, "Yeah, that's nice and all, but you're talking about group policies? Those guys are a nightmare." Yes, they can be, particularly when a group policy refuses to run—"Let's see, I just created this policy that keeps Access from running on Ronnie's desk and he can *still* run Access!" Several things might keep your new policy from running—Ronnie's Desktop might not have refreshed policies, or it might have refreshed policies but your policy might have been overridden by another policy. You look and see that there are only 24 other policies that apply to Ronnie and his Desktop, so time to start sifting through policies. . . or not.

Microsoft has been working on a really terrific group policy troubleshooting tool called Group Policy Management Console. It *didn't* ship with Windows Server 2003, but as of this writing Microsoft expects to give it away free on their Web site by March/April 2003. You'll learn more about it in Chapter 9.

## Tightened Security

Sometime in late 2001, two things occurred to Bill Gates: first, network security is important and, second, Microsoft software is buggy as heck when it comes to security (among other things), so a lot of Microsoft security is lacking a bit. So he derailed virtually all of Microsoft's coding efforts for two months as Microsoft trained nearly everyone about security.

In the end, this was a good thing. NT has always had a reputation of being an insecure operating system, but it's an inaccurate reputation. NT (3.1–4, and Windows 2000) is an extremely secure OS in that it provides the option to lock many things; a properly tweaked NT server is a secure server indeed. NT's reputation comes, however, from the fact that a default installation leaves the vast majority of those locks unlocked. For Windows Server 2003, that changes.

For example, NT 4 and Windows 2000 installed an unsecured Web server by default on every server you ever installed. Not a good idea, as we learned in June 2001 when a worm called Code Red infected millions of servers—*though the Web server*. (As I write this in late 2002, there are still thousands of servers out there infected with the Nimda virus, a year after Nimda's arrival.) With Windows Server 2003, in contrast, you don't get IIS unless you ask for it. And even then, it's a pretty locked-down version of IIS. (You'll learn how to set up IIS in Chapter 17.)

To see another example, look at the NTFS permissions on the C: drive of any Windows Server 2003. Where the default permission for every previous version of NT was Everyone/Full Control—"C'mon in, y'all, we're all friends here!"—Windows Server 2003 gives Everyone only Read and Execute permission on the root of C:. The Users group has more power, as it can read files and create folders on C:, but it cannot create new files on the root of C:. You can change all of this, of course, but by default Windows Server 2003 is a bit tighter security-wise than its predecessors.

That's a good thing. But it won't be an unmixed blessing. I'm sure that at least once in your Windows Server 2003 career you will be sitting at the server trying to get something done but getting nowhere. You've got Help open, or a book at your side—this one, I hope!—clicking where the book says to click and dragging where the book says to drag, but it's not working. In that case, you may be doing the right thing but lack the permissions to do it. So Windows Server 2003 offers you one more impediment to getting our jobs done: you'll have to wend a maze of security to do some things.

But don't take that as a negative comment. It is simply a fact of life in the twenty-first century that there are tons of dirt bags out there and the Internet has now given them the chance to come knock at your door so we have no choice but to install locks on our doors. Yes, it was nice back in the days when we didn't have to lock our doors or carry keys, but those days are gone forever. NT 5.2 changed, yes, but it was just changing with the times.

## Reliability

Continuing from the last section's topic, what makes an OS secure? In addition to the traditional security topics, like the ones that I just discussed, there's a more visceral sort of security—do you trust the thing not to crash on you?

In general I have always found NT to be sturdier than its compatriots; I think that no one would argue with me when I say that it's always been more reliable than Windows 3.x, 9x, and Me. I'd argue further that it was more reliable than the Mac, at least through OS 9.x. (OS/X is a completely different story; I think Apple did a great thing with OS/X—the result will be eventually be, I think, both Apple and Microsoft sometime in the future both offering OSes so reliable that we'll actually trust those OSes implicitly. Unfortunately we're not there yet. But I think it's possible.)

Windows 2000's System File Protection and Driver Verifier made great strides in making Windows 2000 far sturdier than its NT 4 predecessor; XP took that further with System Restore, Application Verifier, and Driver Rollback. As with some other Windows Server 2003 features, they're not exactly new, as they first appeared in XP, but they're new to Server. Unfortunately, one of the three,

System Restore, apparently doesn't come with Server, and that's puzzling: it's an XP tool that lets you roll back the entire state of a system to some time in the past, undoing the effects of installing some new unreliable program that's made your previously reliable system wobbly. I don't know why they left it out of Server; perhaps we'll see it return with a future version of Server.

Driver Verifier was—and is—a useful tool for checking up on new device drivers and other system-level programs. It was a great addition to 2000 and still is, with Windows Server 2003; smoking out problems with kernel-mode programs is far easier with its help. Application Verifier performs a similar service, but for user-mode programs.

Have a program that ran fine under NT 4 or Windows 9x but won't run under Windows Server 2003? Then run it under Application Verifier. When it fails, Application Verifier will tell you what caused it to fail and, even better, it can add information to the application that lets it run under Windows Server 2003.

Another source of operating system instability can be new drivers. You've got the system running fine, but the vendor of one of your pieces of hardware comes out with a new driver. As it looks like you're running smoothly, you're leery about chancing it with a new driver... there must be some subtle bug that someone found that this updated driver fixes, but this new driver could make your system unstable... what to do? Well, Driver Verifier is a great way to check out a new driver, as it was in Windows 2000. But now it's got a simple partner in Driver Rollback. You load a driver and decide that it's no good... now, where did you put the old driver? Just go to Device Manager, find the device with the new driver, right-click it and choose Properties... you'll see a new button, Rollback Driver. Like XP, Windows Server 2003 keeps the previous version of all drivers.

## Storage News

XP and Windows Server 2003 brought some much-needed fixes to NTFS and one great new feature: volume shadowing.

In brief, volume shadowing lets you take snapshots of a file share. At predetermined times of the day, Windows Server 2003 will record the status of whatever it's shadowing and let you roll back to that quickly and easily. For example, suppose you keep your important documents in a share \\serv01\documents. You could tell Server 2003 to take snapshots—*shadow copies* is the Microsoft term—of the files in that share at 7 A.M., 10:30 A.M., noon, and 6 P.M.

A few days later, at 10:15 A.M., you realize that you've accidentally deleted an important document. But all's not lost; just fire up the shadow copy client software (included with Server 2003) and restore the 7 A.M. version of the document. A few hours' work lost, but that's all. And no need to go find the tape librarian and beg to get a tape with last night's backup mounted.

Volume shadowing lets you create a kind of imaginary copy of a file, with the state of that file frozen in time. That means that you can take shadow copies of open files and then back up the shadow copy! For example, suppose you have a SQL database that you need to back up every day, but there's never a good time to stop the database server. No problem: take a shadow copy at 3 A.M. That copy does not change on a second-by-second basis, unlike your real SQL database file, so you can back it up at your leisure.

I told you that NTFS got some other improvements; they include

- ◆ NTFS clusters can be any size, unlike Windows 2000, where their cluster size could not exceed 4KB or the volume could not be defragmented.

- ◆ A server can now host as many Dfs (Distributed File System) roots as you like; Windows 2000 only allowed each server to host just one root.
- ◆ Offline files can now cache encrypted files.
- ◆ You can set up encrypted files so that more than one person can view an encrypted file.
- ◆ You can now both compress and encrypt a file.
- ◆ EIDE drives can now run independently, meaning that you can run a small database server with two EIDE drives rather than SCSI drives—one drive for the database, the other for the transaction log. This was always possible in NT, but never made sense, as EIDE drives were limited to only run one at a time—if your SQL software said to the hardware, “Save these bytes to the database file and those bytes to the transaction log,” then in actuality the OS would make the EIDE drives take turns. It might first write the bytes to the drive holding the database file while the drive holding the transaction log cooled its heels, and then write to the transaction log while keeping the database idle. The techie term for this would be that EIDE drives are now *asynchronous*, at least when they are on different channels—for example, this works if one hard disk is on the primary EIDE channel and the other is on the secondary EIDE channel.

None of those are truly earth-shaking, but they’re all quite welcome improvements. Which brings me to my last point in this chapter...

## Windows Server 2003: Not Yet or Good Bet?

Should you upgrade? Is it worthwhile to move up to Windows Server 2003, Standard Edition? That’s a really tough question.

On the one hand, it’s hard to point to any one feature that grabs you by the throat and says, “You gotta have me.” For some people it’ll be the new Active Directory stuff, either forest roots, domain renames, or the new branch office–friendly features. Or it might simply be that they’ve been waiting to go to a full-blown LDAP-based directory service like Active Directory for a while but were leery of the version 1 feel of Windows 2000’s AD. But are these reasons to toss out an already-existing infrastructure built on Windows 2000 Servers? Buying all of those server licenses might be a hard sell in a place with a lot of servers. For those with just a handful, then the upgrade might be simple, not too expensive, and the fact that you needn’t buy new client access licenses when upgrading to Windows Server 2003 has to make Server 2003 go down easier. But again 2003 seems to lack that one killer feature.

Furthermore, as I wrote this book I found time and time again that some section of Windows Server 2003 didn’t do anything that Windows 2000 Server didn’t do but that Microsoft had changed the user interface, wizards, syntax or the like. As a result, much of the time that I spent researching the book was time spent trying to figure out how to do something that I’d already figured out in 2000!

On the other hand, Server 2003 has a real preponderance of attractive features. Even the much-maligned (by *me*, to tell the truth) XP user interface has been toned down in Windows Server 2003 and is pretty nice—it’s convenient in the Active Directory tools to select a group of users and do one operation on them, or to just drag and drop them between organization units. The more I work with Windows Server 2003, the more I like it. This is always true, of course—features that you first think are kinda okay soon become “man, do I miss them” when running an earlier version of the operating system. Some people will find particular small aspects compelling, as in the case of conditional DNS forwarding.

I first met Windows Server 2003 in its beta 2 form in 2001, and I can't say that I was impressed. But from beta 3 onward it's grown on me and as I write this, just before its final release, I can say honestly that I will replace all of my Windows 2000 Servers with Windows Server 2003s, as soon as I can. That's not to say that I think that all of you should do that—read the rest of the book and decide for yourself.

As you can see, there's a lot of fun new stuff to play with and learn about in Windows Server 2003. But Windows Server 2003 is sort of the second chapter in the second book in a series—NT 3.1, 3.5, 3.51, and 4 were basically chapters in the first book, and Windows 2000 was the first chapter in the second book. Some of you have been following along with the Server story and you're ready for the new Server 2003 stuff; but for those of you just joining us, we've got the next chapter, which brings up to speed those who are new to Microsoft networking. So if you're already NT-savvy, skip ahead to Chapter 3. If you're new to the Microsoft networking game, or just want a short refresher, then turn the page and let's review The Story So Far.

## Chapter 2

# The Basics: Networking Software, Servers, and Security

IN A LOT OF ways, Windows Server 2003, Standard Edition (which I'll call "Server 2003" or "2003" in this chapter) should be named "NT 2.1." Anyone coming into the Microsoft networking story without any previous experience with some version of NT, Windows 2000, or Server 2003 probably feels just as lost as someone who gets dragged into a movie theater to see *The Empire Strikes Back* while knowing nothing of the original *Star Wars*. They end up asking things like, "Who is the tall guy with the black shiny mask and the bad attitude; and speaking of attitude, what is *with* that woman whose hairdo looks like she strapped a couple of Danishes on her head?"

In this chapter, I'll give you a bit of history on Server 2003 and then take a very high-altitude look at why we're using Microsoft's networking software in the first place. This is *not* intended to prepare you for a test on networking essentials, nor is it a complete book on NT's past and present. (When I say "NT," remember that Windows Server 2003, Standard Edition is really just NT Server 5.2.) What I'm trying to accomplish in this chapter is to answer the questions:

- ◆ Why should I care about all of this networking stuff, anyway?
- ◆ Why does Microsoft's networking software approach networking the way that it does? Here, I'm referring to the fact that much of why Server 2003 works the way that it does is simply *because NT always did it that way*—so knowing more about NT's history makes 2003 make more sense.

## What's the Point of Networks and Networking?

In a way, this chapter is penance for my youthful misdeeds.

When I was in the seventh grade, I had a math teacher named Mr. Schtazle. Seventh-grade math was a kind of potpourri of mathematical topics—I recall one chapter that took pains to drill into our heads the difference between precision and accuracy—and I'd plague the poor man at the beginning of every chapter by asking him, "How will we use this?"—a slightly more-polite version of "why do

we care?” Well, nowadays I find that when I’m teaching a room full of people about Windows 2000, I’ve got to be careful to answer that question, “Why do you care?” even if it isn’t asked. Because if I don’t answer that, then many people in the room will leave the class with a pretty good notion of *how* to accomplish a bunch of tasks but not a really good feel for *why* they’d do the tasks in the first place. And you know what? Answering the “Why do I care?” question can be pretty rough some times.

So, Mr. Schtazle, if you’re out there...my apologies.

Let’s consider the two questions that I asked a paragraph or two back:

- ◆ Why network in the first place, and
- ◆ If we agree that networking is a good thing, why do we do it this way?

The answer to the first question will turn out to be pretty straightforward: Networking solves a set of problems for us. The answer to the question, “Why do we do it this way?” is a bit longer.

First and foremost, you’re doing this to try to solve some problem that networking can help you with. Your company might want, for example, a great Web site, or to be able to send and receive e-mail, or a simple file and print server for a small office. These are the goals; a network is the means or tool to reach them. In short: *The ultimate goal of any networking project is to provide some kind of service.* Everything else is just a necessary evil—but there are a *lot* of those necessary evils!

Second, there are many kinds of services that networks can provide, and every kind of service needs different software to make it work. For example, suppose you wanted to set up a Web site on the Internet. Network services, including Web sites, need two main pieces: a *server* piece and a *client* piece. To put up that great Web site, you’ll create the site itself with HTML and drop that HTML onto a Web server. One way to get a Web server is by taking one of your computers and putting a piece of software on that computer to make it function as a Web server. But that’s only half the story—in order for your customers to enjoy that Web server’s content, they will need a piece of client software called a *Web browser*. That’s our first networking piece: *Every network service needs server software and client software.*

Third, you need to ensure that there’s a way for your information to get from your server to your clients, a physical system that the service can travel over. If the clients and servers are in the same building, then you only need a local area network (LAN), and setting that up only requires pulling wires through the building. If, however, you want to offer your service to the world, as in the case of a Web server, then you’ll need some kind of WAN (wide area network) connection to the Internet. In other cases, you’ll need a WAN connection, but not to the Internet: many organizations with more than one location connect those locations via private communications links with names like *leased line*, *T1*, or *frame relay*. That’s our next networking piece: *Networks need connection hardware (switches, hubs, routers, modems) and links (phone lines, network cables, frame relay, DSL, cable modem, ISDN, etc.) or the clients can’t connect to the servers.*

Fourth, to provide a service over a network, your server and your clients must agree on how to transmit information over that network. That agreement is called a *network protocol*, and the one that you’ll most probably use in the Windows 2003 world is called the Transmission Control Protocol/Internet Protocol (TCP/IP). You may have heard of it before, as it’s the network protocol that the Internet uses, but you needn’t be on the Internet to use it. In short: *Clients and servers must speak the same network protocols.*

Fifth, once you’ve got the channels open, and before information starts flowing in both directions, you’ll almost certainly need to worry about security. When you use the tool that is networking, you

want to be sure it doesn't increase your risk, and in fact you can shape the tool so it reduces hazards. Briefly: *Networks need security.*

Sixth and finally, once you've set up that terrific network service, you need a way for people to *find* that great service. You do that with a "naming" system. Windows 2003 has two of them—one that appeared years ago before the first version of NT, and a newer (to NT, anyway) method that the Internet's been using for years. The last network piece, then is that: *Networks must provide a way for users to find their services.*

Let's examine these pieces in order, take a closer look at why they work the way that they do, and get some insight into how Windows 2003 in particular handles them.

## Network Client and Server Software

The reason that we network computers in the first place is so that computers acting as clients can benefit from the services of computers acting as servers. For example, suppose you want to visit my Web site, [www.minasi.com](http://www.minasi.com). Two of the ingredients that you'll need to make that possible are software:

- ◆ You'll need a computer running a program that knows how to request Web information and then how to receive it—in other words, a *client application*.
- ◆ I'll need a computer running a program that knows how to listen for requests for Web information and then how to deliver that information—in other words, a *server application*.

As sometimes occurs *too* often in the computer business, you've got choices about both the client and the server.

### THE CLIENT PIECE: A WEB BROWSER

I've said that first you'll need a computer, of course, one that's running a Web browser program like Netscape Navigator or Internet Explorer. But let me rephrase that in basic network client-server terms.

There is technically no such thing as "the World Wide Web." Instead, there is an agreement about how to transfer text, pictures, and the like, and that agreement is called the HyperText Transfer Protocol—which is normally shortened to HTTP. The phrase World Wide Web just refers collectively to all of the HTTP servers on the Internet. When you think you're surfing a Web page, what really happens is this:

1. Your client computer asks the Web server (oops, I meant *the HTTP server*) something like, "Do you have any documents?"
2. The Web server responds by saying, "Here's my default document," a simple text file that is the so-called home page for that Web server. The Web server sends that file to your client using the HTTP protocol.
3. Once your client receives the text file, it notices that the page is full of references to *other* files. For example, if the home page that you requested has pictures on it, your Web browser (HTTP client) didn't originally know to ask for them, so the Web server (HTTP server) didn't send them. Your client notices the lack of the images and requests that the server send them, which it does—again using the HTTP protocol.

Here, “HTTP client” just means a program that knows how to speak a language that transfers a particular kind of data—Web data. Your computer is deaf to the Web unless it knows how to request and receive data via HTTP.

Notice what *client* means here. It doesn’t refer to you, or even to your computer. Instead, it just means a program that your computer runs.

### THE SERVER PIECE: A WEB SERVER

Next, let’s consider what’s sitting on my side of the conversation.

I’ll need a computer running a special piece of software that is designed to listen for your computer (or anyone else’s, for that matter) requesting to see my Web pages via the HTTP protocol, and that can respond to those requests by transferring those pages to the requesting client software. You *might* call such a piece of software an “HTTP server” program, although almost no one calls it by that name. You’d more *commonly* call it “Web server” software. There is a variety of Web server software that I might run on my Windows Server 2003 computer, but I’m most likely to run the one that comes free with Server 2003, a program called Internet Information Services (IIS) 6. Alternatively, I might find, download (probably using HTTP!), and install a popular piece of free Web server software called Apache.

Once again, notice carefully what “server” means here. It does not really refer to the particular computer hardware that I’ve got stashed in my network room connected to the Internet. Instead, “server” means “the program running on Mark’s computer that listens for HTTP requests and knows how to fulfill them.”

Now that I’ve gone through all of that, consider again the question that I asked at the beginning of the chapter—why are you bothering with a network? The answer is probably “because you want to offer a Web site, either internally or on the public Internet, and you think that IIS is the best (highest-performance, cheapest, or some combination of the two) Web server software around”—which means that you must use Server 2003, as it’s the only operating system that supports IIS 6. (Or you could use an earlier version of Server and an earlier version of IIS, but why not go with the latest and greatest?)

### OTHER TYPES OF SERVERS

I’ll tend to use the Web client-server example for this discussion. But I don’t want to lose sight of the fact that there are quite a few client-server systems, besides Web servers, that are in common use and that you may want to use 2003 to create. Returning to the theme of this chapter, then—“Why do I care or why do I need this stuff?”—networks offer several valuable services, and you may want to set up a computer to act as a server and offer some of those services. Here are a few besides the Web server example.

**File Servers** File servers act as central places to store data files. Why put them on a server rather than just keep them on your local computer? Well, in some cases someone else created the file, and placing a file on a central server is a simple way to make the files available to others. The other good thing about storing files in a central location is that they’re more easily backed up that way. 2003 comes with file server software built in.

**Print Servers** Print servers let you share printers. Not everyone wants to put a printer on their desk, and besides, if you share the printers, you can afford more expensive (and presumably better) models. 2003 comes with print server software built in.

**E-Mail Servers** Mail servers are essential if you're going to do e-mail. Some computer (or computers) must act as the post office, collecting e-mail from the local users and sending it to other mail servers across the Internet and acting as a receiving point for other mail servers to send mail destined for your organization. You *can* outsource this function by letting your ISP act as your mail server, but running your own mail server gives you more flexibility. (However, it *does* require a persistent connection to the Internet.) 2003's new features include a basic e-mail server. Yes, it's "basic" because Microsoft *really* wants to sell you Exchange as your mail server. But it's not a bad server for many people's needs.

**Group Scheduling Servers** The centralized nature of servers means that they're a great place to keep track of scarce resources like meeting rooms or your time. 2003 does not come with a scheduling server, as Microsoft wants to sell you Exchange to do that sort of thing. But there are alternatives to Exchange; there are some terrific Web-based scheduling tools that work great on 2003—for one example, take a look at [www.mattkruse.com/scripts/calendar/](http://www.mattkruse.com/scripts/calendar/) or other tools, like Lotus Notes.

**E-Commerce Online Stores** If you've got something great to sell, then the Web's one place to do it. There are thousands of online stores on the Web, and a good number of them run on 2003. While 2003 includes a Web server, it doesn't include the other software that you'd need to create a complete online store. But there are a lot of consulting and programming firms that would be happy to help you create an online store atop 2003!

## Networks Need Connection Hardware and Links

If I want to offer a server service and ensure that you can enjoy that service, then we'll both need to be physically attached to the same network—the same series of cables, satellite links, or whatever—or your computer's requests will never get to my computer in the first place. That probably means that we're both on that huge network-of-networks called the Internet, but we could just be working for the same company in a single wired building, or a multilocation firm connected by a private intranet.

Now, notice that if I'm going to run a Web server, I'll need to be connected to our common network (Internet or otherwise) persistently: I couldn't decide to run a Web server out of my house and just dial in to the Internet now and then. Of course, if I'm only serving some private network that we share, then an Internet connection is unnecessary, as we already have connection to a common network.

People who worry about the physical connection part of networking concern themselves with getting cables run through walls, calling the phone company to arrange for persistently connected data links of various kinds—links with names like DSL, cable modem, frame relay, leased lines, T1 or T3 lines—and then work with a family of hardware that helps get the bits going off in the right direction—devices with names like switches, hubs, and routers.

Does 2003 help you with this part of the job? In some parts, it can. Switches and hubs are very basic, simple devices, and 2003 has nothing to do with them—although clearly 2003 depends on their presence in order to network! Routers are, however, more complex devices. You probably know that the market leader in the router world is a firm named Cisco Systems, but you may not know that a router is really just a small, single-purpose computer. If you wanted to, you could use a computer running Server 2003 to replace a Cisco router. Additionally, if you wanted to allow people outside your network to dial in to your network, you could use a Windows Server 2003 to make that possible. (It's not the best answer, as you'll see in Chapter 6, but it *is* possible.)

## Clients and Servers Must Speak the Same Protocols

But simply being connected to the same wire isn't enough—we need a common communications language. If I were to pick up a phone and dial some number in Beijing, I'd have a physical connection with whatever poor soul picked the phone on the other end—but that would be the extent of our interaction. In the same way, computer networks need to agree on things like, “What's the biggest block of data that I can ever send you?” and, “How shall I acknowledge that I actually *got* that block of data?” or, “Should I bother acknowledging receipt of data at all?” and hundreds of other questions.

The answers to all of those questions are contained in the “network language” or, in network techie terms, the *network transport protocol*. It probably won't surprise you that more than one network transport protocol exists, and over the years NT has generally supported three of them:

- ◆ NetBEUI (Network Basic Input/Output System Extended User Interface), an old Microsoft/IBM/Sytek protocol designed to support small networks
- ◆ IPX/SPX (Internet Packet Exchange/Sequenced Packet Exchange), the protocol that Novell NetWare predominantly used for years
- ◆ TCP/IP (Transmission Control Protocol/Internet Protocol), the protocol of the Internet and intranets

Although you have three choices, it's a good bet that your Microsoft software-based network uses TCP/IP. Why TCP/IP? Well, there have been some really great protocols over the years, but as the Internet uses TCP/IP and as the Internet is so popular, TCP/IP has sort of trumped the other protocols. In fact, it's impossible to do a fair number of things that 2003 and its predecessors Windows 2000 and, to a lesser extent, Windows NT 4 are capable of *without* TCP/IP. So I'm going to assume for our discussion and indeed for most of this book that your network will use TCP/IP.

Oh, and one more thing—once you've decided that TCP/IP is your network protocol of choice, then you'll need to install several *more* servers to support TCP/IP's infrastructure. And here again, when I say “more servers,” I'm not suggesting that you have to buy more PCs, although you might. What I mean is that you'll have to install software on some computer or group of computers to perform three basic pieces of plumbing or infrastructure jobs:

- ◆ A Domain Naming System (DNS) server keeps track of the names of the computers in your network (an important task, believe it or not).
- ◆ A Dynamic Host Configuration Protocol (DHCP) server configures the specifics of TCP/IP on each computer in your network, both great and small.
- ◆ A Windows Internet Name Server (WINS) does something like what DNS does—keeps track of names—but isn't really necessary on a “pure” Windows 2003 network—its main job is to support older Microsoft operating systems like Windows 9x, Me, and NT 3.x and 4.

You'll learn more about the specifics of DNS, DHCP, and WINS in Chapter 7. I should point out that if you're a one-person shop, then you might not need all of that, as your ISP might be handling it for you—but I'm assuming throughout this book that you are probably a network administrator/manager for a network of at *least* a few computers, and possibly for a tremendous number of computers.

## Keeping the Bad Guys Away: Security

Once you've gotten the first four things done, then your job's finished, in a sense—people can now read and write files on that file server, view pages on that Web server, print to that shared printer, set up meetings with you over your scheduling server, and so on. I mean, hey, networking's all about sharing, so just open the doors and let 'em in!

As you've probably realized, there's a missing piece here: security. While there's a lot to security, it basically boils down to two things: *authentication* and *permissions*.

- ◆ First, you want to be able to identify who's entering your network. That's authentication.
- ◆ Second, once you know for sure who you're talking to—once you've authenticated—then you must be able to look up somewhere what that person is allowed to do, his *permissions*. For example, a network logon could figuratively go something like, “Okay, now I know you're Jack...but I've been told to deny Jack access to everything.” Merely being authenticated doesn't mean that you get access!

### AUTHENTICATION

The first part of security is called *authentication*, and you usually accomplish it through usernames and passwords, although as time goes on you'll eventually use the more science-fiction means of authentication: One day, the computer may recognize you by your fingerprint, face, voice, retina blood vessel pattern, or some other item that's distinctly you. The geek term for those authentication approaches is *biometric*.

For now, however, it's user accounts and passwords that identify users. I realize that nearly everyone who's reading this book has undergone an authentication at some point—you've logged in to a network some time. It all sounds simple, doesn't it? And yet user accounts and passwords present special problems.

### Storing Authentication Information

First, you'll need some kind of program that lets administrators create user accounts and store them in a file. In their simplest form, user accounts consist of a database of usernames and passwords. That's no big deal—it's a very simply structured database, and there are tons of database programs out there—but don't forget that you need to *encrypt* that information. Otherwise, there's the possibility that someone could come along and steal the database file, take it home, and perhaps crack it for your user's passwords.

Just such a thing happened to NT 4. NT stored user information in a file named SAM. If you leave me in the same room as your server, then I can copy that SAM onto a floppy and take it off-site to analyze it. Wasn't it encrypted? Well, yes, but sometimes encryption isn't enough—a group of hackers figured out how to crack SAM's encryption. With just a bit of work, anyone could extract passwords from an NT SAM. (Which is a good reason to keep your servers behind lock and key, so that it's harder for someone to steal your account files.) Windows 2000- and 2003-based domains (a term I'll define soon) use a more sophisticated encryption scheme on its user account/password file (which is named NTDS.DIT, not SAM), but unfortunately even that file can be cracked with some determination. Again, let me stress that this is only a danger if you let someone physically sit down at the servers that do logons, a set of servers called domain controllers, so don't worry that 2003 isn't secure. Any security person can tell you that you should *never* give the bad guys physical access to your important servers—lock 'em up!

The tool that lets administrators create, modify, or delete user accounts is called Active Directory Users and Computers. *Active Directory* refers to Windows 2000 and 2003's system for storing usernames and passwords. It's called a directory because *directory* is the current network lingo for "database of user accounts." Personally, I think it's kind of confusing—in my mind, directory conjures up visions of drive letters, like C:\DOS—but it's the current argot, so it's worth knowing. And, in case you're wondering, the "Active" part is just Microsoft marketing; don't look for any deep meaning there. (It's not like Novell makes a product called Comatose Directory or Lethargic Directory.)

### ***Authenticating without Compromising Security***

So you've got a server somewhere that contains the list of usernames and passwords. Those are only good if someone can use her username and password to be authenticated and get access to things on the network. So you need some way for a user sitting at her workstation computer to be recognized by that server. You're already familiar with this recognition process: we call it logging on.

Suppose I'm sitting at my Windows XP workstation and I want to get to some files on a file server named files-r-us.bigfirm.biz. Before files-r-us will give me access, I've got to submit myself for authentication—I've got to log on. One of the many programs that comes with every version of NT since version 3.1 is called `winlogon.exe`, and it's the program that pops up when you first turn your workstation on, asking you to punch in your username, password, and domain. (Again, I'll explain what a domain is in a minute.)

So imagine that I'm trying to access some data on files-r-us. Files-r-us responds by asking my workstation, "What's his name and password?" Now I've got a problem.

You see, what I'd *like* to do is to just say over the network line, "This is Mark and his password is 'swordfish.'" Then files-r-us can just look in its directory file of usernames and passwords and see if it has a user named Mark with a password of "swordfish." If so, then it lets me in. If not, it doesn't. Simple, eh?

Well, there's one flaw here—the part where my workstation passes "swordfish" over the network. A class of programs called "sniffers" can record and display any data that passes over a network wire. So passing passwords around on an unencrypted Ethernet cable isn't a great idea. That means you've got another challenge: how to prove to a server across the network from you that you've got Mark's password without actually showing that password to the server.

Over time, networks have come up with different answers, but Active Directories, whether based on Windows 2000 or 2003, use an old authentication method called Kerberos which some folks at MIT first invented in the mid '80s. It replaces an older method employed by NT 3.x and 4 called NTLM, which was short for NT LAN Manager, a reference to one of NT's predecessors. What follows is an extremely simplified version of how Kerberos works. (It's actually a wildly simplified description, but it'll help you understand the more complete explanation that you'll see in the next section.)

Let's return to files-r-us. I try to access its data, so files-r-us needs to first log me in. It does that by saying, "I'll tell you how to access my data," and sends me some instructions on how to get to its data. But the data is *encrypted*—with my password! In other words, *anyone* could claim to be me, and files-r-us would happily send these vital instructions-for-connection. But only I can decrypt those instructions, so only I can benefit from them. So files-r-us ensured that only someone with my password could gain access, without sending my password over the wire.

### **Centralizing and Sharing User Account Information: Domains**

But my simple example about trying to access one file server is, well, a bit *too* simple. Most companies will end up with more than one server, and in fact it's not unusual to end up with dozens or hundreds of servers. And that leads to the following problem. Recall that I said a page or so back that if you're going to employ user accounts, then you'll need a file to store them in. But what if you have more than one server? What if in addition to the server named files-r-us.bigfirm.biz, I've also got a mail server named postoffice.bigfirm.biz and a Web server named www.bigfirm.biz? I might want to log in to any one of those three, so they *all* have to be able to accomplish logons. But now let's examine what that actually means in terms of keeping track of user accounts. Should each server contain a complete copy of NTDS.DIT, the file containing the names and passwords for users?

That might work, but it'd be a pain, for several reasons. First, NTDS.DIT can get pretty big, and I'd end up burning up a lot of disk space copying it to every server in my enterprise. Second, if servers are connected by low-speed WAN links, the process of copying the changes to NTDS.DIT to all of the servers on my network (a process called *directory replication*) would take up a lot of time and network bandwidth. Third, do I *really* want to have to create a network "storm" of file copying amongst the servers every time someone just changes his password? And finally, what about the issue of securing the NTDS.DIT file in the first place? If I copy NTDS.DIT to every single server in the enterprise, there are bound to be a few that are out in the open, not physically secured. It'd be easy for an intruder to copy the NTDS.DIT from a poorly secured computer and spirit it off-site, to crack it at leisure.

The better idea that we've used in networks for years is to put the user directory, the NTDS.DIT, not on every single server, but instead on a relatively small subset of the servers. Those NTDS.DIT-holding servers then serve in the role of *logon server*, doing the job of authenticating for the other servers. In Microsoft parlance, a logon server is more commonly called a *domain controller*. So, to return to the example of accessing data on files-r-us, imagine that files-r-us is *not* a domain controller and doesn't contain a copy of NTDS.DIT, and that another computer, vault.bigfirm.biz, *is* a domain controller and contains a copy of NTDS.DIT. In this newer arrangement, I don't directly log into files-r-us but instead enlist the aid of vault.bigfirm.biz in order to authenticate with files-r-us.

In a purely Active Directory network (which can only include Windows 2000, XP, and 2003 systems), vault.bigfirm.biz would help me log in to files-r-us with Kerberos. In order to understand how Kerberos works, you first need to understand that under Kerberos, not only do the users have passwords, the server programs do also. Thus, the file server program running on files-r-us has its own password. So both the user and the server each have passwords—remember that.

When I tell my workstation to try to get some data from files-r-us, my workstation sees that it'll need to get me logged in to files-r-us. It does that by asking the domain controller, vault, to give me something called a "ticket" to the file server service on files-r-us. The domain controller responds by handing my workstation an encrypted piece of data, which is the Kerberos ticket.

The ticket can be decrypted with my password, making its contents a mystery to anyone but me (or my workstation, which obviously knows my password). My workstation decrypts the ticket, which contains two things. First, it contains a message saying "your special one-time-only password for accessing the file server at files-r-us is 'opensesame.'" Second, it contains *another* encrypted message—but this one's not encrypted with my password, so I can't decrypt it! But my workstation knows to send it to the file server, which decrypts it successfully, as the file server has its own passwords. Once the file server receives and decrypts the part of the Kerberos ticket that I sent it, the file server

sees that that ticket piece says something like, “The special one-time-only password for communicating with Mark is ‘opensesame.’ And by the way, you should have gotten this message from Mark sometime between 10:45 A.M. and 10:50 A.M. from his IP address, which should be 117.39.82.3.”

Once the file server gets its half of the Kerberos ticket, it knows a few things:

- ◆ The user claiming to be Mark who wants access to the file server is indeed Mark.
- ◆ Any messages from that now-authenticated person named Mark should have originated from IP address 117.39.82.3.
- ◆ If Mark and the file server really want to maintain a secure connection, they could even encrypt their communications using this shared—but secret—password, opensesame.

### **Security Roles and Definitions: Domains, Domain Controllers, and Member Servers**

Armed with this information, I can define a few Microsoft networking terms.

**Domain** You just saw an example where one machine (vault) let me log in to another machine (files-r-us). I haven’t mentioned this yet, but before I could get *anywhere* I needed to log in to the computer at my desk, my workstation—and when I first tried to log in to my workstation, it was once again vault.bigfirm.biz that authenticated me. Clearly, then, my workstation and files-r-us “trust” vault.bigfirm.biz in some fashion.

The collection of machines that share the same list of user accounts, the same NTDS.DIT, is a *domain*. Or, to put it a bit more specifically: several computers hold a copy of NTDS.DIT and are willing to act as “logon servers” (domain controllers) with that NTDS.DIT. The collection of machines that are willing to accept logons from those domain controllers (in Microsoft terms, who “trust” those domain controllers) and the domain controllers themselves are collectively called a domain. So my workstation, vault, and files-r-us are all part of the same domain.

**Domain Controller** A server, such as vault.bigfirm.biz, that contains a copy of the user account/password data, and that therefore can let users log in to servers, is a *domain controller*. Domain controllers exist to centralize the user account/password information so that you needn’t put the NTDS.DIT on every server.

**Member Server** A machine that is running NT 3.x, 4.0, 2000, or Server 2003 but *not* acting as a domain controller will not contain a copy of NTDS.DIT and therefore can’t authenticate domain members. Such a machine is called a *member server*.

### **PERMISSIONS AND ACCESS CONTROL LISTS (ACLs)**

Once a server has determined that I am indeed me, does that mean that I’ll get access to the server’s information? Not necessarily. Authentication just identifies me. The next step in security is access control, also known as (depending on what network operating system you are using) *rights*, *permissions*, or *privileges*.

Ever since its earliest versions, NT (which includes Windows Server 2003) has had a very flexible system of file and directory permissions. As you’ll see later in this book, you can exert very fine-grained control, such as specifying that Mary can read or write to a given file, that Bill can only read it, and that June cannot access the file at all. Don’t get the idea, however, that permissions

refer only to files. There are permissions to do things like create, modify, and destroy user accounts, and even permissions to create domains in the first place. The flexibility of these permissions is one of Microsoft networking's great strengths.

Just about everything in the Microsoft networking world has security on it. Want to read a file? You need the permissions to read it. Want to shut down the program that provides the Web server? You need the permissions to shut it down. Want to create a new user account on your network? You need the permissions to create a new user.

These permissions are stored as a list. In the case of the file, the operating system sets aside a little space for every file that it creates, and keeps the permissions in that space. A set of permissions for a file, then, might look like

- ◆ A user named June can do anything that she wants to the file.
- ◆ Another user, Joe, can only read it.
- ◆ Any user in a group named Cube-dwellers can read or modify the file, but not delete it.
- ◆ The operating system can do anything that it wants to the file.

In Microsoft networking-speak, that list is called an access control list or, inevitably, *ACL*. Each of the four entries are called access control *entries* or ACEs. You will learn in this book that *lots* of things have ACLs, and adjusting those ACLs is how you configure security in your network.

#### ACCESS TO EARLIER SECURITY SYSTEMS

The last challenge that Windows 2000 and 2003's security designers faced was the so-called "legacy" support—ensuring that they could interact with the security systems built into Windows for Workgroups, Windows 9x, NT 3.x, and 4. I've described in very broad strokes how Kerberos works, but Windows and NT didn't use anything like that and in fact *couldn't* do Kerberos logons; Kerberos first appeared in the Microsoft networking world in February 2000, with the introduction of Windows 2000. Microsoft knew that you wouldn't be very happy if they required you to throw away all of your old Windows 9x and NT systems before you could implement Active Directory, so Windows 2000, XP, and Server 2003 know a variety of logon methods—NTLM 1.2 for Windows 9x and NTLM 2.0 for NT 3.x and 4—in addition to Kerberos.

It's hard to overstate the importance of security. For example, in the past, one of Novell's *main* advantages over NT was in the way that it stored user accounts and handled logins—Novell's security was faster and more flexible. Sure, one could argue that Novell moved data around file servers more quickly, but not so much more quickly that anyone would really modify a buying decision. Basically, people were buying Novell for Novell's security system, something called NetWare Directory Services (NDS). NDS was essentially a big-time user database, something with a more enterprise feel to it than NT's older SAM-based system. In short, security is *important*.

#### Names: Finding Servers and Resources

When PC-based networking first appeared, we didn't do much Web work—the earliest common LAN functions were file and print services. So from the very beginning (all of 15 years ago) of PC-based networking, we've done file and print services; they're the most basic network services. But now suppose that you've got a network with more than one server on it, and you want to find out

which server has a printer available for sharing, or you can't remember which server holds that share called `hrdocuments`; how do you search for network functions?

That's one of the oldest problems in networking, and not just in Microsoft networking. Microsoft's most current answer to the "how can I find resource X on the network?" question is to store that information in the Active Directory database. But they're not there by any means yet and, even if you have an all-Windows 2003 and XP network (which is unlikely), you'll find that by default the Active Directory isn't all that much help in finding file and printer shares. I'm sure that's going to change as new versions of NT appear, but for now, we Microsoft operating systems users are pretty much stuck with an old technology known colloquially as the Network Neighborhood or, in Windows 2000 and later, My Network Places. Here's where it came from and how it works.

How would you set up a system that provided a centralized directory of services on a network, a kind of "yellow pages" that lets a user quickly find a file share or shared printer? Microsoft networking uses a name server system called the *computer browser* or *browse services*—it has nothing at all to do with the Web, it's had that name since before the Web existed—where you, the network administrator, don't have to do *anything*; the name servers set themselves up automatically. Sounds good? Well, it *is* for small networks, but it gets troublesome for larger ones—which is why Microsoft is trying to phase it out.

The servers in a Microsoft network that contain information about network services are called *browse masters* or *master browsers*. What's different about the concept of Microsoft browse servers is that no one computer is fixed as the browse master. Instead, when your computer logs in to your network, it finds a browse master by broadcasting a request for one, saying, "Are there any browse masters out there?" The first browse master to hear the workstation (there can be multiple browse masters, as you'll see) responds to the workstation by saying, "Just direct all your name service requests to me."

When a server starts up, it does the same thing. It broadcasts, "Are there any browse masters out there?" and when it finds one, it says to it, "I am a server with the following shares. Please add me to your list of servers." The list of servers that a browse master maintains is called the *browse list*, not surprisingly.

**TIP** *This is the really irritating thing about the browse list: it's broadcast-based. That means that if your network isn't 100 percent broadcast-friendly, then you'll sometimes end up with an incomplete list of servers on your network. So if you have a network built in more than one segment (and who doesn't?), or you use some kinds of Ethernet switches rather than hubs, then you may experience missing servers in the browse list. That's part of why Microsoft is trying to phase out the browse list. But for now, understand that the browse list is a largely lame and unreliable technology. You'll see later on, in Chapter 7, that you can install a service called the Windows Internet Name Service (WINS) to reduce the chance that the browser breaks, but trust me—you'll eventually come to a point where you've done everything that you can do, but the browser still doesn't work. When that happens, don't feel bad—we've all been there. I'll suggest some ways to make it work better and reduce your dependence on the browser a bit later in this section.*

By now, you may be wondering, "How come I've never seen one of these browse lists?" You have. If you ever worked with earlier versions of NT or with Windows for Workgroups, then you saw Figure 2.1 when you opened the File Manager and clicked Disk/Connect Network Drive.

**FIGURE 2.1**

Sample browse list from Windows for Workgroups or Windows NT version 3.x

From Windows 9x or Windows NT 4, you can see a browse list by opening the Network Neighborhood folder, as in Figure 2.2.

**FIGURE 2.2**

Sample browse list from Windows NT 4 or Windows 9x

From DOS or indeed any command line, you can see a browse list by typing `net view` or `net view \\machinename`. You see a screen like the one in Figure 2.3.

**FIGURE 2.3**

Sample browse list  
from a command line

```

C:\>net view
Server Name          Remark
-----
\ALDEBARAN
\ARTEMIS
\ASTRO
\ELMATH
\JIM                  JIM BOOTH
\LEUENDIS             Scot's New Super Cool Rocket Machine
\MALCOLM
\MICRON133
\MYIBM               DARCEE MINASI
\POKEY
\QNT166              Quantex P166 anazing toy machine
\SWEETIE
\WARREN
The command completed successfully.

C:\>

```

**NOTE** What's with that `\\` thing? Microsoft's network software has, since 1985, used a way of writing the names of servers and of shares on servers called a Universal Naming Convention or UNC. It looks like `\\servername\sharename`. So, for example, if I had a server named `bigserver` that contained a file share called `mydata`, I'd refer to that share as `\\bigserver\mydata`—that would be the UNC for that share. You'll learn more about this in Chapter 11, on file shares, but I wanted to explain the mystifying `\\` briefly here. And by the way, you pronounce “`\\`” as “whack-whack” in the Microsoft world. Now, to my way of thinking, that'd mean that a regular forward slash—`/`—would be pronounced “backwhack” in Microsoftese, but I've never gotten confirmation on that.

Each figure shows you the list of servers available: Aldebaran, Artemis, and Astro, just to list a few. Other servers—Daffy and MWM66—appear only in some of the browse lists because a few minutes passed between taking the screen shots, and a few “test” servers went up or down in those few minutes. In all three cases, the workstations that these screens were taken from got their browse lists from a local browse master.

You can drill down further into these browse lists, as well. In Windows 9x/Me, Windows NT 4, 2000, XP, or Server 2003 (in 2000, XP, or Server 2003, open My Network Places), you can double-click any one of those servers and see the list of shares that the servers offer; that too, is information from the browse list. In Windows for Workgroups or Windows NT 3.x, you'd just click a server once, and the list of its shares would appear in the bottom pane of the dialog box. From DOS or any other command line, you'd get the list of servers by typing `net view`, as you've already seen, and then you get the list of shares for any given server by typing `net view \\servername`, where `servername` is the name of the server whose shares you want to see.

### WHEN BROWSE LISTS GET TOO LARGE: WORKGROUPS TO THE RESCUE

As I've described them so far, browse lists seem pretty convenient. But in the little test network that I used for the previous screen shots, you saw only a few servers. Hell, *everything* works fine on *small* networks.

Now let's talk about *your* network. Sit down at a corporate network of any size and you see dozens, hundreds, or *thousands* of servers. Scrolling down through a 500-server browse list would be a bit

time-consuming—to say nothing of how much work the browse master would have to do to keep it up-to-date! The problem to solve is, then, managing the size of the browse list. There are two ways to do that:

- ◆ Reduce the number of servers in your enterprise.
- ◆ Divide the enterprise-wide browse list into several smaller browse lists called *workgroups*.

### ***Disable Peer-to-Peer Sharing on Workstations***

The first answer is actually a bit off the main topic, but let me digress for a moment and talk about it before returning to the main item: workgroups. When I say, “Reduce the number of servers,” I’m talking about an unfortunate side effect of running Windows for Workgroups, Windows 9x/ME, Windows NT, 2000, or XP workstations—they all have the capability to become peer-to-peer servers. The browse masters don’t distinguish between industrial-strength servers running NT Server and low-octane peer-to-peer servers, so you could end up with a browse list that’s *supposed* to only list your servers, but *actually* lists all of your servers and workstations. In general, I think peer-to-peer networking is a bad idea. If a piece of data is important enough to be used by two employees, then it’s a company asset that should be backed up regularly and so should go on a managed file server, not a desktop machine that’s probably backed up once a decade. My recommendation is this: Disable the peer-to-peer sharing option on your Windows for Workgroups, Windows 9x/ME, Windows NT, 2000, and XP workstations. How you do this depends on the operating system of the workstations in question. In NT 3.x and 4, open the Control Panel and then the Services applet; locate the service called Server and stop it, as well as disabling it for future reboots. In Windows 9x, go to Control Panel/Network/File and Print Sharing and make sure both options, to share files and printers, are unchecked. In Windows for Workgroups, make sure the sharing control in Network Setup is set *not* to enable file or printer sharing. In Windows 2000 and later, right-click My Computer and choose Manage, then find the Services folder and stop the Server service. (You’ll see more about doing this later in the book.)

Not only will your network have less traffic—workstations will no longer have delusions of serverdom, so they won’t be chattering at the browse master all of the time—but not loading the server part of the workstation’s operating system saves RAM on the workstation.

### ***Divide the Browse List into Workgroups***

The other approach to keeping a browse list to a manageable size is to subdivide it in some way. That’s a reasonable thing to suggest if you realize that, no matter how large an organization *seems* to be, it’s usually composed of lots of smaller groups, such as Manufacturing, Sales, Marketing, Accounting, Finance, Personnel, Senior Management, and so on. Each of those groups can be called *workgroups*, and you can pretty much chop up your enterprise into workgroups in any way you like (but a rule of thumb says that a workgroup should be a group of people for whom 95 percent of the data generated by that group stays within that group).

From a more network-technical point of view, the minimum definition of a workgroup is just *a group of workstations that share a browse list*. (That’s my definition, not Microsoft’s.) The idea is that when someone in Accounting opens up her browse list, you want her to see just the Accounting servers, not the Manufacturing servers, as she has no use for the Manufacturing servers. (Besides,

there's a good chance that she doesn't have permission to access the Manufacturing servers anyway—but I'll get to workgroups and security in a little bit.) How do you join a workgroup? See the sidebar “How Do I Join a Workgroup?”

### HOW DO I JOIN A WORKGROUP?

Generally, all you need to do is to tell the networking software on your workstations and servers that they're members of a given workgroup. There isn't any “security” in being part of a workgroup—you pretty much just declare yourself a member and you are a member. (As a matter of fact, if you misspell the name of the workgroup, you end up accidentally founding a whole new workgroup all by yourself, which I'm sure was not your intention!)

Specifically, you designate which workgroup you're a member of in one of the following ways:

**From a DOS or Windows for Workgroups workstation** In the [network] section of the SYSTEM.INI file you'll find a WORKGROUP=parameter. (You'll have a SYSTEM.INI even if you're just running DOS, because the network client software creates one.) You can also set the workgroup from the MS-DOS Network Client Setup program, or in the Windows for Workgroups' Network applet of the Control Panel.

**From Windows 9x** Open the Control Panel and double-click the Network icon. In the property sheet that you see, click the Identification tab. You see the place to fill in the workgroup name.

**On Windows NT 3.x** Open the Control Panel and double-click the Network applet. You'll see a button labeled Domain or Workgroup. (NT has a kind of confusing way of blurring workgroups and domains, which I'll make clearer later in this chapter.) Click that button, and you can change the workgroup you're a member of. Again, NT complicates choosing a workgroup somewhat, so read the rest of this chapter if you want to change an NT workgroup.

**On Windows NT 4** Open the Control Panel and double-click the Network applet. Like Windows 9x, Windows NT 4 has a property sheet with an Identification tab. Click Change to change the workgroup. Again, with NT you may see no references to workgroups at all; instead you see references to domains. Read on to understand the differences.

**On Windows 2000** If you're a member of a domain, then *do not* join a workgroup—I'll explain that in a minute. Otherwise, right-click My Computer and choose Properties. Click the Network Identification tab and then the button labeled Properties. Fill in a new workgroup in the field named Workgroup; then close the dialog box and reboot.

**On Windows XP and Server 2003** Right-click My Computer and choose Properties. (You may have to click the Start button to find My Computer.) Click the tab labeled Computer Name, then the button labeled Change. In the resulting dialog box, you'll see the choice to become a “Member of:” either a domain or a workgroup. Click the radio button next to Workgroup and fill in the workgroup name, then close the dialog box and reboot.

---

**NOTE** Workgroup names are like Windows 9x and NT 3.x/4.x machine names and can be up to 15 characters long.

So, to review what you've seen so far:

- ◆ Network browse lists allow a user at a workstation to see all of the servers on the network, and from there to see all of the shares on a given server.

- ◆ Browse lists can get fairly long, so you can partition your entire network into *workgroups*, which are just groups of people that share a browse list.
- ◆ When you request a browse list, you don't get the entire list of servers in your enterprise network, you only get the list of servers within your workgroup.
- ◆ Each workgroup has one or more servers that act as gatherers of browse information. They're called browse masters or master browsers, and they're picked automatically.
- ◆ Machines that are only workstations and don't act as servers even in a peer-to-peer capacity do not appear on browse lists.

As the question of what machines go on a browse list and what machines don't is important to the length of a browse list, let me list the kinds of machines that can act as servers in a Microsoft enterprise network:

- ◆ Windows 3.x (with the Workgroup Add-On for MS-DOS clients)
- ◆ DOS (with Workgroup Add-On for MS-DOS clients)
- ◆ Windows for Workgroups
- ◆ Windows 9x/Me
- ◆ NT Workstation
- ◆ NT Server
- ◆ Windows 2000 Professional
- ◆ Windows Server 2003

## HOW DO I VIEW A BROWSE LIST?

Microsoft has built different browse programs into its various network client software.

**From a DOS or NT/2000/XP/2003 Command Line** Type **net view**. That shows you the list of servers. You can view the shares on a given server by typing **net view \\servername**. To see the browse list for a workgroup other than your own, type **net view /workgroup:workgroupname**.

From NT, 2000, XP or Server 2003, don't use **/workgroup:** in the command; instead, use **/domain:**.

**From Windows for Workgroups or Windows NT 3.x** Open the File Manager, click Drive, and then click Connect Network Drive. You'll see a window with two panes. The browse list for your workgroup and a list of the other workgroups on the network appears as the list of possible servers in the top pane and, when you click a server, that server's shares appear in the bottom pane. To see the browse list for a workgroup other than your own, double-click the name of the workgroup in the top pane.

**From Windows 9x or Windows NT 4** Open the Network Neighborhood folder. You'll see the servers in your workgroup represented as PC icons in a folder. Double-click one of the servers, and a folder will open up showing you the shares. To see the browse list for a workgroup other than your own, double-click the Entire Network icon and you'll see a list of workgroups. On Windows NT 4, click Entire Network and then Microsoft Network, and you'll get a list of the other workgroups.

*Continued on next page*

### HOW DO I VIEW A BROWSE LIST? (*continued*)

**From Windows 2000** If your system is in a workgroup, open My Network Places and then the icon labeled Computers Near Me. If your system is part of a domain, then that icon isn't available. Instead, open My Network Places and the icon labeled Entire Network, then the icon named Microsoft Windows Network. You'll see one or more icons representing the workgroups on your network—open the one representing your workgroup and you'll see your workgroup's browse list.

**From Windows XP or Server 2003** Open My Network Places. It might be on your desktop, or it might be on the Start menu, or you might have to right-click the Desktop and choose Properties, then click the Desktop tab, followed by the Customize Desktop button, then check the box next to My Network Places and click OK twice. My Network Places will be on your desktop. Once you have My Network Places open, then you'll either see a Network Task on the left of the folder labeled View Workgroup Computers or you might have an icon labeled Entire Network, in which case you should double-click that, then double-click Microsoft Windows Network. You'll then see an icon of three PCs representing your workgroup—click that and you'll get your workgroup's browse list.

As it's an unusual product, let me just explain that the Workgroup Add-On for MS-DOS is a separate Microsoft product that lets you use a DOS machine as a peer-to-peer server. (Also, it's pretty old, so I have no idea where you'd get a copy these days.) Again, I recommend that you disable file and print sharing on all of these machines except, of course, for the machines dedicated to the task of being servers, all of which are probably running NT Server.

And once you're in a workgroup, you'll no doubt want to see your browse list; the sidebar "How Do I View a Browse List?" tells you the specifics.

Now, if you *tried* that on a working network, then you might have gotten one of NT and family's less helpful responses, like "System error 1230 has occurred." That gives me the chance to offer another important bit of advice for anyone using a modern Microsoft operating system: how to convert a numeric error code into a bit of explanatory English text—see the sidebar for more information.

### HOW TO CONVERT A NUMERIC ERROR CODE TO ENGLISH TEXT

Just type **net helpmsg *number***, where *number* is the error code. For example, you'll probably stumble across error 5 now and then: "access is denied." It means that you didn't have the right to do something that you tried to do. Another common one is error 53, "the network path was not found." It means that you tried to access some server that the system can't find or, as is usually the case for me, you misspelled the server's name.

Before leaving the topic of the browser, let me offer one more piece of advice: try to avoid it, as it's unreliable. If your users need access to particular file shares, then you can deliver access to those shares in a few ways. First, you can map file shares, which means that you can create imaginary drive letters on your user's workstations. In other words, if the user often uses \\server1\compdata, then you could set up her workstation so that she'd see a new drive V: which isn't a local hard disk—although it *looks* like a local hard disk—but is instead a network drive. Or you could simply create a shortcut to the UNC on her desktop. You'll learn how to do both of those things in Chapter 11.

## Summary: The Necessary Evils

I hope in this section that I've provided a bit of an answer to the question, "Why do we have to worry about all of this stuff just to get a mail server up and running?"

- ◆ First, you need a piece of server software that can accomplish whatever it is that you're trying to do—Web server, mail server, or whatever.
- ◆ Next, you need to be compatible with and connected to a physical network that connects to your clients—either the public Internet or a private network of some kind.
- ◆ Then your server must move its data around in the same way that your clients' machines do, using the same network language or protocol, probably TCP/IP. TCP/IP itself will require some server functions as well, to maintain it.
- ◆ It wouldn't be necessary in a perfect world, but in our imperfect world your network needs to protect its data with a security system, and in today's world that unfortunately means an *elaborate* security system.
- ◆ Finally, you'll need some way of finding what you put in that network, once you've got it working. Active Directory will become that way in the future, but for now it's a kludgy thing called the Computer Browser that you see in My Network Places.

So presumably you now see why your network needs so many moving parts. Why buy them from Microsoft?

## So Why Use NT/2000/Server 2003?

I hope that by now I've convinced you that networking seems like a good thing. But you could build your network atop any number of operating systems, including Unix, Linux, Novell NetWare, IBM's OS/400 or MVS, or Compaq's VMS, just to name a few. Why NT or its most recent incarnation, Windows Server 2003?

Well, understand when I answer that question that (1) I'm not from Microsoft, (2) I'm not here to sell NT/2000/2003 to you, I'm just here to tell you how to make it work, and (3) the reality of the matter is that every one of the OSes that I just named are good products that have not only their adherents and detractors, but that also have many solid positive features. After decades of business computer use, the market has filtered out both the truly terrible products and some perfectly good but inadequately marketed products, leaving only products that are at least competent (and always well-marketed). So if you want to read that Server 2003 is not only your best choice, but also that you're a total fool to try to use anything else, then I'm afraid you've come to the wrong place. Yes, I like NT, including its latest incarnation (Server 2003), but it's not the only answer.

But it *is* a very good answer. Here's why.

## It's the Market Leader

Most stats that I see say that the Microsoft family of operating systems has the largest market share—43 percent of servers according to the last set of numbers that I saw. Being part of the biggest market share means that it's easier to find consultants, support, and third-party tools. Oh, and it *also* means that there's plenty of demand for your services once you become an expert!

## Its Familiar GUI Makes It Easier to Get Started

The fact that Windows Server 2003 uses a GUI that is basically the same as Wintendo—oops, I meant Windows 9x/Me—means that hundreds of millions of people already know how to navigate the 2003 Desktop. Yes, some things have been moved around, but in general once you know Windows, you know how to get around on 2003.

In contrast, I have recently done a lot of work with Linux and, while it's a quite powerful operating system, the user interface is *not* for novices; even its multitude of GUIs are still clumsy, although that'll probably change with time. (That's not to say that you shouldn't use Linux—just that I think the Microsoft OSes have an easier-to-use GUI.) With 2003, you can often figure out how to solve a problem by noodling around in the GUI—it lends itself more to exploration than would an operating system that relies mainly upon command-line commands to control it.

## Many Tools Come “in the Box”

When NT 3.1 first came out, it was pretty amazing that it came with a dial-in module and a host of other goodies that you had to buy separately in order to run its competition at the time, Novell NetWare. NT had a free TCP/IP stack when many other OSes were charging big bucks for it, a free Web server, and so on. Since then, other server operating systems have continued to include more and more things with the basic operating system—for example, the variety of tools that comes with Linux is nothing short of stunning—but Microsoft has kept the heat on the competition by including a variety of new tools with every release. At this point, the basic version of Server 2003 includes (in addition to its basic functionality of a file and print server) a Web server, an FTP server, a sophisticated Internet router, automated workstation rollout tools (Remote Installation Services), centralized software distribution tools (Group Policies), a two-level disk storage system (Remote Storage Manager), encryption (Encrypted File System), an e-mail server, a SQL-based database server and lots of other tools.

Not all of the tools are stellar; for example, the disk quota system, which allows you to keep any given user from stealing all of the disk space on the shared file servers, is pretty lame. But because Server 2003 provides at least a basic quota functionality, the many shops that are trying to minimize the number of vendors they deal with can get an awful lot of their networking needs met in just one package: Server 2003.

When you view Microsoft products, bear in mind that you usually won't encounter really cutting-edge tools; in my judgment, that's not Microsoft's market niche. Instead, they seem to focus on incrementally improving existing products, as well as adding new tools by imitating competitors. Not being the first on the block can sometimes be a pretty good thing, as you get to watch the competition's mistakes. Very little in Windows Server 2003 is truly never-seen-before-in-the-world new. Instead, it's a distillation of a lot of other people's good ideas. Yes, some may see that as *stealing* other people's good ideas, and there's some merit to that view. And Microsoft has what some might call an unfair advantage in that they've got enough money to keep trying and trying and trying; for example, their first two networking products, MS-NET and LAN Manager, were pretty weak compared to the competition's, but they had the money and tenacity to keep slugging away it, finally releasing the far-better NT product. Another example of this strategy occurred in 2001, with Microsoft's release of the Pocket PC 2002 operating system. They're trying to crush the PalmOS guys in the palmtop market, and they've made two weak attempts with Windows CE 1.0 and 2.0, but

they're learning. I don't know if Pocket PC will beat PalmOS—as a long-time Palm user, I tend to think not—but they'll *definitely* steal more of PalmOS's market share with Pocket PC than they ever did with Windows CE.

And while Microsoft's detractors like to paint Microsoft as nothing but a bunch of rip-off artists, it's actually hard to find who *originated* these ideas. Some say that Microsoft stole Novell and Apple's best ideas; well, Novell certainly didn't invent networking, and their IPX/SPX protocol is blatant "theft" of a Xerox protocol. Apple didn't invent the GUI that Microsoft supposedly stole—Xerox did. (Hmmm, maybe there's a pattern here.) Nor is Active Directory a rip-off of an original Novell product, Netware Directory Services—NDS is based on a directory standard called X.500 and terms that many people think that Novell invented, like "organizational unit," are X.500 terms. In any case, it *is* something of a comfort for people to be able to buy a single product that is a decent fit for just about all of their networking needs, instead of looking for the best of breed in each area. Why? Anyone who's ever tried to troubleshoot a multivendor network problem knows why: Both vendors just point the finger at the other vendor and say, "That's him—he's the guy causing your problem." (They're hoping you'll get tired and go away. Most of us do, sadly.)

In contrast, the same people are developing all of 2003's pieces; so you have to believe that at some point *someone* would have noticed if they didn't fit together. Or that if someone didn't notice it *before* they shipped, they'll get around to fixing it afterward.

In sum, why use 2003? It's fairly reliable, it does most of what you want a network operating system to do, it's reasonably priced, and enough other people use it that you're probably not going to go terribly wrong.

## A Brief History of NT

Let's finish this chapter with a look at how NT has grown and changed since its early days.

Even in the early 1980s, Bill Gates knew that networking was a key to owning the computer business. So, on April 15, 1985, Microsoft released its first networking product, a tool called MS-NET, and its companion operating system, DOS 3.10. Most people knew about the new DOS and were puzzled at its apparent lack of new features. What it contained, however, were architectural changes to DOS that made it a bit friendlier to the idea of networks.

Now, Microsoft wasn't big enough at that time to create much hoopla about a new network operating system, so they let others sell it—no matter how high or low you looked, you couldn't buy a product called MS-NET. Instead, it sold mainly as an IBM product under the name of the IBM PC Network Support Program; IBM viewed it as little more than some software to go along with their PC Network LAN boards and, later, their Token Ring cards. The server software was DOS-based, offered minimal security, and, to be honest, performed terribly. (Believe me, I *know*; I used to install them for people.) But the software had two main effects on the market.

First, the fact that IBM sold a LAN product legitimized the whole industry. IBM made it possible for others to make a living selling network products. And that led to the second effect: the growth of Novell. Once IBM legitimized the idea of a LAN, most companies responded by going out and getting the LAN operating system that offered the best bang for the buck. That was an easy decision: NetWare. In the early days of networking, Novell established itself as the performance leader. You could effectively serve about twice as many workstations with Novell NetWare as you could with any of the MS-NET products. So Novell prospered.

As time went on, however, Microsoft got better at building network products. 3Com, wanting to offer a product that was compatible with the IBM PC Network software, licensed MS-NET and resold it as their 3+ software. 3Com knew quite a bit about networking, however, and recognized the limitations of MS-NET. So 3Com reworked MS-NET to improve its performance, a fact that didn't escape Microsoft's attention.

From 1985 to 1988, Microsoft worked on their second generation of networking software. The software was based on their OS/2 version 1 operating system. (Remember, Microsoft was the main driving force behind OS/2 from 1985 through early 1990. Steve Ballmer, Microsoft's number two guy, promised publicly in 1988 that Microsoft would "go the distance with OS/2." Hey, the world changes and you've got to change with it, right?) Seeing the good work that 3Com did with MS-NET, Microsoft worked as a partner with 3Com to build the next generation of LAN software. Called Microsoft LAN Manager, this network server software was built atop the more powerful OS/2 operating system. As with the earlier MS-NET, Microsoft's intention was never to directly market LAN Manager. Instead, they envisioned IBM, 3Com, Compaq, and others selling it.

IBM did indeed sell LAN Manager (they still do in the guise of OS/2 LAN Server). 3Com sold LAN Manager for years as 3+Open but found little profit in it and got out of the software business. In late 1990, Compaq announced that they would not sell LAN Manager because it was too complex a product for their dealers to explain, sell, and support. Microsoft decided then that if LAN Manager was to be sold, they'd have to do the selling, so on the very same day as the Compaq withdrawal, they announced that they would begin selling LAN Manager directly.

**NOTE** *Interesting side note: Ten years after Compaq decided that their sales force couldn't sell network software, they reversed direction and said that they'd sell a special version of Windows 2000 called Datacenter Server. It's special because you cannot buy it from Microsoft—you must buy it preinstalled on specially certified vendor hardware. In other words, the hardware vendors (Compaq's not the only one selling Datacenter) now believe that they can sell complex network operating systems. I wish them the best of luck, but stay tuned to see the outcome of this particular marketing maneuver!*

LAN Manager in its first incarnation still wasn't half the product that Novell NetWare was, but it was getting there. LAN Manager 2 greatly closed the gap, and in fact, on some benchmarks LAN Manager outpaced Novell NetWare. Additionally, LAN Manager included administrative and security features that brought it even closer to Novell NetWare in the minds of many network managers. Slowly, LAN Manager gained about a 20 percent share of the network market.

When Microsoft designed LAN Manager, however, they designed it for the 286 chip (more accurately, I should say again that LAN Manager was built atop OS/2 1.x, and OS/2 1.x was built for the 286 chip). LAN Manager's 286 foundation hampered its performance and sales. In contrast, Novell designed their premier products (NetWare 3 and 4) to use the full capabilities of the 386 and later processors. Microsoft's breakup with IBM delayed the release of a 386-based product and, in a sense, Microsoft never released the 386-based product.

Instead of continuing to climb the ladder of Intel processor capabilities, Microsoft decided to build a processor-independent operating system that would sit in roughly the same market position as Unix. It could then be implemented for the 386 and later chips, and it also could run well on other processors, such as the PowerPC, Alpha, and MIPS chips. Microsoft called this new operating system NT, for new technology. Not only would NT serve as a workstation operating system, it would also

arrive in a network server version to be called LAN Manager NT. No products ever shipped with that name, but the wallpaper that NT Server displays when no one is logged in is called `LANMANNT.BMP` to this day.

In August 1993, Microsoft released LAN Manager NT with the name NT Advanced Server. In a shameless marketing move, they labeled it version 3.1 in order to match the version numbers of the Windows desktop products. This first version of NT Advanced Server performed quite well. However, it was memory-hungry, lacked Novell connectivity, and had only the most basic TCP/IP connectivity.

September 1994 brought a new version and a new name: Microsoft Windows NT Server version 3.5. Version 3.5 was mainly a “polish” of 3.1; it was less memory-hungry, it included Novell and TCP/IP connectivity right in the box, and it included Windows for Workgroups versions of the administrative tools so network administrators could work from a Workgroup machine rather than an NT machine. Where many vendors would spend 13 months adding silly bells and whistles, NT 3.5 showed that the Microsoft folks had spent most of their time fine-tuning the operating system, trimming its memory requirements, and speeding it up.

In October 1995 came NT version 3.51, which mainly brought support for PCMCIA cards (a real boon for us traveling instructor types), file compression, and a raft of bug fixes.

NT version 4, 1996’s edition of NT, got a newer Windows 95–like face and a bunch of new features, but no really radical networking changes. Under the hood, NT 4 wasn’t much different from NT 3.51.

From mid 1996 to early 2000, no new versions of NT appeared, an “upgrade drought” such as we’d not seen in quite some time from Microsoft. Then, in February 2000, Windows 2000 (“NT 5.0”) shipped. 2000 included a whole lot of new stuff, but perhaps the most significant was a new way of storing and organizing user accounts and related information: Active Directory domains. Closely following AD in importance was the then-new notion of group policies, something that you’ll see has become quite important to anyone wanting to run a network based on XP and Server 2003.

The next version of NT shipped in pieces for the first time since 1993. First NT Workstation 5.1 or, as it’s better known, XP Professional and its lesser sibling, XP Home. Microsoft intended to follow up with the server version of NT 5.1, but events conspired to compel them to wait a bit longer, and produce NT Server 5.2—that is, Windows Server 2003. As you read in the last chapter, it’s a “1.1” version of Windows 2000, a welcome improvement to 2000’s fit and finish.

That’s not the end of the story for NT. Sometime in 2004 or 2005, we will see a re-unified NT (5.3? 6.0? Time will tell) code-named Longhorn. *That* in turn will pave the way for yet another version of NT, code-named Blackcomb, but let’s wait for another edition or two of this book to cover *that* product.

Well, I hope this chapter wasn’t boring for those already expert in NT—I *did* warn you!—and helped bring the newbies up to speed. No matter what version of NT you’re running, however, you’ll need to configure it. And there are, as there always have been, two main ways to do it. The preferred way is through the GUI with windowed programs that offer help and a bit of error-checking, or its somewhat more complex relatives, the command-line tools. The less-preferred, but often necessary, way is to directly tweak some setting in its lair . . . a place called the Registry. The next two chapters introduce these two configuration approaches.

## Chapter 3

# Configuring Windows Server: The Microsoft Management Console

IN WINDOWS 2000 WE saw a significant departure from the NT 4 user interface. Windows Server, however, simply builds on the Windows 2000 interface, with a few enhancements here and there. If you've been working with Windows 2000 for a while now, Server 2003 looks a little different from 2000 at first glance, but don't let the empty Desktop and the new Start menu fool you. Most of your tools are where they were in Windows 2000, and the Microsoft Management Console (MMC) still reigns supreme, with a full array of administrative tools and build-your-own administrator tool capabilities. After a brief detour to make your Desktop more administrator-friendly, we'll take a look at the MMC framework and the prepackaged admin tools. Then you'll learn how to customize a MMC console to fit your needs.

### Fixing the Server 2003 GUI

Although the Windows Server GUI isn't all that different from Windows 2000, there are a few annoyances (I mean inconveniences) for those of us who are used to the Windows 2000 UI. For one thing, the Desktop is now empty of My Computer and My Network Places and the ever-present Internet Explorer. Only the Recycle Bin remains. If it weren't for the Start menu and Taskbar, you could be sitting at a Mac. Also, the Start menu has been redesigned, which isn't a bad thing, except for a couple of nuisances. For one, the Run link has been moved from its former home right above the Shut Down and Log Off options to the adjacent column. If, like me, you are accustomed to rapidly launching programs from Start/Run by entering the program file name (for example, Start/Run/CMD or Start/Run/COMPMGMT.MSC), this change can be a little disorienting. Another little nerve plucker is the new Start menu's way of putting links to your most recently used programs right above the place where the Run link used to be. Even worse, the list keeps changing as you work.

Overall, the changes to the UI are for the better. Several NT 4 applets that were missing from Control Panel in Windows 2000 have reappeared, though sometimes with different names. The Start menu has been redesigned to make it easy to access your most commonly used programs. The empty Desktop acknowledges that users want to customize their Desktops to fit their own requirements and work style. However, this user wants My Computer and My Network Places and Internet Explorer

on the Desktop so I can right-click and get to my destination with as little navigation as possible. This user has decided to stick with the new Start menu, but many admins would rather have the classic Start menu back, at least in the beginning. So the first thing you may want to do is restore those icons to your Desktop and change back to the classic Start menu.

## Restoring your Desktop Icons and Start Menu

To restore the My Computer and My Network Places icons to your Desktop, right-click the Desktop and choose Properties, or click the Start menu, slide over to the Control Panel, and click Display when Control Panel expands. Go to the Desktop tab (take a moment to check out the lovely new background pictures), and click Customize Desktop at the bottom left (see Figure 3.1).

**FIGURE 3.1**

The Desktop tab  
in the Display applet

To show My Computer and My Network Places on your Desktop, check the boxes next to those items in the Desktop Items window (shown in Figure 3.2) and click OK. You can also choose to display My Documents and Internet Explorer on your Desktop.

To change the Start menu back to the Windows 2000 style, right-click the Start menu and choose Properties. Alternately, you can right-click the Taskbar and choose Properties, then go to the Start Menu tab. Choose the radio button for the Classic Start Menu (see Figure 3.3) and click OK.

**NOTE** If you configure your Display applet to show My Computer on the Desktop, you can still right-click it and choose Manage, which launches the Computer Management Tool, or choose Properties to access System Properties. Likewise, after putting it back on the Desktop, right-click My Network Places and choose Properties to launch the Network Connections applet.

**FIGURE 3.2**  
Customize your  
Desktop items.

**FIGURE 3.3**  
The Start Menu  
Properties tab

Finally, if you like the new Start menu in general, but don't like every little thing about it, you may be able to fix it to suit you. Just click the corresponding Customize button in the Taskbar and Start Menu Properties applet to see your options. For instance, many items on the new Start menu can be configured to act either as menus (they expand when you hover your mouse over them) or links (they open in a new window when you click them) or to not display at all.

### Setting Administrator-Friendly Folder Options

For administrators, the default folder options for Explorer can also be annoying. The context-sensitive task links that appear on the left side of every window may be helpful to newbies, but they are just a waste of space to me. Additionally, whenever I want to go do some maintenance in the **Program Files** or **System** directories, I've got to click past patronizing user-proofing screens that essentially say, "Hey, look, buddy, you're probably too stupid to mess with these files, are you *sure* you want to see this directory?" I need to see the hidden and system files, and in general, Details view is best for maintenance operations. Additionally, I've never found the address bar or standard buttons of much value in administrative tasks; they just rob me of screen space.

The first thing that I must do, then, when faced with a new system is to get Explorer into "administrator-friendly" mode. To save you time, here are the steps:

1. Open My Computer.
2. From its menu bar, choose Tools/Folder Options.
3. In the General tab, under Tasks, choose Use Windows Classic Folders.
4. Click the View tab.
5. Check the box labeled Display the Full Path in the Title Bar.
6. Click the radio button labeled Show Hidden Files and Folders.
7. Uncheck the box labeled Hide File Extensions for Known File Types.
8. Uncheck the box labeled Hide Protected Operating System Files (Recommended) and click Yes when it asks you to confirm your choice.
9. Click OK.
10. Back in the main My Computer folder, click View/Details.
11. Right-click any blank space to the right of the menu bar and uncheck Standard Buttons.
12. Right-click any blank space to the right of the menu bar and uncheck Address Bar.
13. Click the close icon on the My Computer window—the icon in the upper right corner that looks like an X.

Now reopen My Computer and apply those settings to all folders:

1. Click Tools/Folder Options.
2. Click the View tab.
3. Click the button toward the top of the page labeled Apply to All Folders.
4. Click Yes to confirm the message.

5. Click OK to close Folder Options.
6. Close My Computer.

Without all those empty calories, Explorer is now a lean, mean administrator's machine. To make it even leaner, you can navigate to individual folders and select Choose Details from the View menu to add or remove the details you want to see for that folder. For example, you might want to see the file system types for each logical drive in My Computer, or you might not want to see the lengthy service descriptions in the Control Panel.

## A Microsoft Management Console Primer

To master Windows Server administration, you must master the Microsoft Management Console. In this section, I'll discuss the key MMC terms you should know, briefly look at the Computer Management console to illustrate these terms, and, finally, introduce you to creating your own MMC-based administrative tools.

### What Is This MMC Thing?

Before Windows 2000 came onto the scene, NT administrators had to master multiple administration tools plus independent third-party tools. With all the different menus, buttons, toolbars, wizards, tabs, HTML, Java (you get the picture), mastering a new tool's concepts took second place to learning how to navigate the software. NT Administrative software also lacked granularity. There was no simplified version of User Manager for Domains for Account Operators to use, and no way to hide sensitive menu items for those without full administrator rights. Administrative folks would typically install the full set of NT administrator tools on their workstations, whether they needed them all or not; if administrators failed to guard access to their desktops, or if regular users were permitted to log on to these administrative workstations, then anyone with the ability and knowledge could gain access to the entire range of management tools—not smart.

The Microsoft Management Console (MMC) was designed to overcome these limitations and accommodate the requirements of today's increasingly complex networks.

MMC is a framework for management applications, offering a unified administrative interface for Microsoft and third-party management tools. MMC doesn't replace management applications; it integrates them into one single interface. There are no inherent management functions in MMC at all. It uses component tools called *snap-ins*, which do all the work. MMC provides a user interface; it doesn't change how the snap-ins function.

### MMC KEY BENEFITS

MMC offers the following benefits:

- ◆ You only have to learn one interface to drive a whole mess of tools.
- ◆ Third-party (ISV) tools are now using MMC snap-ins. IBM, HP, Seagate, and Symantec are all using the MMC framework to build admin tools for their products.
- ◆ You can build your own consoles, which is practical and fun. Admins can even create shortcuts on the console to non-MMC tools like executables, URLs, wizards, and scripts.

- ◆ By customizing MMC consoles, admins can delegate tasks to underlings without giving them access to all functions and without confusing them with a big scary tool.
- ◆ Help in MMC is context sensitive; it displays help subjects for only the appropriate components.

### WHAT'S NEW WITH MMC?

If you've been using MMC-based tools for a while now, you'll notice a few minor changes in the new version (MMC 2 version 5.2). Many of these are enhancements to the Active Directory management tools:

- ◆ In all of the console tools, the Console menu is now renamed the File menu, which makes good sense and is consistent with other Microsoft tools.
- ◆ MMC snap-ins now have "drag-and-drop" capabilities. You'll notice this most in the Active Directory tools if you need to move user, group or system accounts from one organizational unit to another.
- ◆ You can now select multiple objects and perform the same operation on them or edit the properties for them all. This enhancement is long overdue, in my opinion.
- ◆ In the Active Directory Users and Computers snap-in, the ability to save and re-use queries simplifies documentation and reporting as well as preparations for complex operations like upgrades or restructuring the Active Directory.
- ◆ In addition to editing multiple objects, you can now reset access control list (ACL) permissions to the default, show the effective permissions for an object, and show the parent of an inherited permission.

### WHAT CAN'T YOU DO WITH MMC (NON-MMC TOOLS)?

When I said that MMC offers a unified interface for administration, I didn't mean that all administrative tools in Server 2003 are MMC-based. Many system-level functions are accessed using wizards, hypertext applications like Manage Your Server, or plain old executables. In general, you will use a wizard or hypertext app to add or remove new software and services or to set system-level options locally. Then, once a new service (DNS, Remote Access, DHCP, Active Directory) is installed, you can use an MMC tool to remotely configure it and monitor its activity. Let's also not forget all the new command-line tools that Microsoft has written for Server 2003. On the other hand, because MMC tools can be created and customized, you can integrate non-MMC apps into the MMC interface by creating links to them in your custom tools. In "Building Your Own MMC Tools," you'll do just that.

### MMC Terms to Know

This section defines important terms you'll need to know when working with MMC.

A *console*, in MMC-speak, is made up of one or more administrative tools in an MMC framework. The admin tools that are included with Server 2003, like Active Directory Users and Computers, are console files. You can configure your own console files without any programming tools—you needn't be a C or Visual Basic programmer, as I'll discuss a bit later. The saved console file is a *Microsoft saved console (MSC)* file and it carries the .MSC extension.

It's important to distinguish between the Microsoft Management Console and console tools. The terms *console* and *tool* are sometimes used interchangeably when discussing MMC. Strictly speaking though, a console is not a tool, and as I pointed out in the previous section, not all tools are consoles. MMC.EXE is a program that presents administrators (and others creating console tools) with a blank console to work with. When you create a Microsoft Word document, you first load the program (WINWORD.EXE), then create or modify documents within that context. Similarly, you create MMC tools by first loading a blank console (MMC.EXE) and then creating a customized "document" based on the available options and add-ins. In this way, MMC provides a framework for your tool, and the new console you create is the finished product.

*Snap-ins* (also called *plug-ins*) are the administrative tools that can be added to the console. For example, the DHCP admin tool is a snap-in, and so is the Disk Defragmenter. Snap-ins can be created by Microsoft or by other software vendors. (You *do* need programming skills to make these, in other words.) A snap-in can contain subcomponents called *nodes*, or *containers*, or even *leaves*, in some cases. Although you can load multiple snap-ins in a single console, most of the prepackaged administrative tools contain only a single snap-in (including the Computer Management tool, COMPMGMT.MSC).

An *extension* is basically a snap-in that can't live by itself on the console but depends on a stand-alone snap-in. It adds some type of functionality to a snap-in. Sometimes the same code is implemented as both a snap-in and an extension. For example, the Event Viewer is a stand-alone snap-in, but it's also implemented as an extension to the Computer Management snap-in. The key point is that extensions are optional. You can choose not to load them. For example, Local Users and Groups is an extension to the Computer Management snap-in. If you remove the extension from the COMPMGMT.MSC file used by your support folk, or simply don't include it in a custom console that uses the snap-in, those who use the tool won't have the option to create or manage users and groups with the tool. They won't even see it. (Please note that this will not prevent them from creating users and groups by other means, if they have the correct administrative privileges.)

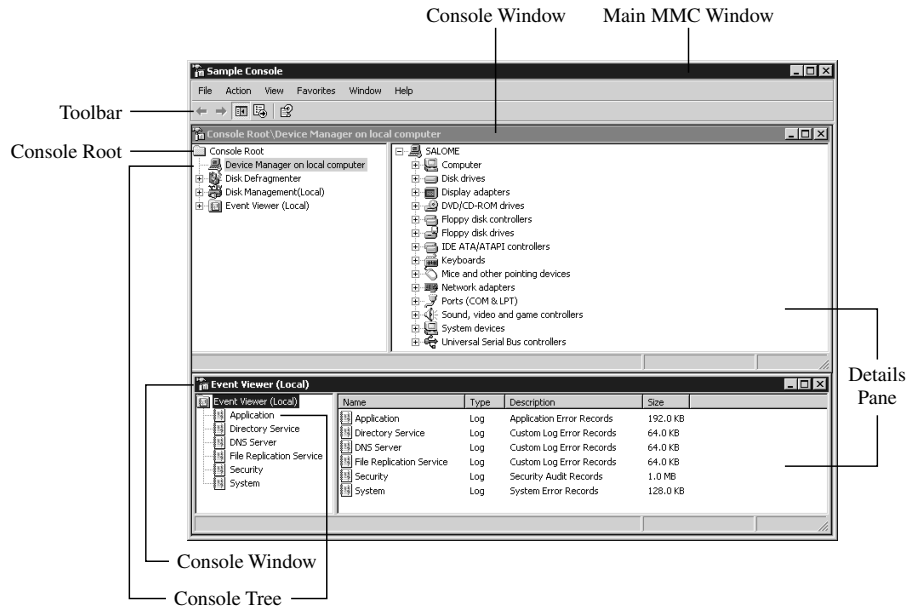

To create a new MSC file, customize an existing MSC file or create one from a blank console. The MMC.EXE plus the defined snap-ins, views and custom tasks create the tool interface. Although it's possible to open multiple tools simultaneously, each one runs in a single instance of the MMC.EXE process. To see what I mean, open an MSC file and check out the Task Manager while it's running—you only see the MMC.EXE process running, not the MSC file, just as you see WINWORD.EXE running in Task Manager, but not the Word document's name. However, you can open separate *nodes* in separate windows within the tool. You could have separate windows open to the Event Viewer and the Device Manager within the same tool, for instance.

By default, prepackaged console tools open in *User mode*. Changes cannot be made to the console design. You can't add or remove snap-ins, for example. To create or customize a console, use *Author mode*. When a user is running a tool and not configuring it, it should be running in one of the User modes. When a tool is running in Author mode, additional items will appear on the File and Action menus. Also, the Favorites menu doesn't appear in User mode consoles. Favorites can only be configured in Author mode.

Figure 3.4 shows a sample console tool, with the parts of the interface labeled. This console is running in Author mode to show all the parts of the MMC interface. This is a custom console, but to open any existing tool in Author mode, invoke it from the Start/Run dialog box with the `/a` switch. Alternately, right-click the tool's icon and choose Author to open it in Author mode. This does work with the links to tools in the Administrative Tools group, but remember not to overwrite the original file!

**FIGURE 3.4**

Anatomy of a console tool

In addition to its traditional functions (New, Open, Save, Save As) the File menu in the Main window is used to add and remove snap-ins and set console options. The Action menu and the Toolbar are context sensitive and will reflect the options of the selected snap-in tool or component. The Favorites menu functions like the Favorites menu in Explorer; however it stores only links to locations in the console tree.

The hierarchical list of items shown by default in the left pane is called the *console tree*, and at the top is the *console root*. The right pane is called the *details pane*. Snap-ins appear as nodes on the console tree. The contents of the details pane change with the item selected on the console tree.

## The Computer Management Console

Now it's time to practice the new MMC terms you've learned as we take a look at the Computer Management console. `COMPMGMT.MSC` is the main tool for administering a single server, local or remote. If you only have one or two Server 2003 servers on your network (and are not implementing Active Directory), the Computer Management console contains most of the tools you'll need. You'll find Computer Management in the Administrative Tools program group, or right-click My Computer on the Start menu and choose Manage.

### USING COMPUTER MANAGEMENT REMOTELY

There are several ways to use `COMPMGMT.MSC` to manage remote servers on your network:

- ◆ Run `COMPMGMT.MSC` with the switch `/COMPUTER=COMPUTERNAME`.
- ◆ If you are working in an Active Directory context, within Active Directory Users and Computers, right-click the machine's icon and choose Manage.

*Continued on next page*

### USING COMPUTER MANAGEMENT REMOTELY (*continued*)

- ◆ Open Computer Manager and highlight Computer Management (local) at the root of the console, then right-click and choose Connect to Another Computer.
- ◆ If you are creating a custom console that includes the Computer Management snap-in, specify the remote server the tool will point to when you add the snap-in, or check the box that allows you to specify the remote computer at the command line, as described in the first option.

There are three nodes in the Computer Management console tree: System Tools, Storage, and Services and Applications (see Figure 3.5). Notice that the tool manages the local machine by default; to connect to other computers on the network, highlight the Computer Management icon at the root of the tree, right-click, and choose Connect to Another Computer. You can also choose Connect to Another Computer from the Action menu, but right-clicking an object in the console tree reveals both the Action and View menu options, so it's more efficient.

**FIGURE 3.5**  
The Computer Management console tree

Expand the nodes in the Computer Management console tree to reveal the configuration tools and objects, as shown in Figure 3.6. Most of the core functions are under System Tools.

**FIGURE 3.6**  
The expanded Computer Management console tree

**NOTE** To manage NT 4 or Windows 98 boxes remotely with `COMPMGMT.MSC`, install the Windows Management Instrumentation (WMI) Version 1.5 Core Components on the legacy system. This is available as a download (`WMICORE.EXE`) from Microsoft's Web site. The WMI add-on component is available for Windows 9x and NT 4. Windows Me, 2000, and XP include WMI.

In the System Tools node, you can perform the following tasks:

- ◆ View events and manage the event logs. The Event Viewer is available as a snap-in, an extension to the Computer Management tool (as shown here), or as a stand-alone prepackaged tool (`EVENTVWR.MSC`). Some services, such as DNS and Active Directory, have their own logs and these will appear in the details pane if the service is installed on the system.
- ◆ Manage shared folders. View, create, and manage shares; view sessions and open files; and disconnect sessions.
- ◆ Create and manage local users and groups (Chapter 9 is all about creating and managing users and groups). If the system is a domain controller running Active Directory, however, the local users and groups extension will not load.
- ◆ Set up performance logs and alerts (see Chapter 18 for specifics on configuring performance alerts).
- ◆ Manage devices. This version of Device Manager functions in read-only mode when it's looking at remote systems, but it's still a good resource if you want an overview of the remote system's hardware or are troubleshooting a resource conflict.

**TIP** For a better (but still read-only) look at a remote system's hardware and software configuration information, run `MSINFO32.EXE`. This little tool is powerful and includes options to run a search, view a history of changes, print out system information, or export the data to a file.

The Storage node includes options for managing removable storage (CD-ROMs and CD Jukeboxes, for example), along with the Disk Defragmenter tool and the Disk Management tool for managing disks, partitions, and volumes. The Logical Drives extension that was present in the Windows 2000 version of this tool is gone now.

The Services and Applications node includes, at a minimum, telephony settings, services configuration, and an indexing extension. As new services are installed on the system, the components available in the Services and Applications node will change. For instance, if the server is a DHCP server or is running DNS, the appropriate management tools will appear under Services and Applications—otherwise, you won't see them. I'm quite fond of this feature; when I'm checking out a server for the first time, I can determine what key services are installed on the system and look at the configuration for those services using the same tool.

## Other MMC Tools

If you're like me, you don't want to get carpal tunnel syndrome just trying to open something from the Administrative Tools group. If you want to have quick and easy access to your tools, and you prefer to use Start/Run as much as possible to open programs, it's nice to know their filenames. To save your hands and your sanity, Table 3.1 lists most of the core MSC filenames. Keep in mind that some

tools, like DNS and DHCP, may not be available on the system until the corresponding service is installed. Also, remember to include the program extension in the Start/Run box. For example, entering just **DSA** to open Active Directory Users & Computers doesn't work. You'll need to enter **DSA.MSC**.

**TABLE 3.1: CORE MSC FILES**

<b>MSC FILENAME</b>	<b>COMMON NAME</b>
AZMAN .MSC	Authorization Manager
CERTMGR .MSC	Certificates snap-in
CERTSRV .MSC	Certificate Services
CERTTMPL .MSC	Certificate Templates
CIADV .MSC	Indexing Service
COMPMGMT .MSC	Computer Management
DCPOL .MSC	Domain Controller Security Policy
DEVMGMT .MSC	Device Manager
DFRG .MSC	Disk Defragmenter
DFSGUI .MSC	Distributed File System
DHCPMGMT .MSC	DHCP Manager
DISKMGMT .MSC	Disk Management
DNSMGMT .MSC	DNS Manager
DOMAIN .MSC	Active Directory Domains & Trusts
DOMPOL .MSC	Domain Security Policy
DSA .MSC	Active Directory Users & Computers
DSSITE .MSC	Active Directory Sites & Services
EVENTVWR .MSC	Event Viewer
FXSADMIN .MSC	Fax Service Manager
FILESVR .MSC	File Server Management
FSMGMT .MSC	Shared Folders
GPEDIT .MSC	Group Policy Editor
IAS .MSC	Internet Authentication Service
IIS .MSC	Internet Information Services

*Continued on next page*

TABLE 3.1: CORE MSC FILES (continued)

MSC FILENAME	COMMON NAME
LUSRMGR.MSC	Local Users and Groups
NTMSMGR.MSC	Removable Storage Manager
NTMSOPRQ.MSC	Removable Storage Operator Requests
PERFMON.MSC	Performance Monitor
RRASMGMT.MSC	Routing and Remote Access
RSOP.MSC	Resultant Set of Policy
SECPOL.MSC	Local Security Policy
SERVICES.MSC	Services Configuration
TAPINGMT.MSC	Telephony
TSCC.MSC	Terminal Services
TSMMC.MSC	Remote Desktops
WMINGMT.MSC	Windows Management Instrumentation

Most of the tools listed in Table 3.1 are found in the `\Windows\system32` directory and are therefore in the default search path; you'll have no problem running them from a command line or using Start/Run. A couple, however, are found in other directories that are not included in the default search path. The tool to manage Internet Information Services (`IIS.MSC`) is a good example; it's found in `\Windows\system32\inetsrv`. If you need to run any of these tools on a regular basis, and they aren't in your search path and you still don't want to use the Start menu (we admins can be stubborn), you have several options to make these tools more readily accessible. You can copy the tool(s) to the `\Windows\system32` directory; or if you don't mind a cluttered Desktop, just create Desktop shortcuts to the tools. Another approach is to change the search path to include the directories that contain your tools. This is a bit more of a pain; you'll need to open the System applet and go to the Advanced tab, then choose the Environmental Variables button to edit the system variable called Path. Oh, yes, and then reboot. Is it worth it? Many don't think so. In the past, I used this strategy: I copied all the tools I needed to a separate directory, and then added *that* directory to the search path. That way I didn't have to edit the path variable multiple times.

You may think this is a lot of trouble just to use a couple of tools, but after you install a bunch of third-party tools on your server you may change your mind. They'll probably all use their own installation directories.

## Building Your Own MMC Tools

If the existing MMC tools don't fit your needs exactly, you can create a customized tool with your most frequently used components. Creating your own admin tool is easy using the MMC framework and snap-ins provided by Microsoft and third-party software vendors.

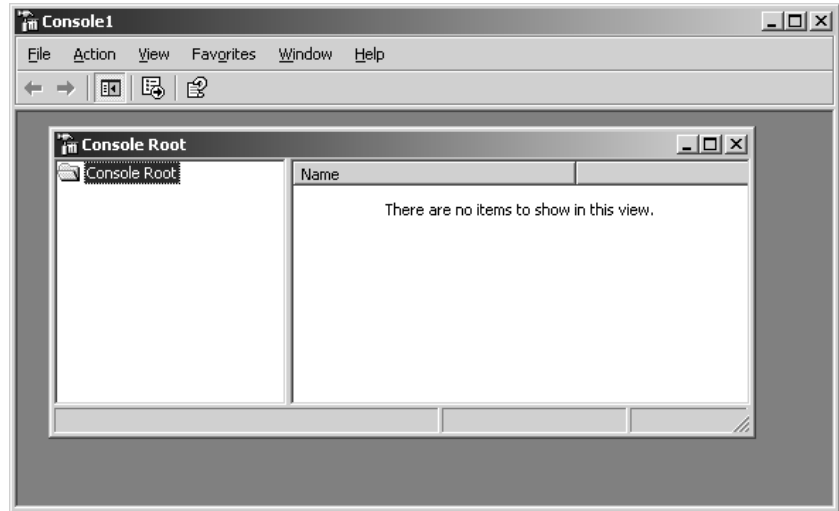

Although it's quite simple to create a customized MMC tool, there are so many options for customizing that I can't tell the full story here. Nevertheless, no discussion of MMC would be complete without an example or two of authoring administration tools.

### Building a Simple Microsoft Saved Console

To configure your own custom admin tool, open a blank MMC in Author mode by opening Start/Run and typing **mmc.exe**. This will open up an untitled console (Console1) and display a generic console root, shown in Figure 3.7. You can now open existing MSC files (just as you open DOC files in Word or XLS files in Excel) by choosing Open from the File menu. These files will automatically open in Author mode if you open them in a blank console. If you wish to open and fiddle with existing MSC files, most (but not all) of them are in the `\Windows\system32` directory. Just be sure to leave the original MSC files intact; you might need them again. In the example that follows, you'll be creating a tool from scratch, starting with a blank console and loading snap-ins.

**FIGURE 3.7**

A generic console root

Suppose you need a tool for hardware management and troubleshooting. To create it, follow these steps:

1. Start by renaming the console root Hardware Tools; right-click the console root and choose Rename (you can perform this step later if you prefer).
2. Now you're ready to add snap-ins. Choose Add/Remove Snap-in from the File menu in the Main window. As you can see in Figure 3.8, you must choose where to add the snap-in. Right now, it's only possible to add snap-ins to the console root (now called **Hardware Tools**), but you can group related tools by first adding folders to the console root. Folders are implemented as snap-ins, permitting you to organize tools into groups on the console tree.

**FIGURE 3.8**

Choosing where to add snap-ins

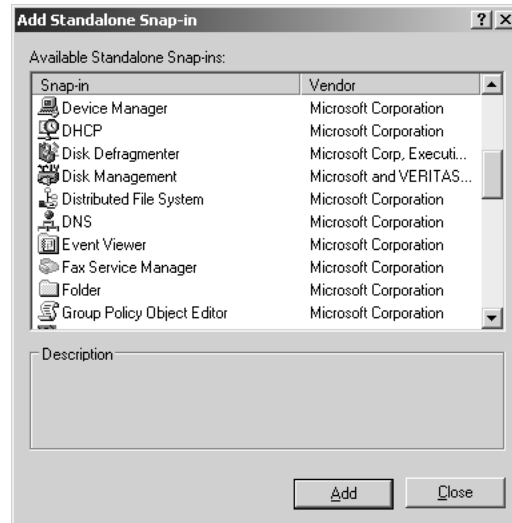

3. To add folders to the console root, choose the Add button to open the Add Standalone Snap-In dialog box (see Figure 3.9). You'll now see both dialog boxes, sort of cascaded. Items chosen from the list in the Add Standalone Snap-In dialog box will appear in the list of snap-ins in the parent dialog box. Scroll through the list until you see the **Folder snap-in**. Choose Add, and the folder appears in your list of snap-ins in the Add/Remove Snap-In dialog box. Choose Add again and you'll see two. Now close the Add Standalone Snap-In dialog box to return to Add/Remove Snap-In, and click OK to close it.
4. Back at the console in progress, right-click the folders to rename them. Figure 3.10 shows a Hardware Tools console with three folders, renamed to **Disk Tools**, **Other Tools**, and **Web Sites**.
5. The **Web Sites** folder will contain snap-ins that are hyperlinks to hardware vendor and support sites. To add links to the **Web Sites** container, open the Add/Remove Snap-In dialog again (choose Add/Remove Snap-In from the File menu), select the **Web Sites** folder as the container, choose Add, then scroll through the list until you find **Link to Web Address**. Click the Add button, and follow the wizard prompts to create a new Internet shortcut; simply fill in the URL and give the shortcut a friendly name. Choose Close and then OK to close the Add/Remove Snap-In page and return to the console. Now when you select the link in the console tree, the Web page will appear within the details pane. You can surf

the Web from within the console, although technically you'll need links to leave that particular site.

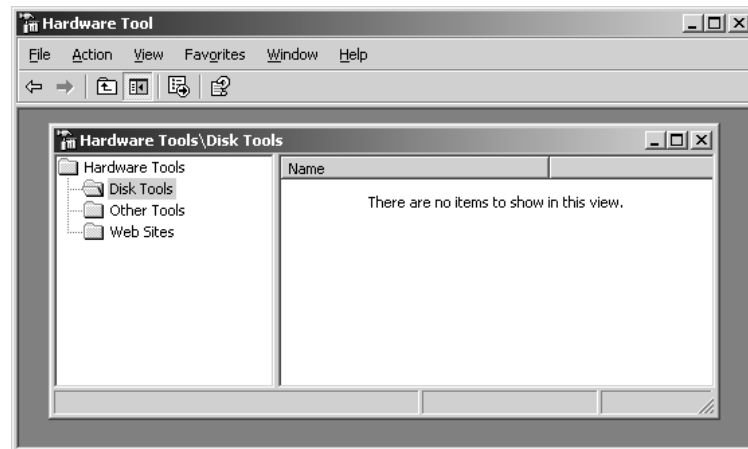

**FIGURE 3.9**

The Add Standalone Snap-In dialog box

**FIGURE 3.10**

Customizing the console

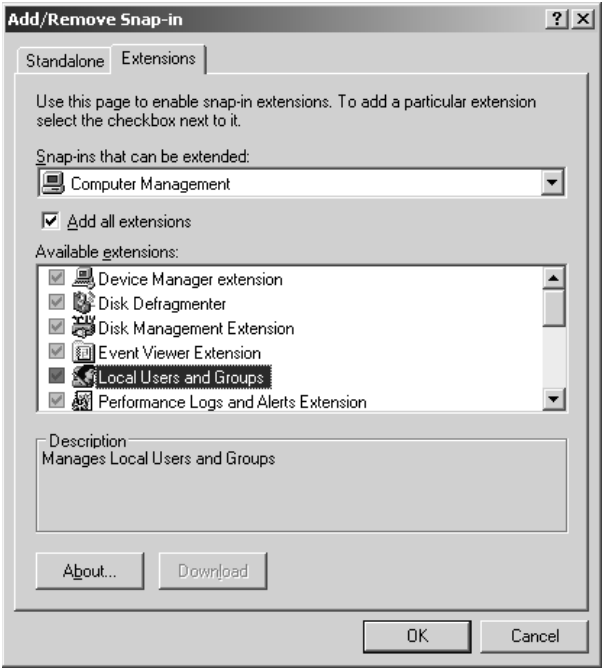

To add tools to the other folders, follow the same process and choose the appropriate tools from the list of snap-ins available. Some third-party software vendors are now implementing their tools as snap-ins, so this list will expand and vary with the system configuration and software installed. Some tools will prompt you to select a computer to manage. Others, such as the Event Viewer snap-in, also present the option to choose the machine when you start the tool from the command line, as shown in Figure 3.11. To specify a remote system to manage when you open the tool, enter **FILENAME.MSC /computer=computername** in the Start/Run box or at a command prompt.

**FIGURE 3.11**  
Selecting a computer  
for the snap-in to  
manage

While adding the stand-alone snap-ins, be sure to check out the available extensions for them. It's interesting to note that the Computer Management snap-in components are all implemented as extensions (see Figure 3.12), although most of these also exist as stand-alone snap-ins. When loading the Computer Management snap-in, you have the option to deselect the extensions that aren't needed for your custom tool. All available extensions are added by default.

**FIGURE 3.12**  
Select or deselect  
extensions

In Figure 3.13, you can see what your final tool could look like: a customized Hardware Tools console. This one consists of a **Disk Tools** folder (with Defragmenter and Disk Management), a folder called **Other Tools** that includes the Device Manager and the Event Viewer, and a **Web Sites** folder that can be filled with helpful hardware support links.

To save the custom console, choose **Save** from the **File** menu, name the file and click **Save**. Now the MSC file is ready to use.

**FIGURE 3.13**

A custom Hardware Tools console

## Designing Tools with Taskpad Views

It's possible to design simple views of an MMC tool for junior administrators, foregoing their need to learn the different tools and navigate the console tree nodes. You might also wish to present a limited set of tasks and hide others that are normally available in a regular MMC tool view. Taskpad views fill this need and allow you to create a tool that looks like the one shown in Figure 3.14. This tool presents a limited set of tasks instead of the entire console tree structure. Now novice administrators can perform delegated tasks without drilling down through the tree, expanding and collapsing, hoping to find the right tool. Instead, they can click the icon and go right to the task.

Taskpad views are HTML-based pages that can include links to console menu commands, wizards, scripts, simple executables, even URLs. At least one snap-in is required to create a taskpad view, although you can create links to tasks that are unrelated to the snap-in, such as scripts. To include menu command and property page tasks, however, the corresponding snap-in must be loaded beforehand.

Before designing a console with taskpad views, or any type of console for that matter, put your thinking cap on and visualize the tool you need. What tasks will the tool include? Which snap-ins will be required? You'll need to be somewhat familiar with the available snap-ins and their functions. Will your tool include only one taskpad view with a bunch of tasks in a single window? Or do you need a tool with several tabs, each containing a set of related tasks? Figure 3.14 shows a tool with

only one taskpad view; tasks are all together in one window, and the console tree is hidden from the user. Figure 3.15 illustrates a multiple taskpad tool with several different tabs, perhaps for a more experienced support person who needs to perform several different types of tasks.

**FIGURE 3.14**

A simple taskpad tool

**FIGURE 3.15**

A multiple taskpad tool

There are a couple of possible strategies for creating taskpad views. One is to assemble a specific set of tasks into one or more taskpad views. For example, when the tool is opened, you might see a single taskpad view called Routine Admin Tasks with links labeled Create New User or Create New Share. If you click the link called Create New User, the dialog box or wizard to create new users appears. In a tool like this, you might want to prevent users from navigating around, so you hide the console tree and present only the taskpad view.

Another technique is to create taskpad views for particular items in the tree; for example, a taskpad for Users and Groups, another for Shared Folders, and a third for the Event Viewer. Again, you might choose to hide the actual console tree and normal views for this tool. In that case, you should create a main taskpad with links to other taskpads located at different branches of the tree. Imagine a taskpad view called Main Taskpad, which contains links called Open Services and Manage IIS. Click the former and another taskpad appears, with a list of services and links to stop, start, or restart

a service. You can use the Forward and Back buttons on the toolbar (as you do in Explorer) to return to the Main Taskpad view.

Alternately, you might choose to present these taskpad views in addition to the normal views without hiding the console tree. In this case, the taskpad will enhance the functionality of the console tool by presenting a set of simple task options (for people who don't like playing Marco Polo in admin tools) without imposing any limitations on what the user can see or access.

Whichever approach you choose, keep in mind that taskpad views are meant to simplify and facilitate the use of a console. They can even limit, to some extent, the administrative options that are presented. However, you should not consider them a foolproof way to prevent admin types from performing certain tasks. Even if they can't get around the limitations of the custom console, which is by no means certain, they may have access to other tools that are not restricted. The best way to restrict another admin's power is to use all of the other built-in security options that are available in appropriate combinations: security group memberships, rights, group policies, and delegation are some of the more reliable tools for this purpose. Don't rely on a customized, locked-down console tool instead.

In this section, you will create a Main Taskpad view for the Computer Management snap-in and then create links to tasks. Then you will set up taskpad views for particular items in the console tree, with links from the Main Taskpad. Finally, you will customize the tool's interface to hide the console tree and present a simplified set of options to the user.

### CREATING TASKPAD VIEWS

Once you've decided which tasks your user or admin person will perform with this tool and identified the necessary snap-ins, you are ready to create the console. To keep things simple in this example, use the Computer Management snap-in to create a view and a select set of tasks.

Open a blank console as described earlier (Start/Run and enter `mmc.exe`) and load the Computer Management snap-in. You can also use an existing console that contains the necessary snap-in as long as you open it in Author mode. Although many of the Computer Management extensions, such as the Event Viewer and Device Manager, can be added as standalone snap-ins, the Computer Management snap-in has a special capability that will facilitate remote management, as you'll see in a moment. As you load the snap-in you may want to point it to your file server and select the option to specify a server to manage when starting the tool from the command link (this option was shown back in Figure 3.11). If you choose not to do this, you can still connect to remote systems, but the tool will always point to the local computer when it initiates.

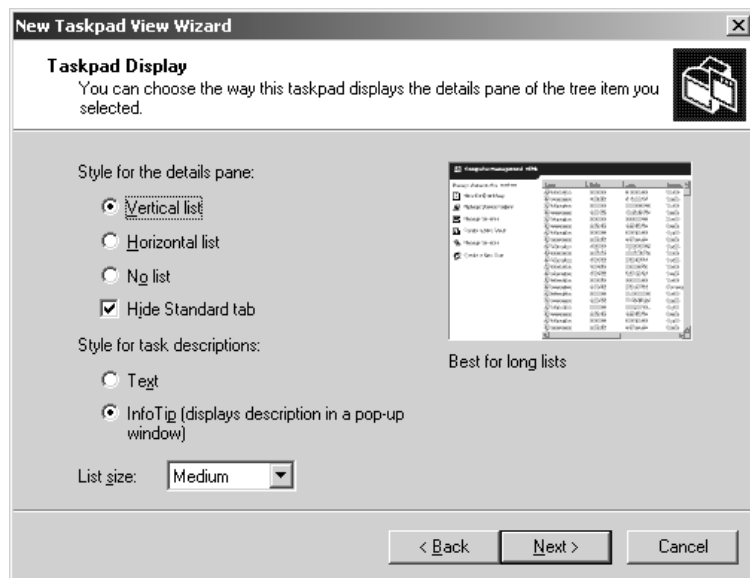

To create a taskpad view at the top of the Computer Management node, follow these steps:

1. Select the Computer Management node in the console tree, right-click it to see a context menu (or pull down the Action menu), and choose New Taskpad View. You will always add, delete or modify taskpad views by first navigating to the node in the console tree where the taskpad is anchored. For instance, if you have a taskpad view created for the Event Viewer, select the Event Viewer node on the tree (the taskpad will display when the node is selected) and then select your option from the context menu or the Action menu.
2. The New Taskpad View Wizard appears. Click Next to continue.
3. Select the style of the taskpad view (see Figure 3.16). Do you want the Taskpad View to also display the actual items that would normally appear in the details pane (such as a list of

users or a list of services)? If so, choose to display either a vertical list (to accommodate lots of columns) or a horizontal list (for longer lists). In this case, you want to create a view of links and don't want to see the details pane information, so choose No List. If you were to choose a list type, however, you would use the List Size drop-down menu to determine how much of the window can be taken up by the list. By default, the "normal" details pane will not be accessible to the viewer once the Taskpad View is created. However, if you want to make the normal details pane available, deselect the option Hide Standard Tab. The standard details pane will then be viewable by clicking the Standard tab. Now, select the style you want for your task descriptions. If you need a longer explanation to appear alongside the link, choose Text. However, for this example you want more room for task links and a description that pops up when you hover over the link, so choose InfoTip. Choose Next to continue.

**FIGURE 3.16**

Configuring  
taskpad display

4. In the next screen (Figure 3.17), you must decide whether to apply the view to the selected tree item only or to any other tree item of the same type. If you choose the latter, you have the option to change the default details pane display for those items to the taskpad view (although the normal view will still be accessible through the Standard tab if it's not hidden). Choose to apply the view only to the selected tree item. This taskpad view will only display when the Computer Management root node is selected. Choose Next.
5. The final step is to supply a name for your taskpad (I called mine Main Taskpad) and an optional description. The description you supply will appear under the title in the details pane. That's it! In the final screen of the wizard, you have the option to kick off the New Task Wizard and start creating tasks (uncheck the box beside Start New Task Wizard to avoid creating a new task for now). Click Finish to close the wizard and create the new taskpad view.

**FIGURE 3.17**

Selecting a taskpad target

Figure 3.18 shows your new taskpad before any tasks are created. Notice the tabs at the bottom of the details pane that allow you to move between the taskpad view and the standard view of the details pane. In a moment, I'll show you how to hide the console tree on the left and remove the Standard view tab to achieve the look and feel of the console shown back in Figure 3.14.

**FIGURE 3.18**

A console with a taskpad view

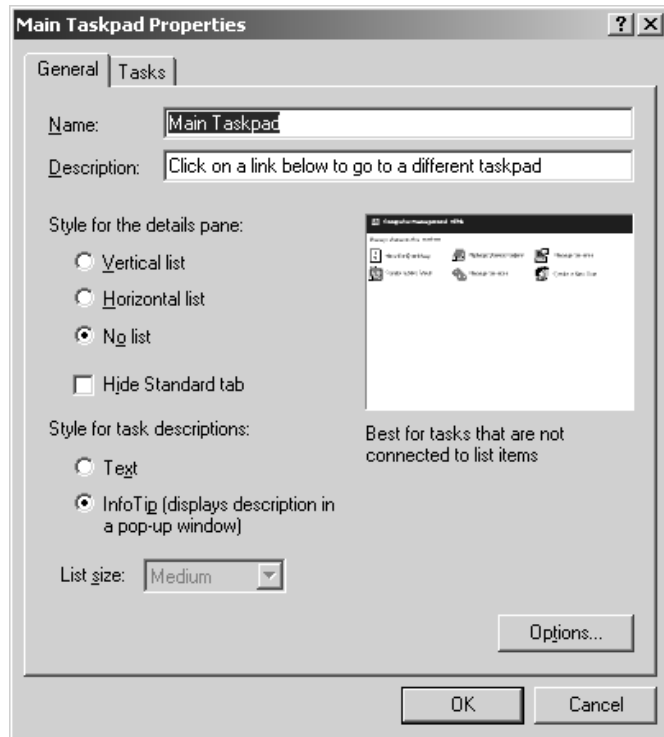

If you want to create multiple taskpad views, as shown in Figure 3.15, follow steps 1–5 again. You can create additional taskpad views at the same place on the console tree or at other points on the tree. To create a taskpad view for Event Viewer, for example, just navigate down to that node and create the taskpad from there.

To remove a taskpad view, select it and choose Delete Taskpad View from the context menu or from the Action menu. Be aware that wherever you have multiple taskpads anchored at the same place on the console tree, you must select the target taskpad's tab before you can delete or edit it. To make changes to an existing taskpad, select Edit Taskpad View from the context menu or from the Action menu. In the taskpad view property page (Figure 3.19), you can change the style of the view and add, remove, or modify tasks.

**FIGURE 3.19**

The taskpad property page

### CREATING TASKS

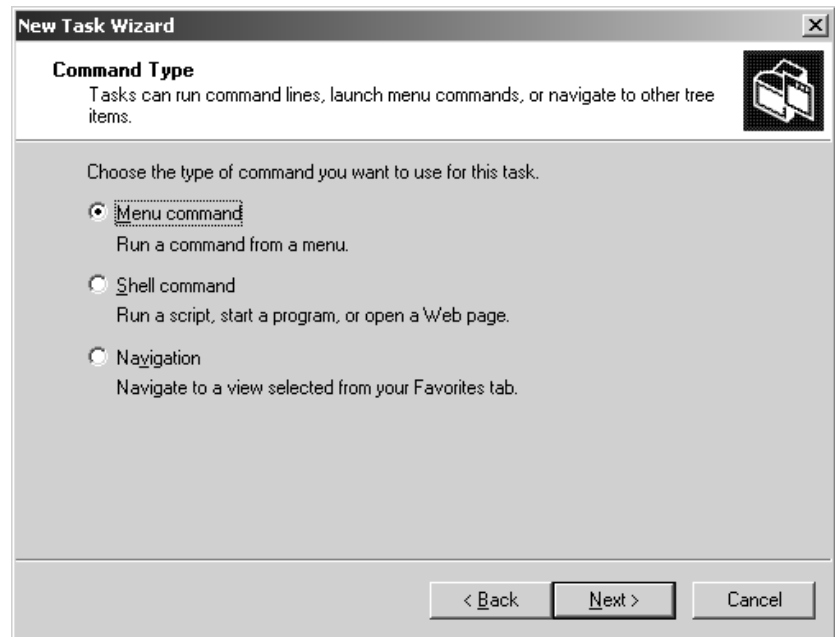

The New Taskpad View Wizard will automatically kick off the Start New Task Wizard if you don't uncheck the box in the last screen of the wizard. Another way to create tasks is by choosing Edit Taskpad View from the Action menu. From the taskpad properties page (shown in Figure 3.19), move to the Tasks tab and click New to start the New Task Wizard. The following steps illustrate how to create a task link for the Connect to Another Computer command:

1. In the New Task Wizard, click Next to begin creating a new task. Click a radio button to choose whether the task will be a menu command (from the context or Action menu in the

console), a shell command, or a navigation command, which points to a link in the Favorites tab (see Figure 3.20). Although menu commands are limited to the functions of a loaded snap-in, a shell command could be an executable (like a wizard), a script, or even a URL. In any of these cases, the shell command task kicks off the command called. So think of it as a shortcut or a link to something outside of the tool. For example, you can create a shell command task to open a related Help (CHM) file or to run a disk usage report script. You'll create a menu command in this example, but if you choose to create a shell command at another time, you'll need to specify the path to the command and any command-line parameters (also called *switches* or *arguments*), the "start in" directory, and whether the command should run in a normal window, minimized, or maximized. Figure 3.21 shows the command-line task dialog box.

**FIGURE 3.20**  
Creating a new task

**TIP** One really neat feature of the shell command task is that little right arrow you see beside the parameters option in Figure 3.21. Some snap-ins and extensions support passing variable values to scripts. To see the variables you can use in that context, click the right arrow. Highlight one of the variables to add it to the list of command-line parameters.

**NOTE** In contrast to shell command tasks, which refer to commands outside the tool, navigation command tasks are shortcuts to places within the console. For instance, if you want a shortcut to the Disk Defragmenter, find and select it on the console tree, then add it to the tool's favorites (just choose Add to Favorites from the Favorites menu). Then, when you create your navigation task, choose the Disk Defragmenter from the list of existing favorites. Once the shortcut is created, clicking the task icon opens the Disk Defragmenter tool.

**FIGURE 3.21**  
Creating a shell  
command task

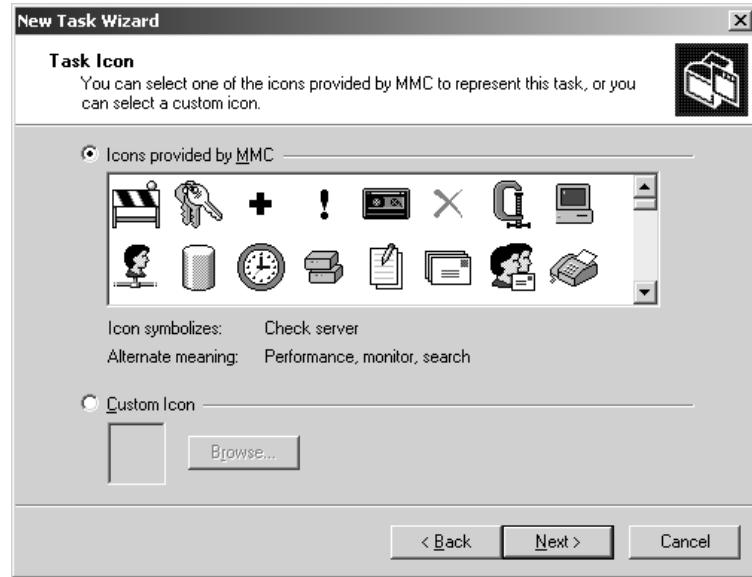

2. After choosing to create a menu command, select a source for the command in the next screen (see Figure 3.22) and choose a command from those available on the right. You can choose whether the source of the command will be an item in the details pane or a specific item in the console tree. In this case, you are creating the latter, a tree item task. Now you'll see the Computer Management node in the left pane, and Connect to Another Computer is among the available commands on the right. Highlight Connect to Another Computer and click Next.

**FIGURE 3.22**  
Selecting a menu  
command

3. Give the task a name and a description. The description you supply will either appear alongside the task icon or pop up when you hover over it, depending on the style choice you made for the taskpad. Click Next.
4. In the next screen (shown in Figure 3.23), choose a task symbol. Unfortunately, the selection of symbols is pretty limited. Some tasks have recommended symbols; highlight a symbol to see its common meanings. Or you might find a custom icon you like better by browsing to `\Windows\system32\shell32.dll`. Select a symbol and click Next.

**FIGURE 3.23**  
Choosing an icon  
for the task

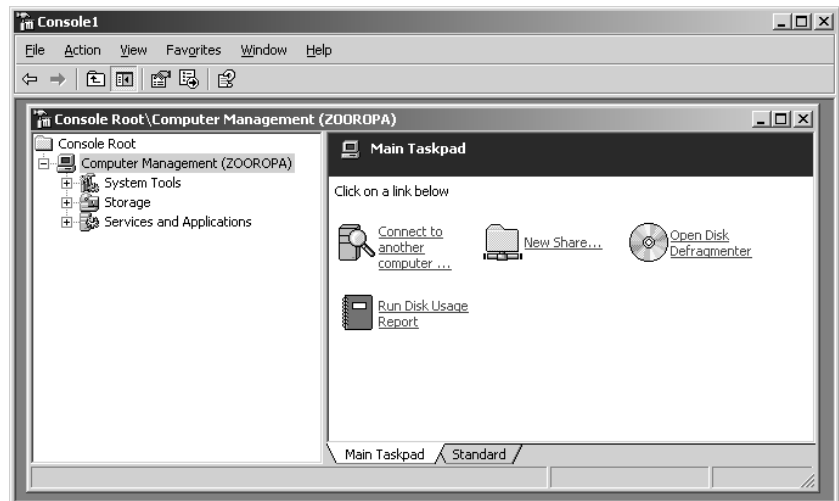

5. The wizard confirms your task creation (see Figure 3.24), displaying a list of created tasks and giving you the option to run the wizard again to create another task. Click Finish, then click OK to close the taskpad property page. The new task will appear in the taskpad as a link. Click the link once to run it.
6. For practice, run the New Task Wizard again, creating a new menu command based on another tree item. In the New Task Wizard, scroll through the Computer Management tree and locate Shares under System Tools/Shared Folders. The task you're looking for is New Share. Running this command will kick off the Share a Folder Wizard. Now your taskpad should look something like the one shown in Figure 3.25. Using the tasks you've created, you can connect to a remote machine and create a shared folder on it. For the sake of completeness, the taskpad shown in Figure 3.25 also includes a shell command task (Run Disk Usage Report) and a Navigation task (Open Disk Defragmenter).

**FIGURE 3.24**  
Completing the New Task Wizard

**FIGURE 3.25**  
A taskpad with tasks

Steps 1 through 5 illustrate how to create a task to connect to another computer, which is important if the tool is to function remotely. This is why the Computer Management snap-in was used instead of the individual component snap-ins. When adding individual component snap-ins like the Event Viewer and Services, the Connect to Another Computer function is also available, but each snap-in has to be pointed to a remote computer separately. If you use the Computer Management snap-in, you can easily change the focus for the entire tree of tools at once. Otherwise, you might find yourself looking at your local Event Viewer while stopping and starting services on a remote machine.

### NOTES ON TASKPAD VIEWS AND MENU COMMANDS

In the example of creating a taskpad, you had the choice in step 4 to apply the view to the selected tree item only or to any other tree item of the same type. When a taskpad view is applied to the selected tree item, it will only be visible when you navigate to that node in the console tree or use a link such as a Favorite to get there. When a taskpad view applies to other tree items of the same type, different event logs, for instance, it will display the same taskpad view and tasks no matter what log is selected for viewing in the details pane. A taskpad view created for the Application log, configured to display for all items of the same type, will also be accessible when you look at the Security log or the System log.

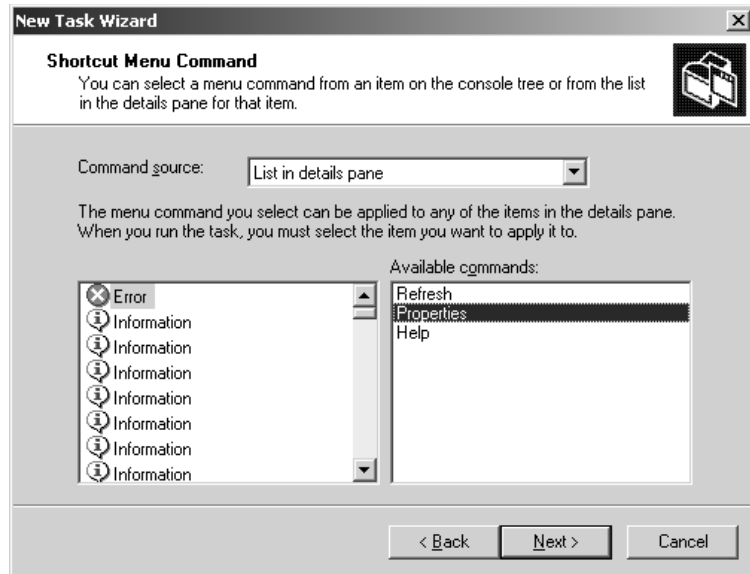

Also, when you're choosing a menu command source in the New Task Wizard, tree item tasks can point to any item on the tree, but detail pane choices are limited to operations you could perform by right-clicking an item in the details pane at that particular place on the tree. The command applies to the selected item. It also follows that detail pane commands don't work unless you actually choose to display the details pane list when you create the taskpad. So why would you want to create task links that are limited to the command options in the details pane at all? Isn't it quicker to right-click? Isn't right-clicking a universal skill at this point? Well, this capability could be useful if you need to frequently perform the same tasks on different items in the list.

As an example of the preceding points (selected tree versus same type views, and tree item menu commands versus detail pane commands), you'll create a taskpad view for an event log and create the following tasks: view the details of a particular log entry, refresh the log view, archive the log, clear the log, and open an archived log file. I would use the Services tool as an example (start service, pause service, etc.) but Microsoft beat me to it: there's already an extended view of Services that covers those functions.

1. First, open the Event Viewer and select one of the event logs. Choose New Taskpad View from the Action menu. The wizard will open. Click Next to continue.
2. Select your display options for the taskpad. There will be a long list of log entries, so a vertical list is appropriate, although selecting a horizontal list will allocate more room to display the columns. I recommend leaving the task description style on InfoTip, as this will allow more room for task links. Click Next.
3. Choose to apply the taskpad view to all tree items of the same type, and to change the default display to this taskpad view. These are the default settings for new taskpad views. Choose Next.
4. Give the taskpad a name (I called mine Log Options) and a description, which will appear under the name in the details pane. Click Finish to create the taskpad and start the New Task Wizard (if you leave the box checked, it's selected by default).
5. To create a task, click Next in the New Task Wizard. Choose to create a menu command and click Next.
6. This time, in the Shortcut Menu Command page, you'll choose your command from the list in the details pane for the log you selected. As you can see in Figure 3.26, the log entry context-menu commands are also available. Select Properties (it doesn't matter what entry is selected on the source side at this point) and click Next.

**FIGURE 3.26**

Creating a detail  
pane command task

7. Name the task View This Entry. Click Next. Now choose an icon from the list, click Next, click Finish in the confirmation page, and you're done.
8. Run the New Task Wizard again to create each of the remaining tasks, but change your selection in the Shortcut Menu Command page to select a tree item task (shown in Figure 3.27). The menu commands to use are Refresh, Save Log File As, Clear All Events, and Open Log File. Name these Refresh Log View, Archive this Log, Clear this Log, and Open Archived Log File, in that order.

**FIGURE 3.27**

Creating a tree  
item task

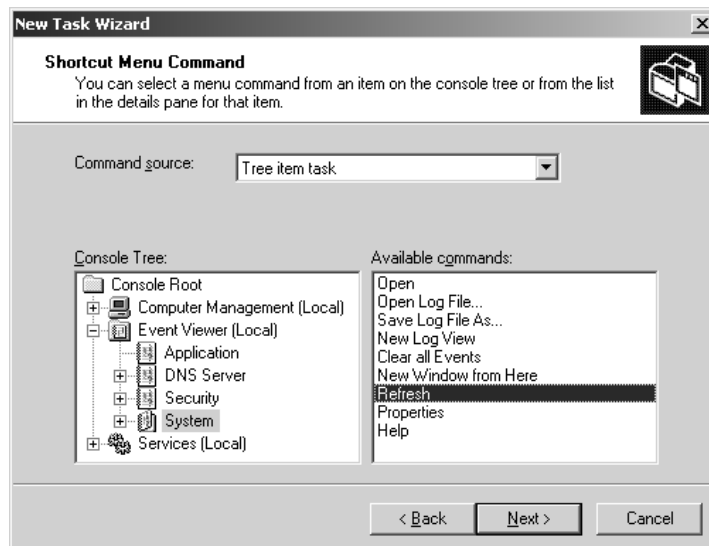

Figure 3.28 shows the final taskpad with tasks. Now when you navigate to any of the event logs in the Event Viewer, the taskpad displays the list of log entries, and the tasks you've created appear to the left (or under) the entries. This effectively illustrates the difference between tree item tasks and detail pane command tasks; to view a particular log entry (a detail pane command), you must first select it from the list and choose View This Entry. To archive the log or refresh the log view, however, just click the link; the context for the command has already been established.

**FIGURE 3.28**

The final Event Log taskpad

### CUSTOMIZING THE CONSOLE INTERFACE

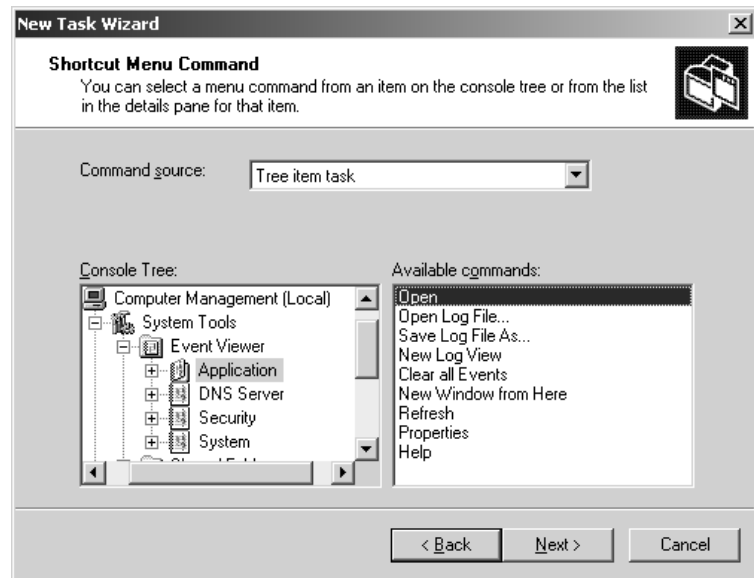

Now that you've loaded snap-ins and created customized taskpad views and task links, you can give your customized tool a simplified look and feel by hiding the console tree and the navigation tabs that allow end users to move between the standard and the taskpad view of the detail pane.

You know, that reminds me, if you hide the console tree and the navigation tabs, lock the tool down, and prevent the user of the tool from navigating the console tree, they have no way of getting down to the Log Options taskpad you created in the earlier example. They'll be stuck at the Main Taskpad. So, before you customize the console interface, you need a task in the Main Taskpad that acts as a link to the Log Options taskpad. There are two ways to accomplish this, and both seem to work equally well.

The first way to create a link to another taskpad is to navigate down to the log while the console tree is visible in Author mode and add that location to the list of Favorites. Then, create a navigation task in the Main Taskpad and select the Favorite as the destination. The Favorites link must exist, however, before you can create a navigation task for it. Remember, though, if you are hiding the console tree altogether, you'll need to create a Favorite and a corresponding link for each log you want the user to access.

If you don't want to use the Favorites method, create a menu command task in the Main Taskpad and select as the source a tree item task. Navigate to the log and select the command Open (shown in Figure 3.29). Or choose New Window from Here to open the log in a new window. Name the task Open Application Log, for example. If the taskpad is configured to be the default display, that's all you need to do. From the Main Taskpad, the user needs only to click the link Open Application Log to go to the Log Options taskpad. Just as with the Favorites method, you'll need to create a link for each log. Of course, you can create a link to the Event Viewer instead of the individual log, and users can then select the log they are interested in viewing, but you won't have the same fine-grained control. It's also possible to create a taskpad consisting entirely of links to other taskpads, which in turn link to other taskpads on the console tree, if you feel up to it. As I said in the beginning of this section, the options are too numerous to cover them completely in this book.

**FIGURE 3.29**  
Creating a task  
to open a console  
taskpad view

A final word before you lock down the console: just as you would create a home link on a Web site to prevent a user from getting stuck on a particular page, it's a good idea to create links back to the main taskpad on second- or third-tier taskpads. This is especially true if you intend to hide the console tree and the toolbar because the forward and back buttons will not be available.

To customize the console interface, choose Customize from the View menu. Figure 3.30 shows the view options, with default values. Items are shown when the boxes are checked and hidden when they are cleared. As you uncheck selections, you can see the changes being updated in the console.

Hide the Console tree to achieve that single window appearance. Clear the Standard Menus check box to hide the Action, View, and Favorites menus. Removing the Action menu prevents the user from selecting an item and pulling down the Action menu to see a complete set of task options, but they can still access the context menu by right-clicking an item. If you clear the check box labeled

Standard Toolbar, the toolbar with the forward and back buttons disappears (along with the Show/Hide Console Tree, Export List, and Help buttons). Remember that you need those buttons if the tool has to navigate the tree. Consider our earlier example of the Main Taskpad with a link to the Application log taskpad. If the Standard toolbar is removed, you cannot return to the Main Taskpad from the Application Log taskpad without a link. If the console tool is only running wizards or scripts, however, removing the navigation buttons won't be a problem. To really simplify the window, clear both the Status Bar and the Description Bar check boxes (the status bar is displayed by default, but the description bar is not). Clear the Taskpad Navigation Tabs check box to remove the tabs from the bottom of the details pane; without access to the Standard view, users will only be able to view the taskpads you've created.

**FIGURE 3.30**

Customizing the console view

Each snap-in can have its own menu items and toolbar buttons. To hide these for all snap-ins in the tool, clear the two check boxes in the Snap-In section of the dialog box. You can't pick and choose which toolbars and buttons to hide; you either hide them for all snap-ins or reveal them for all snap-ins.

## Packaging Up the Tool for Users

When the tool is ready to be published, choose Options from the Console menu of the Main window and change the tool's name (from `Console1` to something descriptive), as shown in Figure 3.31. The new name will now appear in the title bar. You might also want to assign a different icon than the generic MMC icon. Finally, assign a default mode to the MSC file. Use one of the three User modes to prevent changes to the tool, such as adding and removing snap-ins or editing taskpads. The three different User modes represent varying degrees of restrictions, including whether the user can open multiple windows. Limited Access Single Window is the most restrictive.

Notice the two configuration check boxes at the bottom of Figure 3.31. Check Do Not Save Changes to This Console to prevent users from saving any changes they make to the console. Users can customize views by default. To prevent this, uncheck the box that says Allow the User to Customize Views. You

haven't locked down anything at all until you do this. Otherwise, the user can open up Customize View by clicking the Console icon at the top left of the window and undo all your modifications. Choose OK to close the Options dialog box, then save the console as an MSC file if you haven't already.

**FIGURE 3.31**

The Console Options dialog box

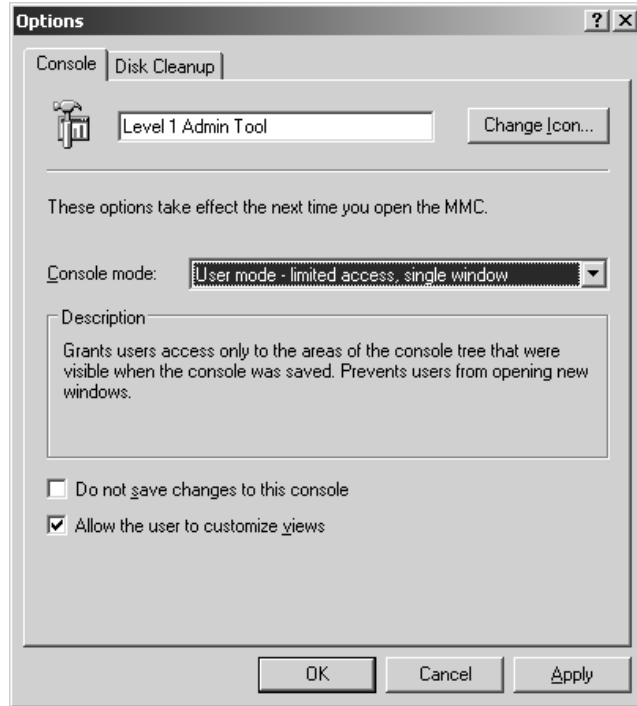

Figure 3.32 shows a basic admin tool running in User mode with limited access and a single window. The console tree and taskpad navigation tabs, as well as the Action and View menus, are hidden. This tool does reveal the Standard toolbar, however, since it's necessary to be able to go forward and back in the tool. Too bad you can't hide some buttons and not others.

**FIGURE 3.32**

The final product

**WARNING** *A locked down MMC tool is not to be relied on as a security or control measure. Control a user's actions using appropriate group memberships, rights and object permissions, and with delegation.*

## Distributing the Tool

When the tool is finished, distribute it as you would a normal file; e-mail it to someone, put it on the network file server in a shared folder, or use Active Directory services to publish it. Appropriate administrative permissions for the tasks and access to the snap-ins, either on the local machine or on the network, are required to use the tool.

Unfortunately, the version of MMC distributed with Windows 2000 and prior versions of Windows client systems will not run tools created using MMC 2 Version 5.2. They will run only on other Server 2003 systems and Windows XP. Windows Server and XP can run consoles created on Windows 2000 systems, however.

## Editing a Custom Console Tool

Making changes to the console is easy, even when the tool opens in User mode by default. The tool can be opened in Author mode using one of several methods:

- ◆ Open the tool using Start/Run and enter the filename with the **/a** switch.
- ◆ Right-click the file's icon and choose Author.
- ◆ Open a blank console using Start/Run and enter **mmc.exe**, then choose Open from the Console menu to pull up any MSC file in Author mode.

How can you keep others from making changes to the tool using these tricks? Chapter 9 explains how to restrict access to Author mode, and even particular snap-ins, using group policies.

In this chapter, you learned how to gracefully weather the minor user interface changes introduced with Windows Server 2003. We also explored the Microsoft Management Console and learned a few of its inner secrets. Now you are ready to unleash the real power of MMC by using its authoring features to create consoles that fit the needs of your MIS/IT department.

## Chapter 4

# Configuring Windows Server: The Windows Server 2003 Registry

ANY EXPLANATION OF HOW to solve problems and get things done in Server 2003 (or indeed any version of NT) will soon turn to a bit of software fiddling called “modifying the Registry” or “hacking the Registry.” This chapter explains exactly what the Registry is, why you care about it, and how to work with it. If you’ve already worked with Windows 9x, Me, or, again, any previous version of NT, then this will be old stuff. But the newcomers should read carefully!

Anyone who works with Server 2003, whether as a user or as an administrator, makes a fair number of adjustments to it—from the small ones, such as changing a background color, to larger ones, like changing a network IP address. Similarly, when you use an application, you inevitably end up configuring it as well, directing it where to save files, how the application should start up, whether to automatically run macros, and the like. And, of course, when you reboot a computer or whenever you start up an application, you expect your configurations to still be in effect—the things that you tell an operating system or application to do should survive a reboot. But where are these customizations stored?

Over the years, different operating systems have answered that question in different ways. Windows 2 and 2.1 actually stored a lot of their configuration information inside their own program files, which unbelievably meant that every time you made a change like installing a new video card, the Windows Setup program would build an entirely new copy of Windows with that driver’s information embedded in the Windows program itself! Not every configuration change in Windows 2.x required a rebuild of the operating system, thankfully, as Windows 2.x and then 3.x used ASCII text files with names like WIN.INI, SYSTEM.INI, CONTROL.INI, and so on to store configuration information. INI files weren’t a bad thing overall—their ASCII nature made changing them simple, a task for Notepad or an easy-to-write BASIC program—but the growing complexity of Windows in both its 9x and Windows NT incarnations created a need to be able to store more complex configuration information.

Microsoft’s answer to that increased need arrived with the first version of NT, Windows NT 3.1, in the summer of 1993. The answer was a group of files with the collective name of the *Registry*.

(Microsoft always capitalizes it—the Registry—so I will, too, but it always seems a bit overdone, don't you think?) The Registry is terrific in that it's one big database that contains all of the Server 2003 configuration information. Everything's there, from color settings to local user account's passwords. (Not domain users—those are in the separate files that store the Active Directory database. And by the way, you can't just look in the Registry to see local passwords—they're encrypted.) Even better, the Registry uses a fault-tolerant approach to writing data to ensure that the Registry remains intact even if there's a power failure in the middle of a Registry update.

So you've just *got* to like the Registry. Except, of course, for the *annoying* parts about it, including its cryptic organization and excessively complex structure. But read on and see what you think.

## What Is the Registry?

The Registry is a hierarchical (that is, tree-structured) database of settings that describe your user account, the hardware of the server machine, and your applications. Any time you make some change with the Control Panel or some MMC snap-in, the effect of that change is usually stored in the Registry. (I say “usually” because some information is stored in the Active Directory, which is separate from the Registry.)

### The Registry Stores Most of a Computer's “State”

If you can make changes to your system and they're then stored in the Registry, you might ask, “Who cares? What's the value of the Registry?” Well, consider how much time you spend configuring a new workstation or server. If that machine died for some reason, you'd want to set up another machine to replace the now-dead one—do you really want to spend all that time reconfiguring the replacement machine to look like the original? No, of course not. You would much prefer to be able to just put Server 2003 on the new machine and then restore all of the preferences and settings in one fell swoop, and you can do that, *if* you've got a backup of the old machine's Registry. Then all you need do is to put Server 2003 on the replacement machine and restore the old machine's Registry to the new machine. That, then, is the Registry's first value: when backed up, it preserves much of a machine's “state.”

### The Registry Stores Dynamic Hardware Information

Preserving user settings is nice, but it's not the Registry's sole value. In addition to storing the settings that *you've* made in the Registry, Server 2003 saves many settings that you never see, such as dynamic settings that Server makes to itself every time it boots—for example, whenever Server 2003 boots, it creates a census of the hardware attached to it and stores that census in the Registry. The Registry also contains internal adjustments that Server's designers preset with the intention that you would never touch them—and *that's* where the fun begins, at least for us noodlers.

### The Registry Is the Only Way to Make Some System Adjustments

Ninety-nine point nine percent of 2003's settings are of no interest whatsoever. But a few are quite powerful and largely undocumented or documented solely by obscure Knowledge Base articles. The occult nature of these Registry settings has predictably become the source of countless “tips and tricks” about how to tune up NT's, 2000's, XP's and now Windows Server 2003's performance or how to solve some knotty problem. Perhaps the most remarkable of these appeared a few years ago when NT internals expert Mark Russinovich discovered that the only real difference between

NT Workstation 3.51 and NT Server 3.51 was a few *Registry settings*! Twiddling the Registry, then, is often of value to Windows troubleshooters.

The tough part about working with the Registry is in grasping the programs and terminology used in editing the Registry. You're just supposed to *understand* sentences like these:

*If you are trying to determine why your user profile did not download properly, then you should activate USERENV.DLL's logging feature and examine the log that it creates in \Windows\Debug\UserMode\Userenv.log.*

*To enable USERENV.DLL logging, go to the subkey HKEY\_LOCAL\_MACHINE\SOFTWARE\Microsoft\Windows NT\CurrentVersion\Winlogon and add a new entry called UserenvDebugLevel of type REG\_DWORD. Set its value to 30002 hex and reboot the system.*

Sentences like these are a major reason for this chapter. You will come across phrases like that in Microsoft literature, magazine articles, and even parts of this book. Much of that information contains useful advice that will make you a better network administrator if you understand how to carry it out—in fact, these snippets are incredibly useful if you've got a busy network and people are having trouble logging in. My goal for this chapter, then, is to give you a feel for the Registry, how to edit it, and when to leave it alone.

## Registry Terminology

What did that stuff with all the backslashes mean? To get an insight, let's look at the Registry. You can see it by running the program REGEDIT.EXE (it's in the \Windows directory); just click Start/Run and fill in REGEDIT.EXE or simply REGEDIT.

Run Regedit and click the HKEY\_LOCAL\_MACHINE window. You'll see a screen like the one in Figure 4.1.

**FIGURE 4.1**  
Registry Editor  
screen

The terms to know in order to understand the Registry are *subtree*, *key*, *value*, *data type*, and *hive*.

**WARNING** While looking around in the Registry, please do not make any changes unless you truly want them! Because Regedit is an “editor,” you might think that it’s like Notepad or Word in that none of your changes actually take effect until you choose to Save them—but that is not the case at all. Make a change in Regedit and Regedit changes the Registry immediately. And, worse yet, there is no “undo” key for Regedit changes. So please... until you know what you’re doing, look—but don’t touch! (Unless you like re-installing from scratch, that is.)

Subtrees

A first look at Regedit can be a bit misleading, as it looks an awful lot like a directory/folder structure on a hard disk—so you may think that you’re seeing some hidden directories somewhere. But you’re not. Regedit’s view of the Registry represents the *logical* structure of the Registry far better than it represents the *physical* locations. (If you just can’t wait to find out where the Registry physically resides, then here’s the quick overview: some of the Registry lives in files called *hives*; the rest of it doesn’t exist anywhere on disk at all, as it’s dynamic data that gets recreated whenever you reboot the server.)

Notice that under the My Computer icon, Regedit shows five folder icons; those icons represent logical groupings of Registry information called *subtrees*. Table 4.1 has an overview of what’s in those subtrees.

TABLE 4.2: THE FIVE SUBTREES OF THE REGISTRY

SUBTREE	DESCRIPTION
HKEY_LOCAL_MACHINE	Contains information about the hardware currently installed in the machine and the settings for systems running on the machine. This key, and HKEY_CURRENT_USER, contain most of the important Registry configuration information. <i>This</i> key contains the information specific to your computer; the next one contains information specific to you, your user account. This subtree is used so often that it has a common abbreviation, HKLM.
HKEY_CURRENT_USER	Contains the user settings and preferences for the person currently logged on to the computer. These settings include things like how you like your desktop arranged as well as settings for particular applications, like Word or Visio. This key’s common use leads to it having the abbreviation HKCU.
HKEY_USERS	Contains a pointer to the HKEY_CURRENT_USER subtree and also to a profile called the DEFAULT profile. The DEFAULT profile describes how the machine behaves when no one’s logged on. For example, if instead of a blue background you wanted a machine to display a green background when no one was logged on, or if you wanted to display a particular wallpaper when no one was logged on (which I’ve found quite useful for keeping clear in my mind which machine was which when using a keyboard switch or just a table full of identical-looking machines), then you’d modify that DEFAULT profile.
HKEY_CLASSES_ROOT	Holds the file associations, information that tells the system, “Whenever the user double-clicks a file with the extension .BMP in Windows Explorer, start up PBRUSH.EXE to view the file.” It also contains the OLE registration database, the old REG.DAT from Windows 3.x. This is actually a redundant subtree, as all its information is found in the HKEY_LOCAL_MACHINE subtree. It also gets placed in the HKEY_CURRENT_USER\SOFTWARE\CLASSES key.
HKEY_CURRENT_CONFIG	Contains configuration information for the particular <i>hardware</i> configuration you booted up with.

In general, you’ll do most of your work in the first two subtrees. Some Registry entries are specific to a machine (HKEY\_LOCAL\_MACHINE, HKEY\_CLASSES\_ROOT, HKEY\_CURRENT\_CONFIG), and some are

specific to a user (HKEY\_USERS, HKEY\_CURRENT\_USER, as well as other Registry files that are in the \Documents and Settings\USER ID directories, which you'll meet later—but for now, just understand that the \Documents and Settings folder is where Windows 2000 and later machines store user preference information). That's important, and it's a great strength of the Registry's structure. The entries relevant to a particular machine should, of course, physically reside on that machine. But what about the settings relevant to a user: the background colors you like, the programs you want to see in your Start menu, the sounds you want on the system? These shouldn't be tied to any one computer; they should be able to move around the network with that user. Indeed, they can. As with NT 4, Windows 2000, and XP, Windows Server 2003 supports the idea that “roving users” can have their personal settings follow them around the network via *roaming profiles*, which you will learn more about in Chapter 9.

## Registry Keys

In Figure 4.1, you saw the Registry Editor display the Registry's sections as folders under a top-level PC icon. The whole window looks like Windows Explorer. In Explorer, those folders represented subdirectories, as I suggested before. In Regedit, however, they separate information into sections. (If you ever worked on the old Windows 3.x systems, then this is kind of similar to the way old Windows INI files had sections whose names were surrounded by square brackets, names like [386enh], [network], [boot], and the like.) Even though their icons look like folders, most people don't speak of “Registry folders”—the folders are called Registry *keys*.

You'll see more folder icons inside other folder icons and so, so it's logical that you'll sometimes hear the word “subkey.” In most cases the terms “subkey” and “key” can be used interchangeably.

To examine one example key, open up the SYSTEM key under HKLM; simply click the plus sign to the left of HKEY\_LOCAL\_MACHINE, then click the plus sign next to the System key. It contains subkeys named ControlSet001, ControlSet002, CurrentControlSet, Select, and Setup, and CurrentControlSet is further subkeyed into Control and Services.

Notice, by the way, the key called CurrentControlSet. It's very important. Almost every time you modify your system's configuration, you do it with a subkey within the CurrentControlSet subkey.

## Key-Naming Conventions

The tree of keys gets pretty big as you drill down through the many layers. CurrentControlSet, for example, has dozens of keys, each of which can have keys/subkeys. (Remember, the two terms are basically interchangeable.) Identifying a given subkey is important, so Microsoft has adopted a naming convention that looks just like the one used for directory trees. CurrentControlSet's fully specified name would be, then, HKEY\_LOCAL\_MACHINE\SYSTEM\CurrentControlSet. In this book, however, I'll just call it CurrentControlSet to keep key names from getting too long to fit on a single line.

## Value Entries, Names, Values, and Data Types

If I drill down through CurrentControlSet, I find the subkey Services, and within Services, there are many subkeys. In Figure 4.2, I have opened and highlighted one of those subkeys—the key HKEY\_LOCAL\_MACHINE\SYSTEM\CurrentControlSet\Services\Browser\Parameters.

**FIGURE 4.2**  
The Parameters  
key of Current-  
ControlSet\  
Services\Browser

In the right pane of Regedit, you can see several lines broken into three parts; two of them look like

IsDomainMaster	REG_SZ	FALSE
MaintainServerList	REG_SZ	Yes

These are examples of two system settings; on this particular computer, a setting called `IsDomainMaster` is set to `FALSE` and `MaintainServerList` is set to `Yes`.

**NOTE** As to what exactly those things mean, look to Chapter 18’s discussion of the browser. It would be really great if you could right-click every line like the two above in the Registry and get a little Help message about what that line does and what modifying it would do, but nothing like that exists. That’s why there are so many books on the Registry!

Each line like `IsDomainMaster REG_SZ FALSE` is called a *value entry*. The three parts are called *name*, *data type*, and *value*, respectively. In this example, `IsDomainMaster` is the *name*, `REG_SZ` is the *data type*, and `FALSE` is the *value*.

Microsoft notes that each value entry cannot exceed about 1MB in size. It’s hard to imagine one that size, but it’s worth mentioning.

What is that `REG_SZ` stuff? It’s an identifier to the Registry of what *kind* of data to expect: numbers, messages, yes/no values, and the like. Microsoft defines five data types in the Registry Editor (although others could be defined later), shown in Table 4.2.

Those who first met the Registry with Windows 95 will notice a few differences here. Windows 95 has six subtrees, but only three data types—*string*, which encompasses `REG_SZ`, `REG_MULTI_SZ`, and `REG_EXPAND_SZ`; *dword*, which is the same as `REG_DWORD`; and *binary*, which is identical to `REG_BINARY`.

And if you’re wondering how on earth you’ll figure out what data type to assign to a new Registry value, don’t worry about it; if you read somewhere to use a particular new value entry, you’ll be told what data type to use. Failing that, I usually just guess `REG_SZ` if it’s textual in nature, `REG_DWORD` if it’s numeric.

**TABLE 4.3:** DATA TYPES AS DEFINED BY THE REGISTRY EDITOR

DATA TYPE	DESCRIPTION
REG_BINARY	Raw binary data. Data of this type usually doesn't make sense when you look at it with the Registry Editor. Binary data shows up in hardware setup information. If there is an alternative way to enter this data other than via the Registry Editor—and I'll discuss that in a page or two—then do it that way. Editing binary data can get you in trouble if you don't know what you're doing. The data is usually represented in hex for simplicity's sake.
REG_DWORD	Another binary data type, but it is 4 bytes long.
REG_EXPAND_SZ	A character string of variable size, it's often information understandable by humans, like path statements or messages. It is "expandable" in that it may contain information that will change at runtime, like <code>%username%</code> —a system batch variable that will be of different sizes for different people's names.
REG_MULTI_SZ	Another string type, but it allows you to enter a number of parameters in this one value entry. The parameters are separated by binary zeroes (nulls).
REG_SZ	A simple string.

## Working with the Registry: An Example

Now, I know you want to get in there and try it out despite the warnings, so here's an innocuous example. Remember, it's only innocuous if you *follow* the example to the letter; otherwise, it will soon be time to get out your installation disks.

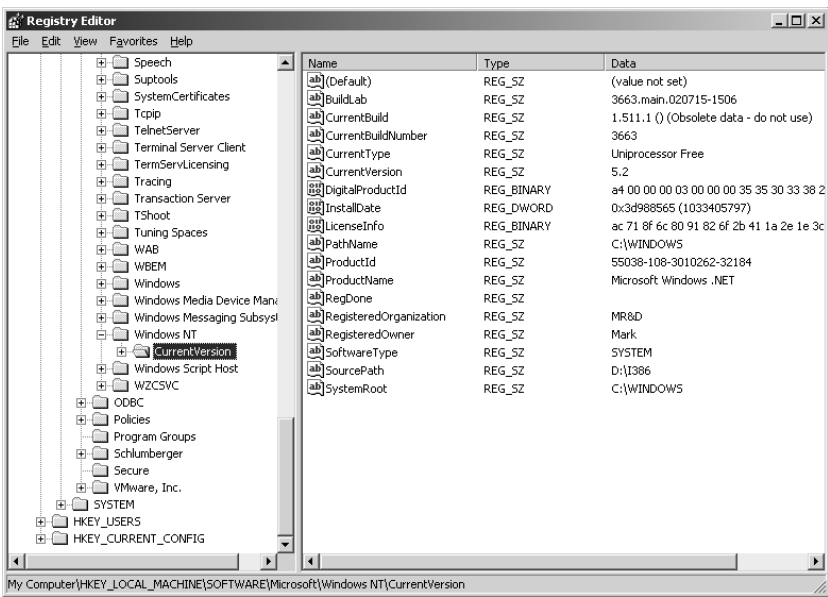

That's not just boilerplate. Don't get mad at *me* if you blow up your server because you didn't pay attention. Actually, you *may* be able to avoid a reinstallation if the thing that you modified was in the `CurrentControlSet` key; Server 2003 knows that you often mess around in there, and so it keeps a spare. In that case, you can reboot the server and, when the boot menu prompts "Please select the operating system to start," press F8 for the Windows Advanced Options menu. (If you don't have a boot menu—as would be the case if Server 2003 is the only OS on your disk—then it's a bit of a video game, I'm afraid; try to press F8 just as the initial power-on screen for your computer appears. With a little practice it becomes easier.) One of the options you'll get will be Last Known Good Configuration (Your Most Recent Settings That Worked). That *doesn't* restore the entire Registry; it just restores the control set. Fortunately, the current control set is a *lot* of the Registry. It doesn't include user-specific settings, however, like, "What color should the screen be?" Thus, if you were to set all of your screen colors to black, rendering the screen black on black (and therefore less than readable), rebooting and choosing Last Known Good Configuration wouldn't help you.

In any case, let's try something out, something relatively harmless. Let's change the name of the company that you gave Server 2003 when you installed it. Suppose I decided to change my company's name from MR&D to Bigfirm, the example that I use in much of this book. Suppose I'd already installed a bunch of Server 2003 machines and filled in MR&D when prompted for an organization. Suppose also that I want to change that so the Help/About dialog boxes say that I'm Mark Minasi of Bigfirm, but I don't feel like reinstalling. Fortunately, the Registry Editor lets me change company names without reinstalling:

1. Open the Registry Editor. From the Start menu, choose Run.

- 2. In the command line, type **regedit** and press Enter.
- 3. Open the HKEY\_LOCAL\_MACHINE folder. Inside that you'll find a folder called SOFTWARE; open that. Inside that you'll find a folder named Microsoft; open that. Inside the Microsoft folder you'll find a folder named Windows NT; open that and you will see a folder named CurrentVersion. Click it and you'll see something like Figure 4.3.

**FIGURE 4.3**  
HKEY\_LOCAL\_MACHINE\SOFTWARE\Microsoft\Windows NT\CurrentVersion

- 4. In HKEY\_LOCAL\_MACHINE\Software\Microsoft\Windows NT\CurrentVersion you can see, among other things, value entries named RegisteredOrganization and RegisteredOwner. Mine say MR&D and Mark, but yours will say different things.
- 5. Double-click RegisteredOrganization, and a String Editor screen appears. You'll see something like Figure 4.4.

**FIGURE 4.4**  
Registry string editor

- 6. Highlight the old value and replace it with **Bigfirm**. Click OK, and close up the Registry Editor. Do the same thing with Mark in RegisteredOwner, changing it to **Mark Minasi**.

Now click Help/About for any program—even the Registry Editor will do—and you’ll see that your organization is now MR&D.

**WARNING** *I remind you again: click all you like; you will not find a Save button or an Undo button. When you edit the Registry, it’s immediate and it’s forever. So, once again, be careful when you mess with the Registry.*

## How Do You Find Registry Keys?

How did I know to go to `HKEY_LOCAL_MACHINE\Software\Microsoft\Windows NT\CurrentVersion` in order to change my organization name? I found it by poking around the Registry. Regedit let me do it with its neat Find feature.

I figured that the word “Name” would appear a lot in the Registry, so looking for a field with my name called “Name” didn’t sound promising. But “Organization” isn’t as common, so I figured I’d try it. Here’s how you can, too:

1. Start Regedit if you haven’t already.
2. Click the My Computer icon in Regedit.
3. Click Edit/Find and a Find dialog box will appear that looks like Figure 4.5.

**FIGURE 4.5**  
Regedit’s Find  
dialog box

4. In the Find What text field, type in **organization**. Note that Regedit will search key names, value entry names, and the actual data in value entries. There is a lot more data in the Registry than there are key and value entry names, so skip searching data whenever possible; uncheck the Data check box and click Find Next.

On my system the first hit I got was for a key called `MSExtOrganization`, which was clearly not what I wanted, so I pressed F3 to tell Regedit to find the next match.

Several false hits later, I found `RegisteredOrganization`.

But how else can I find Registry keys? Microsoft’s Knowledge Base and white papers are great sources of useful Registry keys. Random Web searches can sometimes turn up some pretty neat stuff—or, as is usually the case with random Web searches, neat-sounding stuff that doesn’t work.

## Even More Cautions about Editing the Registry

If you’re just learning about the Registry, you’re probably eager to wade right in and modify a value entry. Before you do, however, let me just talk a bit about using caution when you manipulate the Registry. (I know I’ve mentioned it before, but it’s important, so I’m mentioning it again.)

The vast majority of Registry items correspond to some setting in the Control Panel, Active Directory Users and Computers, or some MMC snap-in. For example, you just saw how you can change the `RegisteredOrganization` directly via the Registry Editor. I only picked that example, however, because it was fairly illustrative and simple to understand. In general, *don't use the Registry Editor to modify a value that can be modified in some other way.*

For example, suppose I choose to set a background color on my screen to medium gray. That color is represented as a triplet of numbers: 128 128 128. How did I know what those color values meant? Because they're the same as Windows 3.x color values. Color values in Windows are expressed as number triplets. Each number is an integer from 0 to 255. If I input a value greater than 255, the Registry Editor would neither know nor care that I was punching in an illegal color value. Now, in the case of colors, that probably wouldn't crash the system. In the case of other items, however, the system could easily be rendered unusable. For example, I'm running Server 2003 on a system with just a single Pentium III processor, so the Registry reflects that, noting in one of the `HARDWARE` keys that 2003 is running in a "uniprocessor" mode. Altering that to a multiprocessor mode wouldn't be a very good idea.

Why, then, am I bothering to tell you about the Registry Editor? Three reasons.

First, there are settings—important ones—that can only be altered via the Registry Editor, so there's no getting around the fact that a Server 2003 expert has to be proficient in the Editor.

Second, you can use the Registry Editor to change system value entries on remote computers. To use a very simple example: I'm at location A and I want to change the background color on the server at location B. To do that I have to physically travel to location B in order to run the Control Panel on the computer at that location. Instead of doing that, however, I can just start up the Registry Editor, choose Registry/Select Computer, and edit the Registry of the remote computer. (This is a lot less true than it once was with earlier versions of Server, as 2000 Server and Server 2003 have some very good remote control tools; but I'm sure that there will be instances where this is still useful advice.) This assumes that you have the security access to change the Registry of the remote computer—that is, you're a member of the Administrators group on that computer.

Third, Server 2003 comes with a couple of programs named `regini.exe` and `reg.exe` that let you write scripts to modify Registries. Such a tool is quite powerful; in theory, you could write a REGINI script to completely reconfigure a Server setup. Again, however, before you start messing with that program, please be sure that you have become proficient with the Registry. I've explained the various kinds of mischief that you can cause working by hand with the Registry Editor. Imagine what kinds of automated disasters you could start at 2.5GHz with a bad REGINI script!

And while I've mentioned REG, I should mention that it does a whole *bunch* of things—it will search your Registry, do automated search-and-replace (think how quickly you could destroy a Registry with *that!*), automate creating and deleting keys and value entries, and import and export Registry data. Do a `reg /?` for more info.

By the way, there's another way to automate Registry changes through REGEDIT. You can create an ASCII text file with the desired Registry changes, then use an undocumented `/s` (for "silent") switch to introduce the changes.

The file has a particular format. The first line must be `Windows Registry Editor Version 5.00`, followed by a blank line. Then you enter a line with the full name of the Registry key that contains the value that you want to modify, surrounded by square brackets. Then type a line for each value that you want to modify, with the name of the value, an equal sign, and the desired value. Strings should be surrounded by quotes, and numbers—as in the `DWORD` type—should be prefixed by

DWORD;; for example, consider the following file:

```
Windows Registry Editor Version 5.00
```

```
[HKEY_LOCAL_MACHINE\SOFTWARE\Microsoft\Windows NT\CurrentVersion]
"RegisteredOrganization"="MR&D"
"NumberOfLicenses"=dword:00000003\
```

The first line identifies the file as a set of Registry changes. That first line is probably to keep someone from accidentally feeding some random file to REGEDIT, causing untold havoc from just an ill-thought-out mouse click. Then there's a blank line and then the description in square brackets. The line afterward sets the `RegisteredOrganization`, as described earlier, and the final entry is just an imaginary setting that I created just to show how to do a number. If I put those five lines—it's *five*, remember the blank line—into a file and called it `mystuff.reg`, I could make REGEDIT modify the Registry with it like so:

```
Regedit /s mystuff.reg
```

And by the way, here's a useful tip: if you use REGEDIT's export function (Registry/Export Registry File), the resulting exported file is ASCII and is in the proper format for using `/s` to apply the values to another computer.

## Where the Registry Lives: Hives

The Registry is mostly contained in a set of files called the *hives*. (“Mostly” because some of it is built automatically every time you boot up your system. For example, Server doesn't know what devices are on a SCSI chain until you boot.) Hives are binary files, so there's no way to look at them without a special editor of some kind, like the Registry Editor. Hives are, however, an easy way to load or back up a sizable part of the Registry.

Most, although not all, of the Registry is stored in hive files. They're not hidden, system, or read-only, but they are always open, so you're kind of limited in what you can do with them.

### A Look at the Hive Files

The machine-specific hive files are in the `\WINDOWS\system32\config` directory. The user-specific hive files are in the `\Documents and Settings\username` directories. (Actually, that's where *local* user settings go; people with “roaming profiles”—discussed in Chapter 9—also store copies of their `NTUSER.DAT` on a network share.) You can see the hive files that correspond to parts of the subtree listed in Table 4.3.

**TABLE 4.4:** HIVE FILES

SUBTREE/KEY	FILENAME
HKEY_LOCAL_MACHINE\SAM	SAM (primary) and SAM.LOG (backup)
HKEY_LOCAL_MACHINE\SECURITY	SECURITY (primary) and SECURITY.LOG (backup)

*Continued on next page*

**TABLE 4.4:** HIVE FILES (*continued*)

SUBTREE/KEY	FILENAME
HKEY_LOCAL_MACHINE\SOFTWARE	SOFTWARE (primary) and SOFTWARE.LOG (backup)
HKEY_LOCAL_MACHINE\SYSTEM	SYSTEM (primary) and SYSTEM.ALT (backup)
HKEY_USERS\DEFAULT	DEFAULT (primary) and DEFAULT.LOG (backup)
HKEY_USERS\Security ID	NTUSER.DAT
HKEY_CURRENT_USER	NTUSER.DAT
HKEY_CLASSES_ROOT	(Created from current control set at boot time)

Table 4.3 needs a few notes to clarify it. First, about the HKEY\_CLASSES\_ROOT subtree: It is copied from HKEY\_KEY\_LOCAL\_MACHINE\SOFTWARE\Classes at boot time. The file exists for use by 16-bit Windows applications. While you’re logged on to Server 2003, however, the two keys are linked; if you make a change to one, the change is reflected in the other.

The local user profiles live in \Documents and Settings\*username*, where each user gets a directory named *username*. For example, I’ve got a user account named mark, so there’s a directory named \Documents and Settings\mark on my computer. If I look in it, I find the files *ntuser.dat* and *ntuser.dat.log*.

To summarize, then, the core of the Registry is the four Ss and DEFAULT:

- ◆ SAM
- ◆ SECURITY
- ◆ SYSTEM
- ◆ SOFTWARE

SAM contains the user database; SECURITY complements SAM by containing information such as whether a server is a member server or a domain controller, what the name of its domain is, and the like. Domain controllers do not have SAM files, but workstations (XP, 2000 Professional, etc.) and member servers all have SAMs. SYSTEM contains configuration information like what drivers and system programs the computer uses, which should be loaded on boot-up, and how their parameters are set. SOFTWARE tends to contain more overall configuration information about the larger software modules in the system, configuration information that does *not* vary from user to user. And then every user has an NTUSER.DAT with their specific application preferences in it.

One question remains about the hive files, however. Why do all the files have a paired file with the extension .LOG? Read on.

**Fault Tolerance in the Registry**

Notice that every hive file has another file with the same name but the extension .LOG. That’s really useful because Server 2003 (and in fact every version of NT) uses it to protect the Registry during updates.

Whenever a hive file is to be changed, the change is first written into its LOG file. The LOG file isn't actually a backup file; it's more a journal of changes to the primary file. Once the description of the change to the hive file is complete, the journal file is written to disk. When I say "written to disk," I *mean* written to disk. Often, a disk write ends up hanging around in the disk cache for a while, but this write is "flushed" to disk. Then the system makes the changes to the hive file based on the information in the journal file. If the system crashes during the hive write operation, there is enough information in the journal file to "roll back" the hive to its previous position.

The exception to this procedure comes with the SYSTEM hive. The SYSTEM hive is really important because it contains the `CurrentControlSet`. For that reason, the backup file for SYSTEM, `SYSTEM.ALT`, is a complete backup of SYSTEM. If one file is damaged, the system can use the other to boot.

Notice that `HKEY_LOCAL_MACHINE\HARDWARE` does not have a hive. That's because the key is rebuilt each time you boot so Server 2003 can adapt itself to changes in computer hardware. The Plug and Play Manager, which runs at boot time, gathers the information that Server needs to create `HKEY_LOCAL_MACHINE\HARDWARE`.

Confused about where all the keys come from? You'll find a recap in Table 4.4. It's similar to Table 4.3, but it's more specific about how the keys are built at boot time.

**TABLE 4.5: CONSTRUCTION OF KEYS AT BOOT TIME**

KEY	HOW IT'S CONSTRUCTED AT BOOT TIME
<code>HKEY_LOCAL_MACHINE:</code>	
<code>HARDWARE</code>	Plug and Play Manager
<code>SAM</code>	SAM hive file
<code>SECURITY</code>	SECURITY hive file
<code>SOFTWARE</code>	SOFTWARE hive file
<code>SYSTEM</code>	SYSTEM hive file
<code>HKEY_CLASSES_ROOT</code>	SYSTEM hive file, <code>Classes</code> subkey
<code>HKEY_USERS_DEFAULT</code>	DEFAULT hive file
<code>HKEY_USERS\Sxxx</code>	Particular user's NTUSER.DAT file
<code>HKEY_CURRENT_USER</code>	Particular user's NTUSER.DAT file

## Registry Permissions

Clearly you wouldn't want just anybody messing with your Registry. So how is it secured? With permissions. Recall in Chapter 2 that you read that things in Server 2003—and let me get technical and stop saying "things," and instead say "objects"—can have *access control lists* or *ACLs* associated with them. You can view and change these ACLs—assuming you have the proper permissions!—in Regedit by right-clicking any folder and choosing Permissions.

As time goes on, Microsoft learns more about how to properly secure Server from outside attacks. Many Microsoft security patches are nothing more than just adjustments to the ACLs on some Registry key.

## Remote Registry Modification

You can modify another computer's Registry, perhaps to repair it or to do some simple kind of remote maintenance, by loading that computer's Registry. Regedit lets you do that simply; just click File/Connect Network Registry, and Regedit then asks for the name of the remote computer. You fill in the name, click OK and, if necessary, Regedit will ask for a username and password with permissions to access the remote computer's Registry. Once Regedit is satisfied that you're Da Man permission-wise, you get a new icon under your My Computer icon and the HKEY\_LOCAL\_MACHINE and HKEY\_USERS subtrees of that remote computer. (The others don't show up, as they're all either dynamic or are simply mappings to subsets of the other subtrees.)

You can then edit the remote computer's Registry as if you were there. When done, just click File/Disconnect Network Registry and Regedit breaks the connection.

You can also load a particular hive with the Load Hive or Unload Hive commands. More specifically, you can load or unload the hives only for HKEY\_USERS and HKEY\_LOCAL\_MACHINE. Here's how:

1. Start Regedit.
2. Under My Computer, click either the HKEY\_LOCAL\_MACHINE folder or the HKEY\_USERS folder.
3. Click File/Load Hive.
4. In the resulting dialog box, point to the exact hive file itself—a particular NTUSER.DAT on a share somewhere.

The hive shows up as another key. You can then edit it and use File/Unload Hive to disconnect from it.

**WARNING** *And I know you're getting tired of me reminding you, but I have to point out that Unload is not the same as Save. Those changes you made happened immediately.*

Again, the Load Hive option appears only if you've selected one of those two subtrees. Unload Hive is available only if you've selected a subkey of one of those two subtrees.

Why, specifically, would you load a hive or a remote Registry? In my experience, you typically load a hive in order to get to a user's profile. Suppose a user has set up all of the colors as black on black and made understanding the screen impossible. You could load the hive that corresponds to that user, modify it, and then unload it.

You could load and save hive files to a floppy disk, walk the floppy over to a malfunctioning machine, and load the hive onto the machine's hard disk, potentially repairing a system problem. This wasn't possible if you used NTFS on the boot disk of an NT 4 system unless you had multiple copies of NT 4—there wasn't an easy way to get to a system with an NTFS boot drive. Under Windows 2000, XP, and Server 2003, however, you can go to the advanced boot options and boot to a command prompt even if the system's damaged.

There is yet another way to control Registries remotely, through something called system policies, which are covered in Chapter 9.

## Backing Up and Restoring a Registry

By now, it should be pretty clear that the Registry is an important piece of information and that it should be protected. It protects itself pretty well with its LOG files, but how can you back it up?

Unfortunately, the fact that Registry hive files are always open makes it tough to back up the Registry since most backup utilities are stymied by open files. The NTBackup program that comes with Server 2003 works well, and, while it's a bit primitive, it *can* back up the Registry hive files. So if you use NTBackup—and it's pretty good, when you consider its price—then you should tell it to back up your Registry every night.

NT 4 had a terrific tool named RDISK that would back up your entire Registry with just a few keystrokes, but that's nowhere to be found in Windows 2000 or later, including Server 2003. The replacement for RDISK can be found in the Backup program, which offers to create a System Repair Disk, just as RDISK did, through these steps:

1. Launch Backup (Start/Programs/Accessories/System Tools/Backup).
2. Click the Backup tab.
3. Make sure all directories and files are unchecked.
4. Look under My Computer's list of drives; the last option will be System State; check that.
5. Next to the list box labeled Backup Media or File Name, fill in a filename or click Browse and choose a filename; this is where the Registry backup will go.
6. Click the Start Backup button.
7. In the next dialog box, click the Advanced button.
8. Uncheck Automatically Backup System Protected Files with the System State.
9. Click OK to dismiss the dialog box.
10. Click Start Backup. Backup will then save the Registry. You can restore the Registry with Backup as well.

What if you want to back up only a portion of the Registry? As you've already read, Server 2003 includes a program called REG.EXE. It will, among other things, let you back up the Registry from the command line and while the system is running—but only *one subtree at a time*. It looks like REG SAVE HKLM\subtreename destination, where *destination* is the place that you want the backup to go, and the subtree names are, of course, SECURITY, SAM, SYSTEM, and SOFTWARE in the case of HKEY\_LOCAL\_MACHINE. Note also the abbreviation: REG accepts HKLM in place of HKEY\_LOCAL\_MACHINE, HKCU in place of HKEY\_CURRENT\_USER, HKCR in place of HKEY\_CLASSES\_ROOT, and HKCC in place of HKEY\_CURRENT\_CONFIGURATION.

A complete Registry backup to a directory named C:\RB would, then, require several lines:

```
Reg save HKCR c:\rb\hkcr
Reg save HKCC\Software c:\rb\hkccsoft
Reg save hkcc\system c:\rb\hkccsys
```

And so on. You'd restore the Registry with REG as well.

No one *wants* to play around in the Registry, but in real life, most network administrators will find a bit of Registry spelunking to be the only answer to many problems. Knowing how the Registry is organized and what tools are available to modify it will prove valuable to all Server repair folks.

## Chapter 5

# Setting Up and Rolling Out Windows Server 2003

EVERY NEW VERSION OF Windows or its big brother, NT, is a mixed blessing. We usually get more capabilities, but also more complexity. Now, you'd think that a more complex operating system would be more complex to set up, but here's a case where Microsoft has done a pretty decent job, as their setup routines get better and better with each OS version.

If you've ever set up an NT 4 system, then you're probably used to struggling with Setup to get it to accept third-party hardware drivers, but Plug and Play—which first appeared in Windows 2000 in the NT family and Server 2003 still has—largely solves that problem. Older NT required us to decide whether a computer would be a domain controller at setup time, but as with Windows 2000, all servers are born equal—you don't have to decide which will be domain controllers until after the servers are deployed.

Even better, Server 2003 comes with a variety of tools to assist you in rolling out servers unattended. You can script an install, as before, but scripts are easier. If you choose to use a disk-cloning routine like Ghost or Drive Image, Server 2003 includes an updated version of Sysprep, the utility that solves the duplicate SID problem that made many people chary of using cloners. And Server 2003 also includes my personal favorite rollout routine, the Remote Installation Service. Even if you're not interested in scripting, cloning, or RIS, you'll still like Server 2003's Setup routine for its simplicity.

The hard part comes when you want not only a stable, reliable installation, but also a *repeatable process*. This repeatable process will allow one-stop shopping for all of your installation needs and give you that clean and efficient install every time. However, to produce those perfect results time and time again, the planning and preparation phase of the install becomes even more important. Failure to properly plan out an install will most certainly result in a reinstall.

Throughout this chapter, I'll cover key fundamental planning steps, help you prepare your system for Server 2003, run through an install, and, finally, troubleshoot the mess we got ourselves into.

## Planning and Preparation

As it's gotten on in years, NT has become more complex; putting an NT 3.1 system side by side with a Windows Server 2003 reveals that the OS's complexity has probably grown by more than a factor of ten. Complexity means options and options require planning.

Well, I guess that's not right—options don't really require planning. So long as, that is, you don't mind frequently reinstalling the operating system...

Server 2003's Setup is indeed better designed than earlier Setups, but it'll still go far more smoothly with a bit of planning. So stay with me in this section and I promise you'll end up saving time overall.

## System Hardware Requirements

Once again, Microsoft has upped the ante on system requirements. Let's see what you'll need, minimum, to build a system with decent performance.

### CPU NEEDS

While you *can* get Server 2003 running on something as slow as a 266MHz system, I strongly recommend at least a 1GHz system. Of course, 2GHz would be better, as would multiple processors. But one gig will do, provided you have lots of RAM. Which brings me to...

### RAM REQUIREMENTS

We tend to think of CPUs as determining a system's speed, but as has always been the case for the NT family, having enough RAM to give the OS a lot of elbow room is every bit as important in ensuring snappy performance in a server.

But how much memory should you have? That's a tough question because it depends on what you want to *do* with the server: a simple file and print server might run just fine with 256MB of RAM, where a system running SQL Server, Exchange, IIS, and the like probably needs at least a couple of gigabytes of RAM to run well. But even though it's impossible for me to tell you *a priori* how much RAM you'll need, let me offer this advice: put at least a gigabyte of RAM on *any* Windows Server 2003 that you build, more if you can. If you turn your server on and the lights don't dim, then you haven't put enough RAM in the system! (Just kidding...)

More memory means more places for the memory hardware to fail, however, and that's why you need error-correcting code or ECC memory. You may recall something called *parity*, a set of circuits attached to memory systems of PCs in the '80s whose job was to monitor the memory and detect data loss in a PC's RAM. Such data loss could be caused by a bad memory chip, and you can find bad chips by testing your RAM with a good RAM tester program like CheckIt or QAPLus before deploying the server. But even perfect RAM chips can fall prey to random events that cause data loss; static electricity, power surges, and, believe it or not, infrequent extremely low-level radioactivity from the memory chips *themselves* can damage memory data. (Don't worry, you won't get cancer or mutations from your memory chips. Many, many everyday things in our world are mildly radioactive: the bricks cladding your house and, indeed, most kinds of ceramic produce an extremely small amount of radioactivity. Memory chips produce a radioactive particle once in a great while, and when they do, that particle may happen to cross paths with a location in memory—and when *that* happens, the memory bit may be flipped from a 0 to a 1 or vice versa.)

In any case, parity was kind of frustrating in that it could detect that *something* was wrong, but it didn't know *what* was wrong. PCs with parity memory were usually designed to simply shut down the PC when a memory error was detected using the parity method (which the error message would usually incorrectly call "a parity error" rather than a "memory error"—after all, if parity detected the memory error, then parity was working fine!), and shutting down an entire system just because parity discovered one damaged bit is a trifle extreme.

In contrast, most modern Pentium II-and-later-based systems (which, again, include the Xeon, Celeron, and of course the Pentium III and 4) can go a step further and implement ECC. ECC is cool because it not only *detects* memory errors, it *corrects* them automatically. So when that stray alpha particle or (more likely) power glitch scrambles a bit, ECC finds that problem and fixes it without ever bothering you.

Now you may be wondering, “How much would such a wonderful feature cost?” Well, back in the old days, I worked on minicomputer systems with ECC that cost thousands of dollars. But most Pentium II-based systems can do it for about \$20 per 128MB of RAM. Here’s the trick: most PC memories these days are implemented as synchronous dynamic random access memory, or SDRAM, packages. SDRAMs come in a 64-bit version or a 72-bit version. The difference in price between ECC and non-ECC RAM is small—about \$25 on a gigabyte of RAM, when last I checked. That’s a pretty good price for a “data insurance policy.”

**TIP** *Recently I’ve noticed that people selling RAM don’t label it as “64-bit” or “72-bit”; rather, they’ve taken to calling all memory modules “64-bit” and then adding the phrase “w/ECC” or the like. If you’re in doubt about what you’re buying, insist that a phrase like “with enabled ECC memory” or something similar be in the invoice. And yes, you have to insist on that. I flatly cannot understand why anyone sells any PC system nowadays without ECC, but the majority of systems are still without the benefit of ECC.*

You may have to go into your system’s setup BIOS in order to turn on the ECC feature. Not all systems activate ECC by default.

## STORAGE REQUIREMENTS

A basic bare-bones installation of Windows Server 2003, Standard Edition chews up about 1.5GB of space on a hard disk. Of course, you’ll want to put things on the disk other than the OS, so you’ll need more than that—how much more is up to you based on what you want to do with the server. But if you’re just planning on building a system to play around with to get to know the OS better, I found a 4GB C: drive to be about the right size.

Server 2003 brings some terrific news about inexpensive EIDE drives in that they are now treated *asynchronously*. Here’s what that means in English: throughout computing history, it’s often made better sense to buy a bunch of smaller drives instead of one large drive. That’s because each hard disk has its own independent set of read/write heads. More than one drive means more than one set of read/write heads, which means that it’s easier for the computer software to do more than one thing at a time. For example, you could often speed up an NT server by spreading its paging file across several separate physical hard disks.

Unfortunately, that advice only worked with SCSI drives. The driver for EIDE drives, atapi.sys, couldn’t “juggle”—if you told it to simultaneously work with two or more EIDE drives, it would instead just alternate between the drives. Whatever software you were running would *work* fine; it would just run more slowly than it would if the EIDE driver *could* juggle.

With Server 2003, that changes, and the atapi.sys driver is more facile. EIDE drives *can* run simultaneously, so long as they are on different EIDE channels. That’s not to say that I don’t recommend SCSI drives for servers—they’re almost always a better answer than EIDE—but for those on a severe budget, EIDE drives now look like an okay idea, where in earlier versions of Server, EIDE drives were a terrible idea.

A bootable CD-ROM drive, although not required, is always highly recommended. A time always comes when your server crashes and you need a reinstall fast. Rather than scrambling for boot disks to get you connected to your installation source on the network, you simply pop the CD in and off you go.

A network-bootable system—one that supports the Preboot Execution Environment (PXE) standard, version 0.99C or later—would be a real plus. This lets you set up a computer to boot from the network. You'll like having this feature because it makes installing Server (or XP, for that matter) from a central RIS server *much* easier.

All of your hardware requirements can be further summed up by referencing the *Hardware Compatibility List (HCL)*. Every piece of hardware in your system should be on the list. Anything not on the list could generate problems from application failures to system crashes and probably won't even install at all. Why? Most likely, if your hardware is not on the list, you will have a hard time locating a driver. Should you happen to have an OEM driver that came with the hardware, you are risking system instability because Microsoft hasn't tested or guaranteed it to work. Why do you care? Because if you get on the phone to Microsoft and give them the requisite \$245 in order to get them to help you with a problem, and *then* you tell them that you've got hardware that's not on the HCL, the Microsoft support person gets to say, "Golly, I'm sorry, your stuff isn't on the HCL, that's the problem," and hang up. Result: a free quarter kilobuck for Bill and no solution for you. If you trust the manufacturer of the hardware who provided the driver to have fully tested it with all aspects of Server 2003, fine. Be cautious, though. The best recommendation is that if you are buying new hardware, consult the list first. You can find the HCL on your Server CD (\Support\HCL.txt) or on the Web at <ftp://ftp.microsoft.com/services/whql/HCL/>.

## Preparing the Hardware

Once you have your hardware, I strongly recommend that you get it working and compatible first. Throughout the process, Setup will examine, activate, reexamine, configure, poke, and prod at every piece of hardware in your system that it can find. This is where the Plug-and-Play intricacies come in. If everything in your system is true Plug and Play, this process should go off without a hitch. Mix in a few older devices that don't fit this bill and you could get some serious problems, including complete setup failure.

In this section, we'll do whatever we can to avoid these problems before we even launch Setup.

## Preparing the BIOS

Most machines have highly configurable BIOSes, which can really play an important role in how Server 2003 operates. For the pre-Setup phase, you can look for obvious settings that may interfere with your installation. Your boot device order may need customizing to allow you to boot to the CD. This, I find, is one of the most convenient ways to do an install. But then again, if you weren't expecting the CD to be bootable, you could inadvertently keep rebooting into the initial install phase from the CD over and over again, thinking you were getting the hard drive. Nothing major, but it has happened to the best of us.

The most important parts of the BIOS you'll prepare are Plug-and-Play configuration and interrupt reservations. Because most systems capable of running Server 2003 are fairly modern by default, this step is a little bit easier. The problem comes when you try to add older, non-Plug-and-Play components into your Plug-and-Play system. For example, you may have a non-Plug-and-Play device

that is an old ISA network adapter, hard-coded for interrupt 10. When your Plug-and-Play devices come online, let's say that you may have one that prefers to initialize on interrupt 10, not knowing that your ISA card will soon request the same. As soon as the driver initializes the ISA card, there's conflict.

The best thing to do is to configure interrupt 10 under your Plug-and-Play BIOS settings to be reserved for a non-Plug-and-Play card. This tells any Plug-and-Play device to leave that interrupt alone. But now you have the problem of determining *what* those interrupts are *before* you start the install. Your non-Plug-and-Play device may have a configuration disk that programs it for specific settings. There may be jumpers on the hardware. Most troublesome, there may be no obvious clue as to what it is set for. In this case, a DOS-level hardware analyzer may be required to identify those resources being used.

**TIP** *Actually, let me rephrase that last topic sentence. The best thing to do is to only buy Plug-and-Play-compatible hardware for your server. Period.*

Once you have identified and recorded all required hardware information, return to your BIOS configuration. You may have a Plug-and-Play configuration screen that lets you define whether certain interrupts are available for general use—including being allocated by Plug-and-Play boards—or whether they should be reserved for ISA boards. Since non-Plug-and-Play boards are generally not BIOS-aware, they will continue to use the interrupt that has been reserved, but note that when your Plug-and-Play boards initialize, they will be denied the resource usage as defined by the BIOS.

In most cases, the procedure of reserving resources through the BIOS will allow all hardware to work in harmony. If not, you may find it necessary to remove all nonessential, non-Plug-and-Play devices from your system before you begin. Then, once you have a successful install, add your hardware. Again, though, let me stress: if all of your hardware is Plug-and-Play, then you will probably have no trouble at all—so avoid that old non-PnP stuff as much as possible!

## Partitioning

In my opinion, planning the partitioning scheme seems to be one of the most overlooked portions of the installation process. Although Server 2003 gives you some more advanced features for managing your partitions after the install, what you decide on prior to the install will most likely stick with you throughout the life of your server.

Knowing what type of server you are building plays a tremendously big part in the planning process. Let's go back to our simple member server that serves out several shared directories and a few print queues. You may find it more convenient in the long run to keep your data on one partition and the system on another. In that case, you only need enough space for the OS, with a little breathing room—my suggestion is a 4GB partition minimum for the OS.

If you are intending to use the Remote Installation Services, then be sure to set aside a *big* partition solely for its use. RIS cannot store system images on either the system partition (the partition that the system boots from, usually C:) or the boot partition (the one containing \windows). (And yes, the definition of “boot” and “system” partitions *is* completely backward, but then remember that this is an operating system where you click Start to stop it.)

At this point, as both drive space *and* drives are cheap, I tend to buy more than one disk drive even for the smallest systems. Even my low-end EIDE-using servers have at least two hard disks—a 20GB drive that I make C: and put programs on, and a much larger other drive (120GB minimum) for data. And please note that I wrote that sentence in late 2002, so if you're reading this in 2004, when the smallest hard disk you can buy will be 300GB, keep the time context in mind!

## Filesystems

How to format your drives—NTFS, FAT, or FAT32? Nowadays, it's a slam-dunk: NTFS. It's secure, resilient, and fast. Yes, people tell me now and then that FAT32 is faster for large sequential reads and writes as proven by some benchmark, but I suspect that benchmark was done a long time ago in the days of slow drives, slow processors, and little RAM; I simply cannot create a scenario where FAT32 mops the floor with NTFS. In the absence of a strong performance difference, I can't imagine why anyone would use anything but NTFS on a Server 2003 server.

The most compelling argument in favor of a FAT C: drive on NT 4 for me was recovery. If I made C: a FAT drive and something went wrong, then I could boot a DOS/Windows 9x bootable floppy and fix things—DOS can't read NTFS drives. But versions of NT from Windows 2000 on include something called the Recovery Console, which is basically a DOS for NTFS repair tool—you'll learn more about it in Chapter 19.

**NOTE** *Speaking of that, you'll sometimes hear people say that NTFS-formatted drives are the way to go (which I agree with) because they're entirely secure (which I don't agree with). The reasoning is that an NTFS drive supposedly can't be read by booting up a DOS diskette, so someone sitting down at your server can't just boot a DOS floppy and see your files. As nice as it sounds, this is a bogus argument because there are several approaches to reading NTFS drives when booted from a floppy running either DOS or Linux. The point is that if you let someone physically sit down at your server and boot a floppy, then you've got a serious security problem. No operating system can protect a server from a physical attack. I mean, it doesn't matter how good your passwords are: if I want to damage your network and can get to your server, then I don't need passwords to drop the server out of an eighth-story window.*

One final point about file systems: if you *do* create a server on a FAT drive, you always have the option to convert the file system to NTFS later; just open up a command line and type **convert /fs:ntfs**. There is *not*, by the way, an option to convert back to FAT, so don't make the change to NTFS unless you're sure that it's the way that you want to go!

## Server Name

This seems like a no-brainer, but it's a good idea to plan your naming convention. There are two ways that most people make living with server names difficult. The first is underestimating the importance of server names. The second is overdoing it when it comes to a standard convention.

By underestimating naming conventions, you end up with server names like GEORGE, ELROY, JUDY, and ASTRO on your network. This is fine for a small office LAN that will never grow too far beyond your ability to remember these names. When you start getting more than those few servers, it gets difficult to remember who is what.

Sometimes people overdo standard conventions by defining so many formats, items, and indexes into the name that it becomes just as confusing. Some of the things people put in a name is the server's geographic location, building location, room number, role, and an index. For example, a server in Annapolis residing in the Commerce Center building that is an Exchange server might be named ANNCCBEXC01. This information is fine, but keep it to useful information that resembles the important features in your network. Does your network and its users really care what building the server is in? What about the city? What if you add another Exchange server in the courthouse? That would be named ANNCRTEXC01. Perhaps a better method here would be to put the EXC first. Simplicity is key. You may want to define your network into systems and that's it. If you had two

Exchange systems, one for the Commerce Department and one for the Treasury Department, you may want COMMAIL01 and TREMAIL01. This may allow a better grouping of servers.

The bottom line here is to really think about it. Get the customers and the people who will manage the network involved. Get a consensus on what is important and what is not important. Although you can easily change the name of the server later, you can't easily change the hundreds or thousands of users' workstations that connect to it.

**NOTE** *Here's an interesting improvement: in earlier versions of NT it was a fairly bad idea to name workstations and user accounts the same—putting Joe on a machine named Joe led to the domain containing two accounts named JOE, both a user account and a machine account. That gave NT a bit of heartburn. But ever since Windows 2000, NT solves that problem by assigning machines account names ending in \$, so Joe's workstation's account wouldn't be JOE, it'd be JOE\$. You do not see this \$ in most domain tools, but it's there.*

## Network Connection and Options

Not knowing your network configuration ahead of time isn't usually going to be a showstopper. Knowing it can save you time though.

### PROTOCOLS

Ever since NT 3.5, Microsoft has been trying to chivvy us into abandoning NetBEUI and making our networks 100 percent TCP/IP. Don't get me wrong, I think it's a great idea, but they've had to move slowly because lots of networks used NetBEUI, *and* because Windows 95 clients never ran very well with *just* TCP/IP—a few things like Network Neighborhood ran better with NetBEUI than with TCP/IP on 95.

With Server 2003, Microsoft takes things a step or two further.

First, as with Windows 2000, the only protocol that Server 2003 installs by default is TCP/IP. But Server 2003 is new in that it doesn't even offer NetBEUI as a protocol option, offering only IPX and AppleTalk as TCP/IP alternatives. NetBEUI *is* available on the Server 2003 CD in the \VALUEADD\MSFT\NET\NETBEUI folder, but you've got to do a bit of looking to find it! So if your network still has a bit of residual NetBEUI, now's the time to do a little spring cleaning and go TCP/IP all the way.

Setting up TCP/IP requires knowing a few things about your system—what its IP address, subnet mask, default gateway, and preferred DNS server will be, for starters, or will you instead use DHCP? (If you're not clear on what those things are, take a look at Chapters 6 and 7.) Find out this protocol info ahead of time—those network gurus are never around when you need them in mid-install.

### DOMAIN MEMBERSHIP

Almost every server will be a member of a domain rather than a workgroup, and in early versions of Windows NT you had to make some serious you'd-better-get-this-right-the-first-time-there's-no-going-back decisions at Setup time. Ever since Windows 2000, however, there's a bit less pressure. In the pre-2000 days, you had to decide at Setup time whether a system was a domain controller or just a member server. With 2000 and later versions of Server, you needn't answer that question now; instead, all systems come out of Setup as member servers and you can decide to change any of them to domain controllers later with a program called DCPROMO, which you'll meet in Chapter 8.

You can, however, join an existing domain from Setup. If you want to do that, you will need to have a computer account created in the domain. A computer account is almost identical to a user account, and like a user account, it resides in the accounts database held with the domain controllers.

If the server is a member of a domain, it can assign rights and permissions to users belonging to its member domain or any of its trusted domains. This is important to your users. They should log in once to the network and never have to be asked for a password again. If the server resides in a workgroup, then the ability to give rights to domain users is out of the question, causing multiple login points.

### UPGRADING DOMAIN CONTROLLERS

Speaking of domain membership, here's an important note about domain *controllers*. If you are thinking of upgrading an NT 4 box that is acting as a domain controller, then I urge you to think once and twice before upgrading. You can cavalierly upgrade just about any other computer, but the domain controllers need some planning, or you'll be very, very sorry!

You see, upgrading an NT 4 domain controller has an important side effect: it upgrades your NT 4 domain to an Active Directory—the Windows 2000 Server and Server 2003 name for a domain. Server 2003's Setup doesn't allow you to upgrade any of your backup domain controllers until you've upgraded the *primary* domain controller. So you might want to think twice before simply upgrading your existing DCs. Personally, I prefer a domain upgrade technique called “clean and pristine,” and I'll discuss it in Chapter 8, the Active Directory chapter. You might want to read up to that chapter before doing any NT-to-Server 2003 surgery on your domain controllers. Basically, however, I advocate building a brand-new, empty Active Directory domain built atop either Windows 2000 Server or Server 2003 systems, then moving the user accounts over to that domain, leaving your old NT 4 domains in place “just in case” as you migrate. For small domains, however—say, 500 users or fewer—you may not have to do that much work, and an in-place upgrade to Active Directory may be an acceptable option. More on that in Chapter 8.

### NETWORKING COMPONENTS

These are the additional services to be installed, like Internet Information Services and DNS Server. This is where I like to say things like “Ooh... Quality of Service Admission Control Protocol... sounds neat, gimme that.” That's exactly what we shouldn't say. Don't overdo it here. Every option selected installs another service or utility that will consume more resources on your server, and more software in your system means more places where bugs could lurk—and *that* means more potential places for viruses to attack. Keep those servers as lean and mean as you can by minimizing the amount of software running on them!

Also be aware of the effect certain services may have on the rest of your network. Some services will require clients to be connected explicitly to a given server. On the other hand, some, like DHCP Server, act on a broadcast level and can affect clients just by being present. In addition, most services, also just by being present, have an adverse effect on available system resources. Hard-disk space is consumed for additional files, memory is taken up by loading more programs, and processor cycles are consumed by running excessive services that really don't have anything to do with what your server is intended to do. Unless you will specifically be using the service on this particular server, don't install these additional components.

### SERVER LICENSING

Licensing options remain pretty much the same as they have since NT 3.51. You are given per-seat or per-server licensing modes:

- ◆ Per-seat licensing requires that every client on the network that accesses your server has its own license. This is the easiest method of adding up your licensing, because you only

account for how many clients you have; you don't need to worry about either concurrent connections from those clients into a single server or to how many servers each client holds a connection.

- ◆ Per-server licensing differs in that each client-to-server connection requires a license. If a client connects to 25 different servers, that client will take up 1 license on each server, totaling 25 licenses. You may know this as a “concurrent use license.” It's simpler because it's easy to track—once that 26th person tries to attach, he's just denied the connection—but it's usually more expensive because you then have to buy a bunch of licenses for *each* server.

Which way to go? Well, the short answer is: Per-seat is almost always the right technique. But if you want more details...

**WARNING** *Let me stress that licensing is not so much a technological issue as it is a legal issue. I'm not a lawyer and therefore not qualified to be your sole advisor about software licensing. The following is just my layman's understanding of a legal issue. Do not make all of your licensing decisions based on information in this book. Microsoft's licensing is so complex that you can ask the same licensing question of four people and get five answers. So the best you can do is to equip yourself with the facts and then go buy the licenses from some firm that sells Microsoft stuff.*

Per-seat is usually the cheapest licensing method if you have more than one server. Under per-seat licensing, you buy a client access license, or CAL, for every *computer* that will attach to your enterprise's servers. Again, that's *computer*, not person. So if Joe Manager reads his Exchange mail from the computer on his desktop sometimes, reads it on the road with his laptop sometimes, and once in a while comes in through the firewall from home, then you need to buy *three licenses for Joe Manager*. Surprised? Most people are. On the one hand, it means that if three people share a computer, then those folks only need one CAL. On the other hand, nowadays everyone has one *or more* computers, so CALs start to add up. By the way, CALs list for around \$40, although you can buy them in bulk more cheaply and large organizations usually have some kind of an unlimited-client deal. But you don't want to run afoul of the software watchdogs, so if you go with per-seat licensing, then be darn sure that you've got every computer covered! (And, sadly, that may mean that you have to disallow employees from checking their e-mail or using other corporate resources from their home, unless they're using a company-issued laptop.)

Per-server licensing is simpler. You tell a server that you've purchased some number of CALs. The server's Licensing Service (a built-in part of Windows Server 2003) then keeps track of how many people are connected to the server at any moment. If you have *X* licenses and the *X*+1st person tries to attach to the server, that person is denied access.

This sounds simple, but the problem is that you've got to buy a CAL for each connection for each server. For example, suppose you have 4 servers, 25 employees, and 40 workstation PCs—there are more PCs than employees because of laptops and “general access” PCs. Suppose your goal is that all 25 employees can access any and all servers at any time.

Under per-server licensing, you'd have to buy 25 CALs for *each* server, or 100 CALs total.

Under per-seat licensing, you'd license each of the machines—all 40 of them—with a CAL. That one CAL would enable someone sitting at a machine to access any and all of the servers, no matter how many domains your system contains. Thus, in this case, 40 CALs would do the trick. In general, you'll find that per-seat is the cheaper way to go, but again, be careful about remembering to license all of the laptops and (possibly) home PCs.

Most likely, especially in larger environments, the licensing has already been worked out ahead of time. Prior to starting your first install, make sure that your licensing is best suited not just for your network, but also for the way your clients use the network.

**NOTE** *Note, however, that if you already have Windows 2000 Server CALs, then you need not purchase upgraded CALs—2000 Server CALs are fine for Server 2003-based networks.*

### UPGRADE OR FRESH INSTALL?

Finally, you need to decide whether you will be upgrading an existing operating system or performing a clean install.

This can be a real toughie. On the one hand, if you’ve got a server that’s already running a bunch of services, and each one took quite some time to get just so, then running Setup as an upgrade is pretty attractive. On the other hand, if you’re upgrading a system that will be working for some time to come, then it’s awfully appealing to use the fact that you’re changing the operating system as an excuse to also clean house, starting from ground zero and building a nice new system uncluttered by who-knows-what old data or programs that are just hanging around.

Personally, I do a clean install whenever possible. But the key words there are “whenever possible.” If I really have about two hours to get an install done before the server’s got to be up and ready in a production environment, then an upgrade’s the way to go. But if I have a bit more time, I go with a clean install. Cleanly installed systems take time to tweak to whatever standards you’re using in your organization.

Furthermore, I’ve had, well, spotty results from upgrades. In my experience upgrading from NT 3.1 to 3.5 (I lost my printer shares), 3.5 to 3.51 (some domain controllers simply refused to work), and 3.51 to 4 (several miscellaneous problems), I’ve run into problems. Having said that, I should in all honesty say that pretty much all of my NT 4-to-2000 upgrades were pretty smooth, so perhaps Microsoft has gotten the hang of upgrades. If you *do* upgrade, however, be sure to defragment your disk when you get done, and use the free `pagedfrg.exe` utility from [www.sysinternals.com](http://www.sysinternals.com)—it defrags your pagefile, a large and important file on your system.

If you’ve decided on a clean install, there isn’t much more you need to do. If you’re running an upgrade, there are still a few considerations. The last thing you want to do is upgrade a cluttered system and carry over any issues that belong to the clutter. Many people sit in front of the server so much that they install their mail client, office suite, and other programs and utilities that are not related to what the server is supposed to be doing. These should all be uninstalled before running an upgrade. Look at your services on the server. Any third-party services, such as antivirus, Web publishing, disk defragmenting, or other types of software, should also be removed prior to beginning an upgrade. By doing so, there is much less to get in the way of your upgrade.

## Setting Up and Installing

Now that we have analyzed the life out of planning for an install, let’s get to it. Setup runs in three stages. First, the Preinstall Setup Wizard runs; you’ll only see this if you’re installing Server 2003 from inside NT 4 or Windows 2000 Server—that is, if you’ve popped the Server 2003 install CD into a system already running NT 4 or Win2K. This process defines those options that configure *how* to do the install. The second stage is the text-based setup, which simply defines where to install. Finally, the

graphical-based setup stage, also called a setup wizard, customizes everything from installed protocols and services to computer name and domain membership to the system time and date. After this final stage is complete, your server should be ready for final cleanup.

## Preinstallation: Phase 1

You install Windows Server 2003 from a set of files on your installation CD, the files in the **I386** directory. As with all installations, though, there's the very important question, "How do I make my computer able to see, copy, and execute these files?" The size of **I386** means that you can't put the whole operating system on a floppy. (Those days are *waaaaay* gone forever.) Instead, you'll have to deliver the files to your computer in one of several ways:

- ◆ Put **I386** on a bootable CD-ROM disc. This is how it ships from Microsoft. It's easy to just boot the CD and follow the prompts, *but* this method won't work for every system because some systems lack CDs, and some older systems *have* CD drives but cannot boot from them. Thankfully, this is not a very common problem, but it *does* pop up now and then.
- ◆ Put **I386** on a shared volume on the network. This works, but you then have to somehow get the computer booted up enough to access network shares. We'll talk more about this later.
- ◆ Set up a Remote Installation Services (RIS) server and set up your computer to boot to the RIS server with a Preboot eXecution (PXE) client. I'll cover that in the later section on RIS.
- ◆ Set up a simpler operating system (DOS or Windows 98 without the GUI, for example) on the computer, copy **I386** to the computer's local hard disk, and start Setup from inside the simpler operating system. You'll see how to do this when we discuss the **winnt.exe** and **winnt32.exe** commands.

NT and 2000 veterans may be waiting for me to list the last option: start from boot floppies. For systems that had CD-ROM drives but could not boot from them, NT and 2000 could generate four floppies that could "wake the computer up" enough to read the CD-ROM drive and commence Setup. That's no longer available under Server 2003.

From MS-DOS, Windows 3.1, or Windows for Workgroups 3.11, you will need to start your setup in the DOS-based mode found with **winnt.exe**. Or, from Windows 9x, you can start in Safe Mode Command Prompt and run **winnt.exe** after issuing the **LOCK** command.

From a Windows 9x system, or earlier versions of NT, you'll launch the installation from the **winnt32.exe**. This GUI version of the setup executable gives you that user-friendly, yes-or-no click method of initiating the install. For this example, I'm using the drive letter F: as the CD source on an Intel-based system. To follow along, select Start/Run and enter the following:

**F:\I386\winnt32.exe**

## WHEN UPGRADING

If you have a system that can be upgraded to Server 2003, you will immediately reach the prompt to decide whether to run a clean install or an upgrade. If you do not have an upgrade-capable machine, you will be informed that an upgrade is not available, and the upgrade option will be grayed out.

**NOTE** Only Windows NT 4 and Windows 2000 servers can be upgraded to Windows Server 2003.

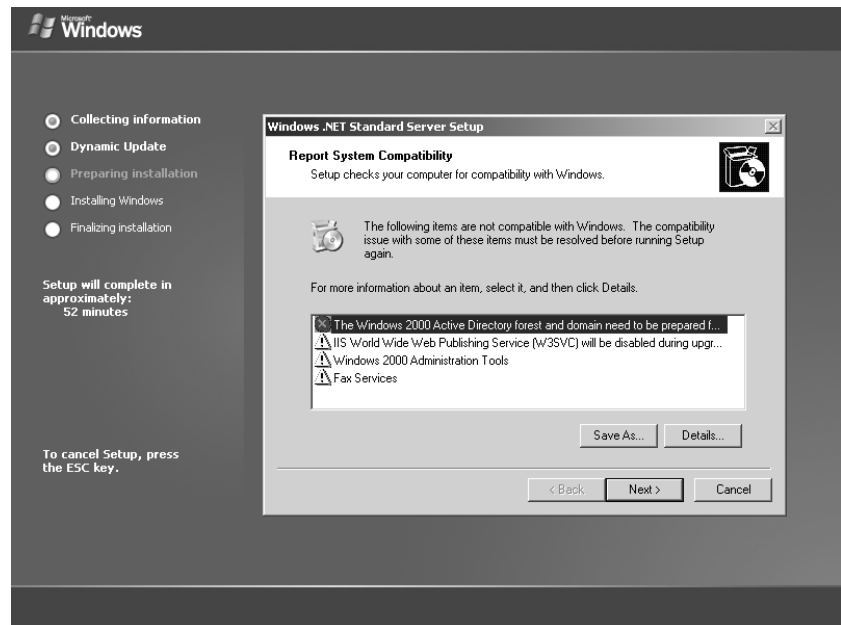

If running an upgrade, you'll see an overall list of things that Setup will do, as well as a Welcome to Windows Setup opening wizard screen where you first choose whether to do an upgrade or not. You'll then see the License Agreement screen, where you click I Accept This Agreement. But *do* take a minute to read it—most people don't realize that in agreeing you assent to becoming an organ donor if Bill Gates needs a transplant. Okay, I'm kidding, but seriously you really *should* read this End User License Agreement or EULA (pronounced "yoola") and every other one that you agree to...some of them are pretty scary!

Following the license agreement, Setup will ask for the 25-character product key, presuming that you have a version of Server 2003 that requires that. Larger organizations will have CD-ROMS with the niftier corporate version of Setup, which does not require a product key.

Next you'll see something new to Server's Setup program: Get Updated Setup Files. (New to Server, but XP's done it since 2001.) The idea here—which is an great one, in my opinion—is that Microsoft realizes that over time bugs and security holes appear; in fact, it's downright scary to install Windows 2000 on a system that's attached to the Internet, as some IIS worms will actually find it and infect it before you're even finished installing the silly thing! The updated Setup files (or Dynamic Update, as it's called) let you pull down installation files that are newer than the ones on your CD, files that would be prepatched against the worm du jour. Now, of course, those files can be pretty large; as I write this there aren't really any downloadable Setup files to speak of, but I'm sure in time you'll need to download a few hundred megabytes of updated files. That's why you'll like that you can collect the dynamic update files to a share on your network and then tell Setup to use those files from a local share, rather than making you do a day-long download every time you install Server 2003. I'll cover more on dynamic updates later in this chapter.

Once you've told Setup whether or not to use dynamic updates, it goes out and checks for any particular items that might cause trouble with the installation. That'll look something like Figure 5.1.

**FIGURE 5.1**  
Setup troubles

You'll likely get at least a few warnings; *read them*, and if they're no problem just click past them to continue Setup. If you have a real showstopper, as in my figure, then Setup will just stop.

Let me say again: read those warnings and errors! Microsoft does a pretty good job of explaining what they mean and how to address them. For example, note the IIS one—believe it or not, Setup *disables* IIS unless you've run their IIS Lockdown Tool, something that I personally don't care for, or unless you make a Registry change. While an automatic Next is often the answer for wizards, it's not in this case. Imagine running what seems to be a simple upgrade on your Web server, only to find that the Web server doesn't work anymore!

Once you've gotten past the warnings, assuming that you have any, then the system doesn't ask you much else—upgrades don't require a lot of interaction.

### WHEN INSTALLING FRESH

If, on the other hand, you started Setup from inside NT 4 or Win2K Server, then you will initially see the same things just described in “When Upgrading.” But in a fresh install, unlike an upgrade, Setup will then need a bunch of answers from you.

Following the Product Key page, you get the Windows Setup page. This lets you set the desired language and accessibility settings.

**Copy Installation Files from This Folder** Refers to the place from which you will be installing Windows Server 2003. This is useful if you're installing from a folder where you've precopied all of the I386 files. If you're installing from the CD, then you typically needn't worry about this.

**Copy to This Folder on My Hard Drive** Tells Setup what directory to install Server 2003 to. This defaults to \Windows (note the new directory—no more *winnt*!) but it can be changed to another directory if you want. If you intend to install multiple copies of Server on a system, then use a different directory name. This field won't take the drive letter. Note that if you're upgrading from 2000 or NT, you'll end up with two OSes—one in \winnt and one in \windows. That can pose some problems, so either tell it to put the OS in \winnt so it'll overwrite the old one, or skip starting Setup from inside the old OS and just boot from the CD and wipe the hard disk clean before installing Windows Server 2003.

**Copy All Installation Files from the Setup CD** Creates a complete setup source on one of your local hard drives under the directory \swin\_nt\$.~1s. Under this directory, you will find the I386 source you are so familiar with.

**NOTE** *Most systems won't need the Copy All Installation Files option selected. Server 2003 will do a pretty good job of loading the right drivers to reconnect you to your source after the reboot. However, if you fail to find your source for the text-based setup, this option will get you back on track.*

**I Want to Choose the Install Drive Letter and Partition During Setup** Allows you to define which partition you will be installing Server 2003 in. Select it and you will get a prompt following the reboot to choose your partition.

**Accessibility Options** Those available for Setup include the Narrator and Magnifier. By selecting these options now, the tools will be available during the next installation phase.

After this page in the wizard, Setup asks about dynamic updates, and then copies the installation files to your hard disk. Setup's now ready for the text-based portion of Setup, and it'll prompt you for a reboot.

### ANATOMY OF A MACHINE READY FOR SETUP, PHASE 2

Ever wonder what makes a system continue along its setup path after a reboot? Or have you ever started into the second phase of the setup, had all sorts of problems, and wanted to start from scratch? It will help to know exactly what causes the second phase to start upon reboot so you can easily remove it later. These components are going to be present on your system after completion of the preinstallation phase of the setup:

- ◆ On the boot partition, a directory named `$win_nt$.~bt` has been created.
- ◆ All critical Server 2003 boot files, including enough drivers to access the network or CD source, have been copied to the `$win_nt$.~bt` directory.
- ◆ In the `$win_nt$.~bt` directory, a file named `winnt.sif` contains the information you provided from the first phase of the setup.
- ◆ The Server 2003 boot files have been copied to the boot partition (unless you've overridden them with `awinnt` or `winnt32` option) if not already present. The system is now Server 2003–bootable. (Note that when I say “boot” I mean it in the standard this-is-the-drive-that-the-computer-boots-from meaning, rather than Microsoft's “official” definition—for some reason, they define the partition that contains the bulk of the operating system files as the “boot” partition, and the partition that you boot from as the “system” partition. Don't ask me why.)
- ◆ The `boot.ini` is configured to default to the `$win_nt$.~bt\bootsect.dat` after 5 seconds.

### Text-Based Setup: Phase 2

The text-based portion of Server 2003 Setup is very similar to Windows 2000's text Setup. You get your welcome screen, make a few selections on where you want to do your install, and then you sit back and watch the Setup program copy a whole bunch of files. It's a really simple click-Next-to-continue process, but there are some gotchas hiding in there, so I'll go through it a bit at a time.

**NOTE** *This is the first phase you'll see if you're installing by booting from the CD-ROM.*

As soon as your machine boots into the text-based portion of Setup, you may notice a prompt at the bottom of the screen that tells you to press F6 if you need to install additional SCSI or RAID drivers. If you don't want these additional drivers, just wait a few seconds and it will go away. But if your system has a SCSI or RAID controller that you know isn't going to initialize without an OEM-provided driver, you'll need to watch this part of Setup closely and hit F6.

The install starts off with a Welcome to Setup screen. You have the choice to set up Server 2003, repair an existing Server 2003 installation, or quit. The Press F3 to Quit option will live with you throughout this phase of the setup. If at any time during this phase you decide that you want to abort your setup attempt, this will be your escape route. Upon this exit, your system will be rebooted, but be aware that your `boot.ini` file will not have been changed. Subsequent reboots will still by default cause your machine to restart the setup after 5 seconds at the boot menu. To get rid of this

permanently, edit your `boot.ini` to reflect the default equal to your other operating system boot path of choice. My machine looked like the following:

```
[Boot Loader]
Timeout=5
Default=C:\$win_nt$.~bt\bootsect.dat
[Operating Systems]
multi(0)disk(0)rdisk(0)partition(2)\winnt="Microsoft
↳Windows 2000 Server"/fastdetect
C:\="Microsoft Windows 98"
C:\$win_nt$.~bt\bootsect.dat="Microsoft Windows Server 2003 Setup"
```

To restore my machine to its original boot preferences, I changed the Default line back to my Windows 2000 Server boot selection and deleted the entire Windows Server 2003 Setup option. Consequently, my `boot.ini` looked like this:

```
[Boot Loader]
Timeout=5
Default=multi(0)disk(0)rdisk(0)partition(2)\winnt
[Operating Systems]
multi(0)disk(0)rdisk(0)partition(2)\winnt="Microsoft
↳Windows 2000 Server"/fastdetect
C:\="Microsoft Windows 98"
```

Press Enter, and if you already have some NT-family operating system running on this computer then Setup will ask if you want to repair it. As we're installing fresh, press ESC to continue. That'll take you to the Disk Partitioning and Installation Location Selection screen. Be careful here. There are two things to do. The most obvious is the selection of the partition in which you want Server 2003 installed. Highlight the partition where you would like Server 2003 installed, and press Enter.

Let's take this a step further. Beneath this screen is a very handy disk-partitioning utility. From here, you can completely redo your partitioning scheme. You can delete existing partitions, create new partitions out of unpartitioned space, and format partitions in either the NTFS or FAT format file systems.

**NOTE** You can find more information on disk partitioning in Chapter 10.

Before we begin partitioning our drives, let's go back to the planning session we had earlier. Suppose for the sake of example that we want a 1GB Windows 98 C: partition, a 2GB system partition on drive D:, and a 4GB data partition on drive E:. Just to give us all the necessary scenarios to describe how the setup phase partitions drives, we'll assume we have a current partition scheme of a 1GB C: with Windows 98, a 1GB D:, a 2GB E:, and a 3GB F: partition. To go from a 1-1-2-3 gigabyte partition scheme to a 1-2-4 gigabyte partition scheme, we are forced to delete almost all partitions, since we cannot reorder partitions. In other words, we cannot massage our existing second partition of 1GB into a 2GB partition without giving it more room first.

Let's start by deleting the 1GB D: partition. Use the arrows to highlight the D: partition, and press D to delete. A confirmation screen will appear asking you to now either press L to continue the partition deletion or Escape to abort.

**WARNING** *Always take this opportunity to second-guess yourself. Once you press L to confirm the deletion of the partition, your partition and everything that was on it is gone. Ask yourself what data is on the D: drive. Make sure you can afford to lose it all. Do you have a backup of the data? If it contains a previous Server installation, do you have a backup of the security and accounts databases? If rebuilding a domain controller, have you promoted someone else to PDC? Do you have a recent Emergency Repair Disk available? If you are 100-percent confident that you don't need anything on the partition, press L.*

When you come back to the main Disk Partitioning screen, you'll see that the second partition of 1GB is now marked as unpartitioned space. Of course, it does no good to repartition this space now because the most you'll get is 1GB again. That would defeat the purpose of the exercise. You need 2GB. So move on down the list to what was the 2GB E: partition and delete it in the same fashion. When you return to the main screen again, after confirming the deletion of the 2GB partition, you'll find that the adjacent, unpartitioned spaces have turned into a single block of unpartitioned space equaling 3GB. Just to keep it simple, we now have our 1GB C:, a 3GB unpartitioned space from our combined, deleted 1GB and 2GB partitions, and a remaining 3GB partition.

At this point, we'll go ahead and create our new 2GB D: partition. Highlight the 3GB free space and press C for create. You'll move into a new screen where you're shown the total available space within which you can create a partition and are asked how large a partition you want to make. By default, the maximum available space is filled in: 3GB. We want to drop that down to 2GB. Press Enter and presto! We have a 2GB new (unformatted) partition, followed by our remaining 1GB that we left out and the 3GB data partition.

After we delete our 3GB partition, it will melt into the adjacent 1GB partition, forming a 4GB unpartitioned space. We can create the new 4GB space and we're set with partitioning anyway.

Now we still have to format our partition before we can use it. To format a partition, highlight the space listed as New (Unformatted) and press Enter to select the partition as your Server 2003 installation directory. Really, you're not selecting a partition to format; you're just selecting a partition in which to install Server 2003. If Setup finds that your chosen installation partition is not formatted, you'll get an additional screen to do just that. You are shown options to format FAT or NTFS, and now Server 2003 includes the options to do "quick formats" in each case. Once again, return to our planning phase of the setup. We should already know what format we want. Once the format is complete, we continue onward with the installation.

**TIP** *If you want only to partition and format drives without continuing to do an installation, you can always choose to go backward after the format and select another partition to format or install to, or you can simply exit the installation program.*

Setup will now examine your disks. This examination is not an intensive look into the reliability of your disk. It merely runs a CHKDSK-like utility to verify a clean file and directory structure. After the examination, Setup will copy all Server 2003 installation files to your chosen install location. Finally, the system will ready itself for the graphical setup phase and reboot.

#### CHANGES FROM NT 4'S TEXT-BASED SETUP

If you're used to NT 4 servers and haven't previously done a setup of either 2000 or Server 2003, then you'll notice some things missing from this phase of the Windows 2000 setup compared to the setup for previous versions of Windows NT. You no longer get the options to define the following:

- ◆ Basic PC type

*Continued on next page*

**CHANGES FROM NT 4'S TEXT-BASED SETUP (continued)**

- ◆ Video system
- ◆ Keyboard
- ◆ Country layout for keyboard (defined in phase 1)
- ◆ Mouse

They're not necessary anymore because Server 2003 (and 2000, for that matter) supports Plug and Play.

**Graphical-Based Setup: Phase 3**

As soon as you boot into the graphical-based setup phase of the install, Server 2003 will run a Plug-and-Play detection phase to configure all your hardware. This can take quite a while, and because disk formatting and file copying (both in Phase 2) take some time and Setup reboots itself and moves directly to the PnP detection phase, I just walk away for a half-hour when the system starts formatting. By the time I come back, the format, copy, and PnP detection's done, and I can start answering the wizard's questions.

**PLUG AND PLAY, REGIONAL AND LANGUAGE, AND NAME AND ORGANIZATION SCREENS**

Something you'll really like about Server 2003 and, for that matter, XP and 2000, is that their PnP engine isn't as annoying as Windows 98's—if it can't find a matching driver, Server 2003 doesn't stop in its tracks and say, "Find me a driver or I won't do anything else." Instead, you just see a question mark in Device Manager, and you can go find a driver and give it to Server 2003 at your leisure. As always, though, it's a good idea to check the Hardware Compatibility List (HCL) at [www.microsoft.com/hcl/default.asp](http://www.microsoft.com/hcl/default.asp) for the most up-to-date list.

**TIP** *If you have a device that isn't supported on the HCL or doesn't have a prepackaged device driver on the CD, you can use the `/copysource` or `/copydir` switch to copy an additional directory to be used during the setup. This can make your device drivers available for detection. Look for more details in "Performing Unattended Installs" later in this chapter.*

Did you take my advice and go do something else while Setup formats the disk, copies the files, and runs the PnP detection? (Try something like computing the first prime number with more than a million digits or designing a working faster-than-light starship. You'll have ample time.) Then, when you return, you'll first see the Regional and Language Options screen. Set it as you like and click Next. (What's that you say? "No Setup war stories about this page, Mark?" Okay, I have to sheepishly admit that as an American I live in the land of Defaultia—that is, all of the default language and regional (currency, date format, keyboard configuration) settings are American. So as a Defaultian I don't honestly have much in the way of advice here, sorry.)

Next is the Name and Organization dialog. The name and organization listed here show who the product is registered to; it isn't used for anything related to the computer name or other means of defining the server on the network.

**PRODUCT KEYS AND WINDOWS PRODUCT ACTIVATION**

Click Next and you'll get the Product Key screen, where you'll type in the 25-character product key that came with your system. As I noted in my discussion of upgrades, your copy of Windows

Server 2003 may not require this if you're one of the lucky dogs who work for a big company and get the no-product-key CDs.

If you *do* have to enter a product key, though, then get ready for a *new* Setup irritation, a brand-new Server feature called Windows Product Activation. You may know it from XP, but this is the first time that it's appeared in Server. It's a Microsoft copy protection scheme, and here's how it works.

When you get a copy of Server 2003, you also get a 25-character product key. Server 2003 tells you when you first run it that you must "activate" it. If you don't activate it within some number of days—14 days on the copy that I'm working with, but I've seen different numbers on different copies of XP, so I presume that Server 2003's got different activation limits as well—then it stops running. Activating Server is pretty easy, just a few mouse clicks and you needn't even tell Microsoft anything about yourself. Your server first inventories the hardware on your server and boils that down to a 50-digit number. Your server then goes out over the Internet to a Microsoft database somewhere and says, "Hi, I'm a copy of Server with a product key of [whatever your 25-character product key is]. Have you seen me before?"

If no one has ever activated a copy of Server with this particular product key, then the database server just says, "No, you're fine, I'll remember your hardware configuration," and you're activated.

But what if the database server *does* have a record that says that someone activated a copy of Server with that product key before? Then one of two things are happening, at least in Microsoft's eyes: either you've reinstalled Server 2003 onto the same hardware, and you just need to be reactivated, or someone's trying to put the same copy of Server on two different machines. So the database server looks at the 50-digit hardware description value that it already has for that particular product key. If the hardware description matches or is very close to the one stored in the database, then the database server tells your copy of Server to go ahead and activate (reactivate, actually) itself. But if the hardware description value already in the database is sufficiently different from the one that the wants-to-be-activated server sent to the database server, then the database server sends a "do not activate" message to your computer. And, by the way, every time your computer boots, it computes that hardware description value and compares it to your system's state upon the last boot. Again, if your system's hardware is too different, then it'll force you to reactivate, or at least to try to reactivate.

How different is "different?" Suppose you have to change the hardware in your system—how much can you change it before it refuses to run? The answer is, no one knows but Microsoft, and they're not talking. As XP's been out for a while, people have come up with some heuristics, but here's one hard fact that Microsoft let out: your base hardware value resets every 120 days. Therefore, if you only make one major change every 120 days, then your system will never come to believe that it should be deactivated.

And in case you're wondering, yes, this *is* incredibly annoying. But there are a few workarounds.

First, if you're going to rebuild your system, back up `\windows\system32\wpa.db1`. It's the file that your system uses when it boots to assure itself that you're properly activated, and it also contains the hardware information. It's encrypted with the RC4 algorithm, so apparently it's not anything that you can look at. But if you back up `wpa.db1`, reinstall your operating system, and restore `wpa.db1` to `system32` and reboot, then in my experience it doesn't annoy you about having to reactivate.

Second, if you *did* change a lot of hardware and your system requires you to reactivate, then go ahead and try. If it fails—it probably will—then the activation program gives you a toll-free number

to call Microsoft where Allen Neiman, the Microsoft guy who is the mad scientist behind all this, assured me, “We’ll trust you,” and reset the database so that you can activate. Now, I’ve never had to actually do this (thank God), but from what I’m told, you have to read the 25-character product key as well as the 50-digit hardware description value (the activation program will furnish it) over the phone to a Microsoft employee, who then reads you back a 42-digit number that you will then type into the activation program. Sounds like real fun; I can’t wait until I have to do it.

### **LICENSING, NAMES, AND PASSWORDS**

Once you’ve punched in the product key and clicked Next, the next dialog configures your licensing options, which are the same as previous versions of NT. There is per-seat licensing and per-server licensing. Per-seat usually makes more sense than per-server, but we’ve discussed licensing earlier—enter whatever makes sense for your network.

After you click Next comes the computer name and administrator password definition. Setup offers a bizarre combination of letters and numbers based on your organization name, which you may want to change, unless of course you really want your servers called CX-7352RR35. You’ve also got to set a password to the local administrator’s account. Between the worms, viruses, and legions of disgruntled unemployed IT people who’ve decided to take up a career hacking, you’ve kind of got no choice these days but to put good passwords on your accounts, and the local administrator is no exception. Server 2003 helps you do that by suggesting that you use a “complex” password—six or more characters and a combination of at least three of the following: uppercase, lowercase, numbers, and punctuation. You don’t *have* to use a complex password, but if you don’t, Setup asks if you’re sure.

**WARNING** *And if you’re thinking of being really lazy and setting a blank password, you might not want to—one of Server 2003’s new features is that accounts with blank passwords will not work over the network!*

No matter what password you give the administrator, though, make sure you can remember it. I get tons of letters from people who say that they (1) did not create any other administrative accounts and (2) forgot the administrator’s password. They then hope that I can help them. I can’t. Winternals ([www.winternals.com](http://www.winternals.com)) has a neat program named ERD Commander that can reset the administrator’s password, but when last I checked it cost just under \$400.

I really want to stress how important this is. On a clean install, the administrator account is the only way to log in. Don’t forget this. But *do* pick good passwords. If a hacker’s going to try to crack into your system by guessing a password, then make his work harder by using a complex password. Then be sure to write that Administrator password on a sticky note and put it on the side of your monitor so you won’t forget it. (Just kidding.)

### **KEEPING TIME—TIME ZONES ARE IMPORTANT!**

Next you’ll see the date and time settings. By default, Microsoft figures that everything is in Pacific time, which is, I guess, in keeping with their Redmond-centric way of thinking—perhaps they want to free us from the tyranny of the Green Witch or whatever the name of those GMT guys are. What I’ve always found odd, though, is that Microsoft sometimes uses a city to represent every time zone, and for Pacific, it’s Tijuana. Now, I’ve got nothing against Tijuana, but I could name a few more important cities in the Pacific time zone. Like Fresno.

Seriously, this dialog is important because of Active Directory, assuming that you will be or are using it. In order for AD logons to succeed, workstations and member servers (which have to log on) must have their internal system clocks pretty well synchronized with the system clocks on domain controllers (which do the logging on of people and machines)—in fact if a DC's time is more than five minutes out of sync with another computer's time, then that DC can't log that computer on.

What gets some folks in trouble, then, is that they say, "The heck with the time zone," and just set the clock to the local time. But Active Directory doesn't care about time zones; it does all of its internal work in universal time—all time is in Greenwich (there's that Green Witch again) Mean Time or Zulu time. So suppose a domain controller (call it DC) and a workstation (call it WS) are in New York. It's 9 A.M. The DC's clock is set to 9 A.M., and its time zone is set to Eastern. Meanwhile, the workstation's clock is set to 9 A.M., but its time zone is set to Pacific. Both clocks look like they're at the same time, but they're not. Even though their clocks both show 9 A.M., the DC thinks it's 2 P.M. GMT (Eastern time is five hours behind GMT for most of the year) and the WS thinks it's 5 P.M. GMT. That's three hours' difference between their internal clocks, so the workstation can never successfully authenticate with the DC. So set your time zones properly!

### NETWORKING SETTINGS

After adjusting the time settings, Setup rattles the disk drives for a couple of minutes, announcing that it is "installing the network." The network settings give you two choices: typical and custom. The typical settings assume that you will want the Client for Microsoft Networks, TCP/IP using DHCP addressing, and File and Print Sharing.

By choosing custom settings, you can add, remove, or customize protocols, clients, and services. If you want to assign static IP information, highlight TCP/IP and click Configure. By clicking the Add button, you will be given a choice of Client, Protocol, or Service. You can add more clients, like Client for Novell Networks; more protocols, like AppleTalk, IPV6; or more services.

At the Workgroup or Computer Domain selection page, you can join either a workgroup or domain by selecting the appropriate radio button and typing the workgroup or domain name in the corresponding box. If you join a domain, you must have an account created for your machine name. You can do this two ways.

The first way is to select the Create Computer Account button. After clicking OK to join the domain, you will be asked to enter an administrative account name and password. This account must be one with either Administrator or Account Operator rights. If you're using an account from the domain you are joining, enter the account name and password. If you're using an account from a trusted domain of the one you are joining, type the full domain and account name in the *DOMAIN\USERNAME* format. This will inform the validating domain controller of the location of your account. The account creation will be initiated from the server you are installing.

The second method is to not select Create Computer Account but have one created ahead of time. You may want to employ this method if the person running the install doesn't have the appropriate rights and doesn't want to have to hunt down an administrator when this step comes up. In this scenario, go to Server Manager for the NT 4 domain on which you want to add the server and select Computer/Add to Domain, or go to Active Directory Users and Computers and select New/Computer. Select NT Workstation or Server and type the name of the computer. During the installation of the server, leave the Create Computer Account option unselected, enter the correct domain name, and you should be set.

Because of security concerns, though, the computer account you create will change its password immediately upon a successful joining of the domain. This means that if, for some reason, you redo a clean install of a machine that already has a computer account, you can't have your new install assume that account. You must either delete and re-create the account with the same name, or build the new server with a different name.

## COMPUTER ACCOUNTS

Computer accounts are just like user accounts, and you can see them in the Active Directory Users and Computers tool (which we'll discuss in Chapter 8) or in Server Manager on NT 3.x and 4. If you have enabled auditing of successful account management on the domain, you will see an Account Manager security event #624 logged in the PDC of an NT 4 domain or a similar event on any DC of an AD domain. A 624 event is a "create user account" event. Let's say you create a computer account for a new server named CADDY in the LAB domain. Under the details of the security event, the account name that was created will show as CADDY\$. This CADDY\$ account will be used for all communication between the server and the domain, such as validating user passwords. Once the new server and the PDC "shake hands," the server will initiate a password change for the CADDY\$ account. Every 7 days thereafter, the server will again initiate a password change. The same procedure of account and password maintenance is used between domains for trust relationships.

So why is changing a password such a big deal? Well, the server is going to assign permissions to its resources based on domain user accounts. The server isn't going to blindly trust that anyone who claims to be from the LAB domain is a valid user; it wants to make certain that they are in fact a LAB user from the real LAB domain. By having this unique account with a highly secured password, the server can do just that. If the server asks the LAB domain to validate a user but the LAB domain doesn't recognize the correct CADDY\$ account and password, authentication fails. This makes it nearly impossible to transport a server out of its domain and gain access to its data.

Once you've clicked Next, Setup starts actually, well, setting up. The system will reboot and you've got a working server. The `boot.ini` will now be changed to reflect the new Server 2003 install as the default boot option. There is, however, one more step that can optionally be done here. If you need to run another program, perhaps a setup program for some utility or application, then you can tell Setup to run it automatically, using the `winnt32.exe` command-line parameter `/cmd:command`. (Of course, using this command-line parameter means that you needed to add that `/cmd` option when you started running Setup, so if you've been doing Setup while following along, this advice is a bit late.) This could be used to run a batch file or utility to perform such tasks as transferring user data, installing programs, or other means of further automating your installs. (This is covered in more detail later in this chapter in the section on unattended installs.) The system will now reboot into a full-fledged Server 2003 operating system.

**TIP** But if it doesn't, then try running `WINNT32` with its debug switches, `WINNT32 /debug2`, `/debug3`, or `/debug4`, which offer more information. `Debug3` gives more information than `debug2` and, in case you're wondering, `debug1` is just the default. The log file is in `\windows\winnt32.log`, or you can add a colon and the name of a log file, as in `winnt32 /debug4:whathappenedanyway.log`.

## Postinstallation Procedures

After the installation is complete, there are still a few more steps to perform to finalize the server and prep it for production:

- ◆ On the first reboot, the Manage Your Server page will pop up automatically. It will identify the last few steps that must be completed to configure your server based on the additional network components you installed. It will also ask you some questions about your existing network to help you determine whether you want to install an Active Directory. I personally find the Manage Your Server page unhelpful and tend to just close it, but that's just my opinion—try it if you like. I'll show you how to manage *your* server with as few of those dumb wizards as possible!

**NOTE** See Chapter 8 for more information about Active Directory and when and how to launch the Active Directory Installation Wizard, *DCPROMO*.

- ◆ Check your device manager for undetected or nonfunctioning hardware components. If you removed any hardware prior to the install due to conflicts, add them back in now. Before you are truly done with the install, every piece of hardware should work properly.
- ◆ You'll want to finalize your disk partitions. In many clean install scenarios, you may have unpartitioned space left on your hard drive. Refer to Chapter 10 and take care of these partitions now.
- ◆ For most new installations using TCP/IP, a DHCP address will be in effect. This may not be a standard practice for production servers. If necessary, acquire and configure the appropriate static TCP/IP information. See Chapters 6 and 7 about TCP/IP and related services.
- ◆ In many larger network environments, certain services, utilities, tools, or other programs are loaded on all servers. For example, some sites may utilize enterprise management tools that require the usage of an agent that runs on the server to collect and pass information up to a management console. Most likely, some sort of backup software will need to be installed also. Find out what additional software is needed and install it now.

**TIP** You always want to completely configure a server and install all of its additional components before it goes into production. By production, I mean the point at which the first user connects to the server. Since many additional services, configurations, and software components will require a reboot, you'll want this out of the way up front to avoid further disruptions of your users' work.

- ◆ Run through the Control Panel applets to set all server configurations the way they should be for the long haul. Especially noteworthy are the System Control Panel settings for the pagefile and maximum Registry size.
- ◆ At this point, you may get the urge to walk away. Well, hold on just a minute. Too many times, people make some last-minute changes, like the Control Panel settings, and leave it at that. Even though you were never told to reboot the system—your changes were instantly accepted—there may be some unexpected side effects the next time you reboot. Just in case, give it another reboot now, before your users begin counting on the server being available.

- ◆ If the system is a dual-boot machine, which is usually not the case on a server, boot into all operating systems to make sure the system integrity is intact and all data is available from all required operating systems.
- ◆ Once the system itself is complete, create an automated recovery disk. And as an extra safeguard, you may also want to run a full backup.
- ◆ Finally, a step we rarely perform is documenting the server. Ask yourself if anyone else could take care of the server should you decide to take a week off for a golf vacation. If there are any special things you have to do, like restart a service every day, it should be documented. This is a step you *must* take before you can consider your operating system “installed.” See Chapter 19, which covers preparing for and recovering from server failures, for more details.

At this point, you should have a production-ready server and a method for creating this same server time and time again. It seems like a lot of extra work is required in addition to actually installing Server 2003, but it is well worth the trouble.

## Troubleshooting an Installation

Server 2003 produces a relatively smooth installation. Plug and Play helps in many ways by eliminating the need to know and preconfigure all of your hardware prior to launching an install. There will be a few instances where you will have problems, though.

We discussed failed hardware components earlier. If your system locks up during the hardware detection and configuration phase, you have something that does not play nicely in the sandbox. Sometimes it will be obvious which component is the culprit. Sometimes it won't be so easy. Start with the obvious methods of troubleshooting—the `/debug` setup parameter discussed in the “Command-Line Automation” section later in this chapter. This will definitely help identify where the install goes wrong. The next step is to either resolve or work around the problem.

If you have hardware conflicts causing problems with your install, you have a couple of options. First, you could configure the hardware and BIOS, as was discussed earlier in “Preparing the Hardware,” to get along with the other hardware. Maybe the troublesome hardware is a sound card that refuses to accept the detection phase. Rather than spend  $x$  amount of time trying to get it to work, pull it out of the system. Get the Server software running first. Then add the component later.

Let's say you completely blow an install at some point. You want to start over from scratch, but you don't want to format your partition and lose potential data. There are three things on your hard drive related to the install that you will want to clean up before starting over:

- ◆ The `$win_nt$.~1s` directory if you copied all files to the system
- ◆ The `$win_nt$.~bt` directory
- ◆ A line in your `boot.ini` pointing to `$win_nt$.~bt\bootsect.dat`

Removing these entries will make your system completely forget that an install was ever happening, allowing you to start over at square one. Be careful when modifying the `boot.ini`. If you're reverting to an old operating system, make sure your `boot.ini` default is put back to the way it was. Leaving an entry pointing simply to `C:\` will let your DOS or Windows 9x operating system's files boot the system. Here's a sample `boot.ini` file for a dual-boot Server 2003 and Windows 98 machine:

```
[boot loader]
timeout=30
```

```
default=C:\
[operating systems]
multi(0)disk(0)rdisk(0)partition(2)\windows="Microsoft Windows Server 2003"
C:\="Microsoft Windows 98"
```

The [boot loader] section defines how your boot menu will act. This example shows a time-out of 30 seconds, at which point the default operating system on C:\ will be booted. Once the boot process continues to the C:\, it will require the standard boot files of that operating system. In Windows 98's case, that is the MSDOS.sys and IO.sys. The [operating systems] section defines the selection menu and where the operating system corresponding to each choice resides. Here, Windows 98 resides in C:\, and Server 2003 resides on multi(0)disk(0)rdisk(0)partition(2)\windows. This translates into the \winnt directory of the disk and partition defined by the address of multi(0)disk(0)-rdisk(0)partition(2). (And in case you're wondering, no, I wouldn't put 98 on a disk with Server—this is just an easy-to-follow example.)

**NOTE** See Chapter 10, “Managing Windows Server Storage,” for complete details on how logical drives are defined in Server 2003.

**NOTE** In the unlikely event that you have put both 98 and Server on the same system (perhaps for testing) and you want to get rid of the Server 2003 boot menu altogether and return to your single bootup in Windows 9x, you must delete the boot.ini, NTDetect, and NTLDR from your boot partition. After they are gone, you will need to re-SYS your boot partition to make it fully DOS- or Windows 9x-bootable again. The best way to make sure this will work is to first boot into your DOS or Windows 9x operating system, format a bootable floppy, and copy sys.com to the floppy. Delete the Server 2003 boot files just listed, reboot your system to the floppy, and run a SYS C: command.

## The Recovery Console

Server 2003 has a nifty new Recovery Console that can go miles farther than the old methods of fixing broken installations. Take this scenario—one that I've dealt with numerous times. An important system file gets corrupted...umm, deleted. You know how it goes, “Let's see, NTFS.SYS, I never use NTFS.SYS, let's just delete it to make more space.” The next time you reboot, the system won't come up. Go figure. Now you need to copy a new NTFS.SYS to your hard disk. You make a bootable floppy, put NTFS.SYS on it, reboot to the floppy, and find out that your system partition is NTFS. We all know that you can't boot to a DOS floppy and access an NTFS partition. Enter the Recovery Console.

What is the Recovery Console? It is a scaled-down cross between a DOS command-line environment, certain Server 2003 Setup functions, and partition-correcting utilities, all with the capability to access NTFS partitions.

The first thing you need to do is get into the Recovery Console. There are two ways to do this. First, you can launch the WINNT32 Setup program with the /cmdcons parameter. A brief setup routine and file-copying session will take place to create your console. Once completed, your boot.ini will reflect a new operating system selection, Microsoft Windows Server 2003 Command Console. Simply boot your machine and then select that menu item. Of course, this method would only work if you had the foresight to install the console before the system broke down. If you haven't created it ahead of time, don't worry, you can get there from the normal setup routine.

Launch Setup as you normally would—from the CD, the boot floppies, whatever you prefer. At the Welcome to Setup screen, select the Repair option. From there, you will get the option to repair your installation using either the emergency repair process or the Recovery Console, and off you go.

Once you enter the console, you get a selection of all Server 2003 installations on the system. Enter the number of the installation you want to work on and press Enter.

**NOTE** *When entering the console from Setup, you go straight into the console. When entering the console from your boot menu, you'll need to press F6 at the Press F6 prompt to install SCSI drivers. This will let you access your SCSI hard drives or CD-ROMs that require a driver.*

The next step is validation. One of the major differences between the FAT and NTFS filesystems is security. Even though you can see the NTFS partitions now, you still need to have access to the filesystem. The console will ask you to enter the Administrator password. After you enter the password, you are dropped at a command prompt in the `systemroot` directory of the installation you chose. Simple!

Well, now what? You're at this command prompt. What do you do with a command-prompt-only version of Server 2003? Start off with a `HELP` command, which shows you a list of all available commands. You can do things like copy files, change directories, format drives, and other typical DOS-like file operations. To resolve the current problem, you just copy your `NTFS.SYS` from your floppy to your Windows Server 2003 installation folder and you should be back in business. In addition, there are some other commands that can help you get your server back up and running:

**DISKPART** This command will launch a disk partitioning utility almost identical to the utility we used during the text-based phase of setup.

**FIXBOOT** This command will make a new boot sector on your drive of choice and make that partition your new boot partition. If you happened to destroy your boot sector information and can't boot at all, this may be your best bet.

**FIXMBR** This command will repair the master boot record on the selected drive.

**DISABLE** If you are having problems with a device that is not letting Server boot completely—let's say you accidentally changed a device's startup parameter or installed a new service that keeps killing your system—the `DISABLE` command will let you prevent that service or device from starting.

**ENABLE** This is just the opposite of `DISABLE`. Let's say you disabled an important boot device; reenabling it may be the easiest solution.

**LISTSVC** Both the `DISABLE` and `ENABLE` commands require that you tell it *which* service or device to alter. This command will give you a list of all devices and services.

**SYSTEMROOT** This command gives you a quick return path back to your `systemroot` directory without having to fight those long, pesky CD commands. It also helps you when you forget which drive and directory your chosen Server 2003 installation resides in.

**LOGON** The `logon` command takes you back to your first prompt of the Recovery Console so you can choose another installation to repair.

**HELP** In case you can't remember the command, this is a nice little reminder.

Now that you know what the Recovery Console does, let's run through a couple of examples. We'll take the first example from our earlier scenario, a known missing or corrupt NTFS.SYS. Once we've logged in to the Recovery Console for our Server installation and copied a fresh NTFS.SYS to our A: drive, we need to copy it to our **systemroot** directory. We should already be in the **systemroot** directory, but just to be sure, we type **systemroot**. Now, we type **copy A:\NTFS.SYS**. Easy, huh?

Here's another problem. We have recently installed a new service named RudysNeatVirusScanner. It is set to start automatically during boot up, but as soon as it does, blue screen! Into our Recovery Console we go. At the prompt, type **listsvc**. We should see, among our many devices and services, RudysNeatVirusScanner service set to automatic. Now, we type **disable RudysNeatVirusScanner**. Next time we reboot into Server, we should get in just fine and should probably uninstall the problem software.

The Recovery Console is a handy utility that can get you out of a lot of trouble. Once you have installed Server 2003, it might not be a bad idea to run the **winnt32.exe** with the **/cmdcons** parameter. This won't actually launch Setup, just configure the console. You will always have the console available in your boot menu, although it won't be set as default.

## Performing Unattended Installs: An Overview

Got 50 servers to install? Getting a little tired of shoving CD-ROMs into drives and baby-sitting the setup process, answering the same dumb questions over and over again? Then you need to learn about unattended installs!

An unattended install is simply a method of providing the answers for the setup questions before they are asked in order to automate the installation process. There is no other difference in the install itself. But why do you need to automate? Usually, automation is most beneficial in large networks where Server 2003 machines will frequently be built. By automating these installs, numerous hours can be spared that would otherwise be spent sitting at the console. Another benefit of unattended installs is that they can be run by non-experts and produce the same wonderful results every time. This could help in those environments where the only on-site server operator is not an experienced administrator. Rather than spend hours walking them through an install to your specifications, you can merely give them a single command line and be done with it.

Microsoft provides three different tools to make it possible for you to do unattended installations, and I'll explain them to you in the remainder of this chapter. Before getting into the details of these tools, however, I want to provide some perspective on how you'd use these tools. I'll cover three major areas:

- ◆ Scripting installations
- ◆ Using Remote Installation Services
- ◆ Using Sysprep

### Scripting

In its simplest form, a script is just a file that preanswers all of those questions that Setup asks—what shall we call the computer, what is your name, what's the product ID value, that sort of thing. So what's to learn? Well, first of all, you have to learn the language of scripts; like most computer things, scripts have a specific syntax that you must follow or they won't work. It's not a *hard* syntax—I don't

want to scare you away—but there’s a syntax nonetheless. Microsoft has made your script-writing job pretty easy, in that they’ve included with Server 2003 a program that asks you some questions and then spits out a script. It’s only a basic one, and you’ll have to add a few lines to make it useful, but it’s a good start.

Once you’ve done a little scripting, however, you’ll soon want more flexibility and power out of the scripting language—and you can get it. There’s a whole next level of scripting power via what are called the OEMPreinstall options, and you’ll learn them next.

## Delivery: CD-ROM or RIS

All a great script does is to save you having to answer questions while running Setup—but first you’ve got to get Setup running in the first place. The next set of tools simplifies the process of delivering all of the setup files to the new PC to begin with.

The simplest way to start up a setup is to shove a CD into the computer’s CD-ROM drive and then boot from the CD. But how to supply the script? With a trick, as you’ll see—put the script on a floppy disk and call the script `winnt.sif`. But who wants to walk around with a CD-ROM, and, besides, what if you want to deploy more than just the operating system? Well, under NT 4, you’d have to create a network share that contained all of the NT installation files, then you’d have to figure out how to get a computer with nothing on its hard disk connected to the network in the first place.

Windows Server 2003 (and 2000, for that matter) again simplifies matters with a tool called Remote Installation Services (RIS). With RIS, you can store prebuilt Windows 2000, XP, and Server 2003 installation files and scripts on a server—a RIS server. Then RIS eliminates the need to wonder how you’re going to get your new computer attached to the network in the first place by supporting a network boot standard that many new computers support called PXE, the Preboot Execution Environment. And if you don’t have a PXE-compliant computer, that’s not a problem; RIS can generate a generic floppy disk that will allow most desktops and some laptops (laptops are the weak point here, as you’ll see) to connect to a RIS server, with no built-in PXE support needed.

And if you’re a current Windows 2000 RIS expert, then you might be thinking, “Wait a minute, Mark—RIS only distributes 2000 *Professional*. You can’t use it to deliver *Server*.” But you *can*, actually; that’s one of Server 2003’s new features.

## Sysprep

For some folks, the two things that I’ve just described—scripting and delivering setups—is the slow way to do things. Many firms prefer to first create a computer that looks just exactly as they’d like all of their computers to look. Then they create hundreds of exact duplicates of that prototype computer, “cloning” the prototype’s hard disk, and in the process quickly roll out hundreds of ready-to-work desktop or server computers.

The only problem with this method is that until the advent of 2000, Microsoft didn’t support people who do that, as cloning results in computers that lack unique SIDs, security identifiers. But, as of 2000, Microsoft has a tool that makes a prototype computer “clonable,” called Sysprep. And, as you’d imagine, it’s gotten better with Server 2003.

Now we’re almost ready to get into the details of scripting—but before we do, let’s take a quick look at the program that starts off a Server 2003 Setup in the first place or, rather, the *two* programs that start a Windows Server 2003 Setup: `winnt.exe` and `winnt32.exe`.

## Command-Line Automation: Controlling WINNT[32]

When you simply boot a system from the CD-ROM, then you're not aware of the name of the program that starts off the setup process. But you can also initiate a Windows Server 2003 setup from the command line with one of two commands: `winnt32.exe` if you're starting the setup from a computer that's already running Windows NT or later, or `winnt.exe` for a system running DOS or Windows 3.x or 9x.

**NOTE** *Someone always e-mails me to correct me, saying that you use `winnt32.exe` for Windows 9x. Not me. I boot 9x systems to Safe Mode Command Prompt, use the `LOCK` command to lock the C: drive, and install. There you need `winnt.exe`.*

The command-line parameters of these programs tell the Setup program where your source installation files are, where you want to install Server, where your answer file is located, and other information needed to prepare for the setup. A command-line parameter can also be used to copy an additional folder to your setup source so that those files will be available during the installation. This is handy when you have OEM drivers for the hardware you want to install during the setup rather than waiting until afterward.

Before you start using command-line parameters, it is important to *really* understand them. They can have a very profound impact on the installation process, so let's go over the WINNT32 options:

**/checkupgradeonly** Whenever Setup begins, it checks to see if an upgrade is possible. Setup will not attempt to actually run the install.

**/cmd:command** This option will launch the given command line before the setup process has completed, which will allow you to perform some additional customization or launch other programs.

**/cmdcons** If you have a failed installation on your system, this option will add a Recovery Console item to your `boot.ini` operating system selection menu.

**/copydir:folder** When you're doing automated installs for a large number of machines, this may be one of the most useful options in your arsenal. How many times have you been stopped in the middle of an installation because your network card drivers are, well, on the network? You resort to copying files to a floppy, spend 10 minutes trying to find one, format it, copy files, and hike them back to your server. What a bother. The `/copydir` option can really help you out here. It will copy the specified folder to your installation directory during setup—while you're still connected to your network.

**/copysource:folder** Similar to the `/copydir` option, the `/copysource` option copies a specified folder to your installation directory. The major difference between the two is that the `/copysource` directory is deleted after setup is complete.

**/debug[level][:filename]** You can tell Setup to log debugging information to a given file based on the following criteria. Level 0 logs severe errors only, 1 adds regular errors, 2 includes warnings, 3 adds all informational messages, and 4 incorporates detailed information about the setup for complete debugging purposes. For example, you could use `/debug3:setuplog.txt`.

**/dudisable** This option lets you skip the dynamic update part of Setup.

**/dupprepare:path containing CAB files with updates** This is not a command that you'd run at Setup. Instead, you use this to prepare a directory that contains updates so that when you *do* run Setup on a system, you can use the /dushare option to point Setup to these updates. This is a pretty new process in the Microsoft OS world and the instructions on how to do this change regularly, but the most current details are at [www.download.windowsupdate.com/msdownload/update/v3/static/DUPProcedure/Dynamic%20Update.htm](http://www.download.windowsupdate.com/msdownload/update/v3/static/DUPProcedure/Dynamic%20Update.htm). You don't go to the regular windowsupdate.microsoft.com location to download fixes en masse; instead, you go to windowsupdate.microsoft.com/catalog.

**/dushare:path to share created by dupprepare** Once WINNT32 /dupprepare has reconfigured the patch and update files that you downloaded from Windows Update, you can set up a new computer and simultaneously apply the latest patches with the /dushare: option.

**/m:folder** This option can be dangerous. When the setup process begins to copy files, the /m option tells it to look in the specified folder first. If that folder contains files to be used in setup, those files will be used. If the files are not present, they will be retrieved from the regular installation source. This can be helpful if a hotfix or alternative version of a file that you choose to use for every install (rather than the default version on the CD) is available. Instead of running your install and then running an update or replacing files, you can use /m and perform these tasks in one swift step.

**/makelocalsource** Have you ever had problems reconnecting to your installation source after you've rebooted and started the setup? This could be due to things like Setup not recognizing your CD-ROM or network card. This option tells Setup to copy the entire source to your hard drive so that you can guarantee it will be available later.

**/noreboot** There may be times when you want to launch the first stage of Setup, get your machine ready for the installation, but not reboot quite yet. This option will bypass the screen at the end of the first setup wizard and return you to your existing operating system without a reboot. When you do reboot, though, Setup will continue.

**/s:sourcepath** This seems like a redundant switch. You've already found your source path if you've gotten as far as launching the setup. Setup even knows where it's coming from. This parameter does help identify where your source is—the I386 directory—but it also does something better. You can specify multiple source paths and have Setup copy files from each simultaneously. This can really save you time if you have a slow CD and a slow network. Be careful, though; the first source path identified must be available or Setup will fail.

**/syspart:drive** Another very powerful option here when you're considering mass deployments is the /syspart parameter. This will start your setup to the specified drive and mark that drive as active. Once Setup is complete, you can physically take that hard drive out of the system, place it in a new system, and boot right into Setup. You must use the /tempdrive parameter with /syspart.

**/tempdrive:drive** Setup will use the specified tempdrive to place temporary setup files. If you have space concerns with drives or merely a preference on where you want temporary files to go, use this parameter.

**/unattend** The /unattend option will do an automated, no-input-required upgrade of your previous operating system. All configurations and settings of the old operating system will be used for the upgrade.

**/unattend[num]:answer\_file** This launches one of the most powerful features of unattended installations: the answer file. The answer file is a text file containing any or all answers to be used throughout the entire setup process. I'll talk about building the answer file in the next section. If your current operating system is Windows 2000, you can also specify a time delay for the reboot, determined by [num].

**/udf:id[,udf\_file]** One of the problems with automated installations is that you can't fully automate an install unless you provide a name for the server, and all servers—all machines for that matter—on your network *must* have a unique name. This requires that you either enter the name during the setup or use an answer file on all machines, giving them the same name. Neither of those are viable options. The /udf parameter allows you to specify unique information about each installation based on the file specified in the UDF file—uniqueness database file. Here's how it works. In the UDF file, there is a listing of names and a section matching each name with computer-specific information. Usually the computer-specific information will be just the computer name, but anything you put in this file will override the same entry in the answer file. Take a look at a sample UDF file named `unattend.udf`:

```
;SetupMgrTag
[UniqueIds]
    BS01=UserData
    BS02=UserData
    BS03=UserData
    BS04=UserData
    BS05=UserData
[BS01:UserData]
    ComputerName=BS01
[BS02:UserData]
    ComputerName=BS02
[BS03:UserData]
    ComputerName=BS03
[BS04:UserData]
    ComputerName=BS04
[BS05:UserData]
    ComputerName=BS05
```

I have five specified, unique computers defined—BS01 through BS05. If I'm sitting down to install a machine for BS03, I would send the /udf:BS03,unattend.udf parameter. The Setup program will look in the UDF file and have any entries under the BS03 section override those in the standard answer file. So if the ComputerName entry in the answer file is BSxx, Setup will substitute BS03 in its place for my installation.

Those are all of the possible command-line parameters that you can feed the WINNT32 program. To better see how they work, let's try a few samples of running WINNT32 from the CD located in F:.

We are installing to a server that is very specific about using OEM drivers for the network card. If we start the setup and reboot, the default drivers with Windows Server 2003 won't get us back online. We'll use the `/copysource` option to copy down our drivers from the network folder of `Z:\NIC\OEM`. Just to be on the safe side, we also want to use a `/makelocalsource` option so we have all files available for use. We'll launch the following command:

```
F:\I386\winnt32 /copysource:z:\nic\oem /makelocalsource
```

During the first phase of Setup, the entire `z:\nic\oem` directory will be copied to the hard drive to be used during the installation. Once completed, the directory will be removed to free up our space again. We will also get a complete copy of the `I386` directory copied to our local installation source. Between the two, we should have no problems with the installation not being able to find files.

Now, we want to launch a setup using an answer file named `C:\w2k\setup\unattend.txt` and a uniqueness database file named `C:\w2k\setup\unattend.udf`. To keep parity with the earlier scenario, we'll install this machine with the `BS03` ID. In this case, we run this command:

```
F:\I386\winnt32
  ⚡ /unattend:c:\w2k\setup\unattend.txt
  ⚡ /udf:BS03,c:\w2k\setup\unattend.udf
```

WINNT supports a subset of those options—`/s`, `/t`, `/u`, and `/udf`—as well as these

- `/e:` Specifies a command to execute after Setup finishes
- `/a` Enables accessibility options
- `/r:` Tells Setup to copy a folder to the target machine, leaving it in place after Setup finishes
- `/rx:` Like `/r`, but deletes the folder after Setup finishes

## Scripts, Part I: Basic Answer Files with Setup Manager

The easiest way to get started with scripts is to let a program called Setup Manager build one for you.

### INSTALLING SETUP MANAGER

Setup Manager isn't installed by default—here's how to get it.

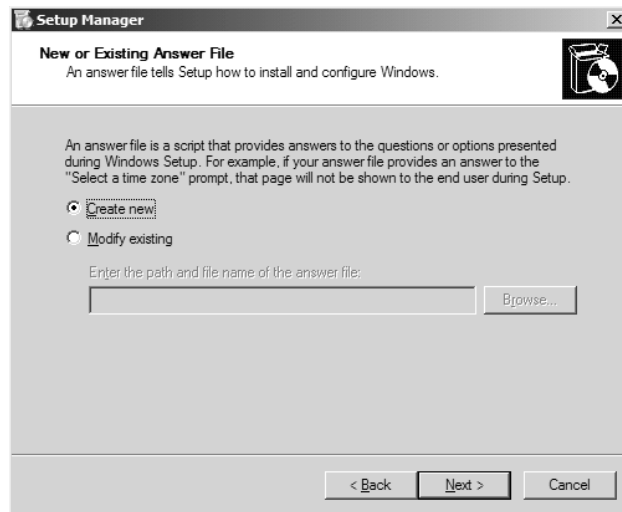

1. Insert the Server 2003 CD into your computer's CD drive.
2. Open the folder named `Support` and, inside that, another folder named `Tools`.
3. In `Support\Tools`, you'll see a file named `deploy.cab`. Double-click it to open it.
4. Select all of the files in `deploy.cab`, right-click, and choose `Copy`.
5. Create a directory named `DepTools` on your computer's hard disk. Right-click the `DepTools` folder and choose `Paste`.
6. Open the `DepTools` folder and double-click the `Setupmgr.exe` icon.

### RUNNING SETUP MANAGER

That starts up Setup Manager, which is a wizard and therefore starts off with a `Welcome` screen. Click `Next` to get past it and you'll see a screen like Figure 5.2.

**FIGURE 5.2**

New file or modify  
an old one?

As you can see, Setup Manager will either create a new script file or edit an existing one.

**WARNING** *In general, I recommend that you never use Setup Manager to edit an existing script, because when starting up Setup Manager to change just one thing in a script, I find that it sometimes gets a bit rambunctious and decides what-thehey, while I'm here why don't I fix all of these other bad ideas that I see in this script?*

Tell it that you're creating a new script and choose Next. You'll see a screen like Figure 5.3.

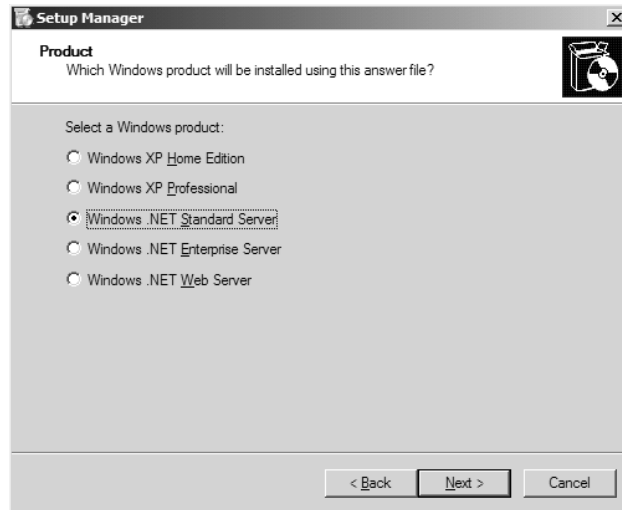

**FIGURE 5.3**

What kind of script?

Setup Manager can build scripts that you can use either for a simple unattended install, for RIS, or for Sysprep. We're doing just a simple install, so choose that and click Next. You'll then see a screen like Figure 5.4.

**FIGURE 5.4**  
What flavor?

Setup Manager will create scripts to install either Professional or Server in any of their incarnations (except Datacenter); choose Windows .NET Standard Server and click Next to see Figure 5.5.

**FIGURE 5.5**  
Just how hands-off?

This screen advises Setup Manager how thorough it should be in creating the script. In theory, choosing Fully Automated will cause Setup Manager to fill in enough information that you can just start an install using WINNT or WINNT32, walk away for 45 minutes, return, and be done. In actual fact, you'll have to include a few other things, as you'll see. Choose Fully Automated and click Next to see a screen like Figure 5.6.

**FIGURE 5.6**  
Configuring a  
distribution share

One approach to automated rollouts involves copying all of the installation files to a share on the network; Microsoft calls this the *distribution share*, and Setup Manager will help you create one if you like. We're just looking to create an answer file here, though, so choose Set Up from a CD and click Next to see Figure 5.7.

**FIGURE 5.7**  
Agreeing to the  
EULA

From this point on, the Setup Wizard mainly asks the same kinds of questions that Setup has already asked, so I'll go through them quickly. First, there's the end-user license agreement (EULA). As with every other piece of software nowadays—both Microsoft and non-Microsoft—Server 2003 comes with a sign-it-or-else “contract” called a software license. The point of the software license is to

give the software vendor more ability to restrict what you do with the software than they'd normally get from copyright laws. By agreeing to it here, you avoid having the Setup program stop and ask you to agree to the EULA in mid-install. Check the box and click Next to fill in your name and organization, and then Next to configure the display settings, Next for time zone, Next for product key, Next to fill in the client licensing option, per-seat or per-server. Click Next to see Figure 5.8 and set the computer name.

**FIGURE 5.8**

Machine names and automatic UDFs

You can enter a name and click Add, or you can, as I have, check the Automatically Generate Computer Names... check box. Computer names aren't very interesting, but what *is* interesting is that you can use the Setup Manager to create a UDF, like the one you saw earlier in this chapter; if you enter more than one name, that's how to make this answer file useful. Click Next to see Figure 5.9.

**FIGURE 5.9**

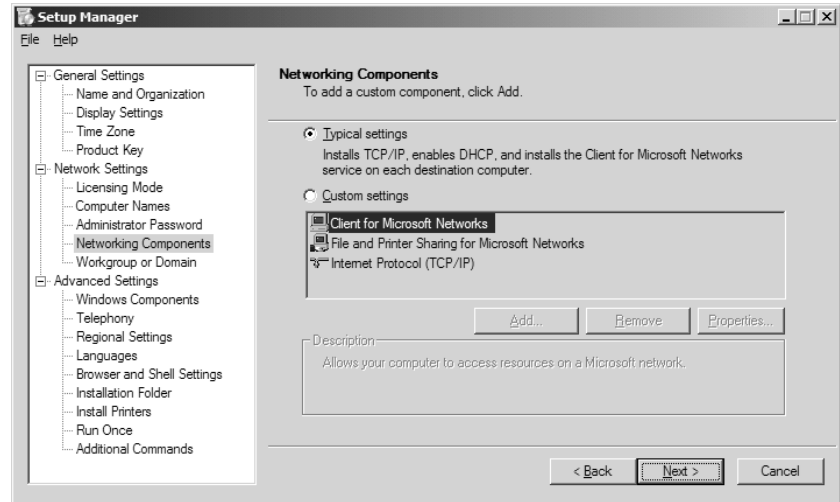

Setting the admin password

This is really good news for anyone who's built an answer file in the past. Most of it's self-explanatory, but notice the new check box that says Encrypt the Administrator Password in the Answer File. Very cool—now we don't have to worry about people looking in the scripts and seeing the admin's password! Click Next to see Figure 5.10.

**FIGURE 5.10**

Typical or custom network settings?

You'll usually choose Typical Settings, but let me take a moment and point out one of Setup Manager's strengths. If you decide to take Server 2003's default networking settings, then you'll get a pretty basic setup script—you'll use DHCP to get your IP address (and if you don't know what DHCP is, don't worry, I'll be explaining it in the next few chapters—for now, just understand that it makes the process of setting up the TCP/IP software on a computer far easier). But what if you *didn't* want to use DHCP for configuration—what if you wanted to script an install with a specific set of TCP/IP configuration parameters, like a specific IP address? Here's where Setup Manager shines. Perhaps it's the fact that I seem to be afflicted with AFS (After-Forty Syndrome), but I can never remember the combination of script commands needed to specify an IP address. So I cheat by just running Setup Manager and telling it to set up a simple script for a system with a prespecified IP address. I can then look at the resulting script and cut and paste to create my desired script. That's not to say that Setup Manager knows how to create *every* possible kind of script, but it's pretty smart, making it a kind of automated cheat sheet.

Anyway, after deciding to do typical network settings and clicking Next, you'll get a panel that lets you specify whether you're going to join a domain or a workgroup. Click Next to see a new screen for Server 2003's Setup Manager, as in Figure 5.11.

With this very useful screen, Setup Manager lets you choose what does and doesn't get installed on your system, a real, *real* plus! Instead of just automatically installing (for example) the Index Service on every system when only two or three systems in your whole enterprise need it, this lets you just say no to every component but the ones that you need. This is an improvement over Windows 2000's Setup Manager, which made you do this answer file-tweaking by hand. Go through it, make your changes, and click Next.

**FIGURE 5.11**

Choosing components

If you've got a modem, you'll be asked about Telephony settings; fill them in and click Next. You can then adjust Regional Settings—keyboard, currency, that kind of thing and, in the next panel, language support. (Things we Defaultians must shamefully admit that we don't know jack about.) Then you get to set up the Browser.

It really irritates me that every time I set up a new computer and start Internet Explorer for the first time, it jumps out to MSN; I've always wanted to say to NT, 2000, and now Server 2003's Setup programs, "Look, I swear, I will *never ever use MSN in my entire life*—so stop making me either wait for MSN to load or have to click the Stop button!" When I start up a browser, I want it to start *immediately*, so my home page is "about:blank." I can make that happen in an answer file with the following commands:

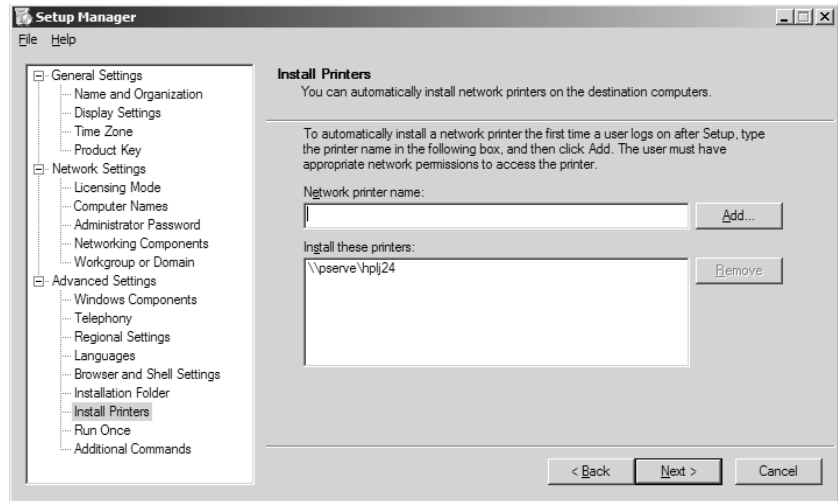

```
[Branding]
BrandIEUsingUnattended = Yes
[URL]
Home_Page = about:blank
```

But I don't have to mess with the answer file to do this, as Setup Manager gives me those options. The next page lets you specify an installation folder—whether to put the files in `\windows`, `\winnt`, or whatever you want. Administrators will love the next screen, as you can see in Figure 5.12.

Set this up, and your users will log in already set to use a networked printer. The next two screens are a bit out of order, in my opinion. The first one specifies things that go in the Run Once Registry key. This lets you enter commands that you want run the first time that the computer has rebooted after completing Setup. You'd use this to tell your new copy of Server 2003 to do something like run DCPROMO to create a domain controller automatically, or perhaps to kick off a SQL Server installation. The screen after that lets you specify additional commands, which are commands to execute at the end of Setup. This can be useful if you want to do something like automatically install the Recovery Console; the command would be

```
e:\i386\winnt32 /cmdcons
```

**FIGURE 5.12**  
Preconfiguring  
network printers

The only problem with this is the *e:*—I typed that for example, but what actual drive letter will your CD-ROM end up being at the end of Setup? On a complex system, this might not be obvious. In any case, this seems out of place to me because *these* commands execute *before* the Run Once commands—wouldn't you think the panels would appear in something resembling the order in which they occur?

Finally, Setup Manager will ask you where to put the answer file, and what to call it. Click OK and you'll then be able to exit the Setup Manager.

#### EXAMINING SETUP MANAGER'S SCRIPT

The script that Setup Manager created for me looks like this:

```
;SetupMgrTag
[Data]
    AutoPartition=1
    MsDosInitiated="0"
    UnattendedInstall="Yes"

[Unattended]
    UnattendMode=FullUnattended
    OemSkipEula=Yes
    OemPreinstall=No
    TargetPath=\WINDOWS

[GuiUnattended]
    AdminPassword=43e140893084ea91cd85ddcc2cd0905daf4d42d86df9ebd57b0641c94aa4c438
    EncryptedAdminPassword=Yes
    OEMSkipRegional=1
    TimeZone=35
    OemSkipWelcome=1
```

```
[UserData]
    ProductKey=11111-22222-33333-44444-55555
    FullName="Mark Minasi "
    OrgName="MR&D"
    ComputerName=*
```

```
[Display]
    BitsPerPel=16
    Xresolution=1280
    Yresolution=1024
```

```
[LicenseFilePrintData]
    AutoMode=PerSeat
```

```
[Components]
    accessopt=Off
    calc=On
    charmap=On
    clipbook=On
    deskpaper=On
    templates=On
    mousepoint=On
    paint=On
    freecell=Off
    hearts=Off
    zonegames=Off
    minesweeper=Off
    solitaire=Off
    spider=Off
    indexsrv_system=On
    msexplr=Off
    certsrv=Off
    certsrv_client=Off
    certsrv_server=Off
    iis_www=On
    iis_ftp=Off
    iis_smtp=On
    iis_smtp_docs=On
    iis_nntp=Off
    iis_nntp_docs=Off
    reminst=Off
    rstorage=On
    TerminalServer=On
    wms=Off
    wms_admin_asp=Off
    wms_admin_mmc=Off
    wms_server=Off
    chat=On
```

```

dialer=0n
hypertrm=0n
cdplayer=0n
mplay=0n
media_clips=0n
media_utopia=0n
rec=0n
vol=0n

[GuiRunOnce]
Command0="rundll32 printui.dll,PrintUIEntry /in /n \\pserve\hplj24"

[Networking]
InstallDefaultComponents=Yes

[Identification]
JoinDomain=bigfirm.biz
DomainAdmin=adminude
DomainAdminPassword=hihihihi

```

This is a pretty basic script. Notice that an answer file is like a typical INI file, around since the early days of Windows; it's a simple ASCII file that you could, if you wanted to, create with Notepad. There are sections of the file that are broken up into groups; they're identified by their headers and surrounded by square brackets, like `[HEADER1]`. Within each section are different settings and the corresponding values to be used during the setup, formatted as `ITEM=VALUE`.

The first section is called `[Data]` and it's pretty much boilerplate, simple you-gotta-have-them instructions. `MSDOSInitiated` should equal 0 if you're doing an install from the CD-ROM, or 1 if you're doing an RIS install. `AutoPartition` must be equal to 1, or Setup will stop and ask you which partition to install Server 2003 into. `UnattendedInstall` should be, um, obvious.

The `[Unattended]` section tells Setup what level of user interaction to expect, and you see `FullUnattended`, which is the script-syntax equivalent of the Fully Automated option we chose from Setup Manager. `OEMSkipEula` just says "don't make him accept the license agreement." `OEMPreinstall` is a *very* powerful command that you'll meet later. Turning on the `OEMPreinstall` features will, as you'll see, unlock a whole bunch of extra automated setup capabilities—but for now, let's stick with the basics; "no" leaves those features off.

`[GUIUnattended]` controls the second, graphical part of Setup, answering many of the questions that section asks. Without `OEMSkipWelcome=1`, Setup would stop at the beginning of Setup and ask if you want to continue. (Now, what part of `FullUnattended` did you not understand, Setup Manager?) Note `AdminPassword=` and that big long string—that's my password, encrypted. Set it to just `*`—that is, asterisk—to make it blank, although I don't know why you'd do that nowadays.

`[UserData]` lets you brand the PC with your name and organization, and the name of a PC. `"ComputerName=*"` tells Setup to cook up a name for this machine. Windows 2000 vets may recall that the command for the product key used to be `ProductID`; now it's `ProductKey`, as you see. (And no, that `ProductKey` doesn't work!)

`[Display]` sets up the video display. `[LicenseFilePrintData]` just specifies how you're going to license the clients. `[Components]` is a simple, if lengthy, list of all of the things that you can

choose to install or not install on a Server 2003 system. As you'd guess, you tell Setup to install or not to install with "On" or "Off," which would lead you (incorrectly) to believe that everything gets installed but is turned off.

[GuiRunOnce] contains our printer setup command.

[Networking] is simple in this example; it just says to take the defaults.

Look at the [Identification] section, and let's consider what that does. You want to join this computer to a domain, and of course you'll need at least *some* level of administrative control to do that. That's what that administrative name and password are for—to give Setup the authorization to create a computer account. But obviously you might not be too happy about the idea of putting the account name and password of a domain administrator into an unencrypted ASCII file. Fortunately, you can create a lower-power administrator that can only create and destroy *machine* accounts—it can't mess with user accounts or anything else on the domain—and you'll learn how to do that at the end of the chapter.

## Improving Setup Manager's Script

We didn't ask Setup Manager to do anything fancy, which is why we got a pretty short script—I just wanted to create a basic script. But you might want to add one command: Repartition. You might want to add the command Repartition=Yes, which goes in [Unattended]. This command tells Setup to delete all partitions on the first physical drive and create one big NTFS drive. If you *don't* use the Repartition command, then you have to either prebuild the partitions on the computer somehow (there are third-party tools that can do that) or accept that Setup will stop partway through the text portion and prompt you to ask which partition to place Server 2003 on.

## Getting the Script Ready to Try

Want to try this out? Add the Repartition command that I just mentioned and, of course, make whatever changes will work in your system. If this is just a simple tryout then you might not want to join a domain; in that case, change the [Identification] section so that it looks like this:

```
[Identification]
JoinWorkgroup=(your workgroup name--anything will do)
```

Then you'll need just a few ingredients:

- ◆ First, of course, you'll need a computer. Note that as I've included the Repartition=Yes command, this will blow away any partitions on its first physical hard disk.
- ◆ Next, you'll need to copy your script file to a floppy. The floppy needn't be bootable. Rename the script file name to `winnt.sif`. That's a "magic" name—if you name it something else, then this won't work. Put the floppy in the A: drive.

**NOTE** Please note that if you have told Explorer on your system to hide file extensions, the filename looks like `unattend` rather than `unattend.txt`. Now and then someone will not realize that the filename is actually `unattend.txt` rather than `unattend`, and when they try to rename the file to `winnt.sif`, Explorer renames it instead to `winnt.sif.txt`. Now, it still looks like `winnt.sif` in Explorer, but its real name is `winnt.sif.txt`. So be sure to tell Explorer to show you file extensions before renaming `unattend.txt` to `winnt.sif`.

- ◆ After that, insert the Server 2003 installation CD in the CD-ROM drive.
- ◆ Finally, in your computer's BIOS, you need to rearrange the boot order.

Ideally, you'd like a system that lets you tell it to first boot from the CD-ROM and then, if that wasn't bootable, to try the C: drive, and only if *those* two weren't available, to boot from A:. Now, with the CD-ROM in its drive and the floppy in the A: drive, boot the system. It'll ask you to press a key to boot from the CD-ROM and, if you don't, then it boots from the hard disk.

Then you just walk away.

What's going on? A trick built into Windows 2000 and later versions of NT. If it boots from its setup CD, it then looks on the A: drive for a file named `winnt.sif`. If it finds one then it presumes that the `winnt.sif` file is the script that it should use to do an unattended install. Pretty neat, eh? Hey, stay tuned, it gets even better.

## Improving the Script More

Once you've got a basic script like that working, you can take it considerably further, as the script language is pretty extensive. Look back in the directory where you copied the files from `deploy.cab` and you'll see a large WordPad document named `unattend.doc`—a roughly 180-page document—that documents all of the scripting parameters. Here are a couple suggestions.

### MOVE DOCUMENTS AND SETTINGS

Windows 2000 and later OSes store the user profiles by default in a directory `C:\Documents and Settings`; if you want to move that, then add the line `ProfilesDir=path` to put the profiles somewhere else.

### PRECONFIGURE INTERNET EXPLORER

As I mentioned a few pages back, you can configure Internet Explorer in the script as well. For example, here's a piece from a script that I use:

```
[FavoritesEx]
    Title1="Mark Minasi Home Page.url"
    URL1="http://www.minasi.com"
[Branding]
    BrandIEUsingUnattended=Yes
[URL]
    Home_Page=about:blank
```

The first section preloads my home page into my Favorites. The second just warns Setup that we'll be configuring IE via a script, and the third section defines my home page as `about:blank`.

Now, for those of you who are IEAK (Internet Explorer Administration Kit) wizards, then your hard work isn't wasted—there's a script setting that tells Setup to find the file containing your IEAK settings and then to apply them. (Run Setup Manager and you'll see the option.)

### POSTINSTALL POLISHING: ADDING SUPPORT AND BRANDING INFO

Now that you've got your system set up, let's add a bit of branding and support info. (Truthfully, the branding info is a bit silly—though fun—but the support info isn't silly, it's useful.)

Try this: log in to your Server 2003 system as Administrator (that's probably the only account you've got built yet anyway), and find the icon on the Desktop labeled My Computer in the upper-left corner. Right-click it and choose Properties. You'll see a multitabbed properties page like the one you've seen elsewhere in Windows. You can add a picture (or any bitmap) to it in the empty space on the left side, like so:

- ◆ Take any bitmap that's roughly  $175 \times 175$  pixels.
- ◆ Name it `oemlogo.bmp`.
- ◆ Place it in `\windows\system32` or `\winnt\system32`, whichever you've got the OS in.

Next, let's add some support information. You can "brand" a computer to describe its model, and also add an arbitrary set of lines of text for support information by including a file in `\winnt\system32` named `oeminfo.ini`. This is an ASCII text file with two sections, [General] and [Support Information]. It looks like this:

```
[General]
Manufacturer=<descriptive vendor name>
Model=<particular model>
[Support Information]
Line1=<first line of text>
Line2=<second line of text>
Line3=<and so on >
```

For example, you might have an `oeminfo.ini` file that looks like the following:

```
[General]
Manufacturer=Clonetronics
Model=DeskWidget 820 (60GB disk, 733 Processor)
[Support Information]
Line1=For Tech Support call:
Line2=(555) 555-1212
Line3=After hours, call Bill
Line4=(If you can find him)
```

Try it and you'll see that it works quite well and can be a useful way to "brand" a system.

## Scripts, Part II: Distribution Shares and \$OEM\$

You've seen that one way to start an unattended install is to shove a floppy and a CD into a system, boot, and walk away. But that's really only of value if you just want to install the operating system with the basics. Next, let's see how to load a whole *bunch* of new software, and also do some other great stuff, including installing applications on top of the OS.

### STARTING A SETUP WITH WINNT/WINNT32

Like previous versions of NT, Server 2003 ships on a CD and includes a large directory called `I386`. Inside `I386` are a pair of programs that you've already met, `winnt.exe` and `winnt32.exe`. As you've already read, one way to start Windows Server 2003's Setup program is to just type `winnt` or `winnt32`

with a sequence of options. You *could*, then, install Server on a system this way (I don't recommend it, although there's a good reason why I'm explaining it):

1. Clean up about 2GB of space on a drive on a computer's hard disk.
2. Copy the I386 directory on the CD and its subdirectories to the drive with 2GB or more space.
3. Change directories over to the copied I386 directory that is now on the computer's local hard disk.
4. Open a command line and type either **winnt** or **winnt32** with whatever options are appropriate at the time, depending on what kind of install you want to do. (And, again, use WINNT if you're currently running DOS or Windows 9x, WINNT32 to start a Server 2003 Setup from inside NT, 2000, XP, or Server 2003.)

### **WINNT[32] AND DISTRIBUTION SHARES**

Now, why did I explain this to you if I recommend that you not use it? Because many people *do* use a variation on this theme. Over the years, many of us have done WINNT/WINNT32 installs not by copying I386 to the target machine, but instead by putting I386 on a shared folder (called a *distribution share* or *distribution folder*) on a file server. Then you walk over to the machine that you want to put Server 2003 on, connect to the file share, and type **winnt** or **winnt32**. Summarized, then, the idea with a distribution share is that you first copy the I386 files over to some share on the network; then to put Server 2003 on a new machine, you just walk over to the machine, log in to the network, connect to the distribution share, run the WINNT program in the share, and Setup starts. You can, of course, script an installation this way as well, and so the whole process can become basically unattended.

### **THE CHICKEN AND THE EGG**

The only problem with this whole approach has always been that part about taking a brand-new machine and logging in to the network with it—namely, how the blazes do you *do* it? Computers with empty hard disks don't know jack about networks (at least, not usually—stay tuned for the RIS section to see the alternative), so simply stuffing an Ethernet card into a new PC and hooking it up to the company network accomplishes nothing besides making another LED on the Ethernet switches light up. You need a network stack—protocols, a network file client, all that kind of stuff. It's always sort of been true that “you need to be on the network to be able to connect to the software that you'll need to install in order to get onto the network.” Kind of a chicken-and-egg thing.

Microsoft used to offer a two-floppy set of code called the MS-DOS Client for Microsoft Networks that helped a bit. You'd first stick DOS on the new machine, then load the MS-DOS Client for Microsoft Networks, then reboot the system. That would let you log in to a domain and from there attach to a distribution share—but it was an awful lot of installing just to start off the Setup programs for NT 4 or later OSes. Worse yet, the Client didn't include drivers for any NICs built after the Punic Wars, so you always had to hunt around for a set of DOS-compatible drivers for the modern network card in your computer.

With a bit of luck and determination, I was sometimes able to fit the whole mess onto a floppy, and that wasn't so bad—just boot the new computer from the A: drive and I'd be connected to the network. Of course, I had to reengineer the floppy for every different model of NIC, which partially explains why I (a) only bought 3Com Ethernet cards for years and (b) resisted going to 100-megabit Ethernet a year or two longer than I should have—I was reluctant to have to create a new network boot floppy.

Where does that leave you nowadays? Well, to my knowledge, Microsoft doesn't distribute the Client anymore. You can solve the how-do-I-get-to-the-distribution-share in the first place problem in one of three ways:

- ◆ Find an old copy of the MS-DOS Client for Microsoft Networks and cook up network boot floppies. (And please don't e-mail me, I can't distribute them—they're copyrighted.) There are some useful bootable disk images at [www.bootdisk.com](http://www.bootdisk.com); it's worth a moment or two to see if they've got one you can use.
- ◆ Given that many new systems ship with Wintendo (Win 9x) on them anyway, you already have a network-aware operating system sitting on your new computer's hard disk. Use that to connect to the distribution share.
- ◆ A lot of new computers have the ability to do a PXE or "network boot." Windows 2000 and Server 2003's Remote Installation Services (RIS) is built to support PXE boots, and so can let a computer with even an empty hard disk get to an RIS server and then install Server 2003 from a server. Fortunately, Server 2003's RIS can roll out not only Professional but Server images as well—an upgrade from Windows 2000!

### EXTENDING I386: PREINSTALLING SERVICE PACKS

Let's presume, then, that you've figured a way to get your workstations attached to a network distribution share. Now we can start reaping the benefits of doing installs from a share on a hard disk rather than a CD-ROM: we can *add* to the data on the CD.

The first terrific thing that we can do is to preinstall service packs. You can typically download a service pack as one big EXE. As I write this, there aren't any service packs for Windows Server 2003—it's just been released!—but assuming that Server 2003's service packs continue to work as 2000 and XP's do, this should work. First, download the service pack; let's call it `sp20031.exe`, although I have no idea what Microsoft will call Server 2003's service packs. You can attach a service pack to Server 2003's I386, "assimilating" it so that when you do an installation from that I386, you instantly have a copy of Server 2003 with some service pack installed, rather than having to first install Server 2003 and *then* apply the service pack. Here's how.

1. Create a directory on a server's hard disk and copy the I386 folder to it. Let's say, for example, that you put it in `C:\I386`.
2. Put the `sp20031.exe` file on that computer's disk (it doesn't matter where and please remember, that's a hypothetical filename), open a command line, and type `sp20031 -x` to extract all of the service pack files. It'll ask you where to put them, so specify a directory wherever it makes sense for you. Let's just say you tell it to put the files in `C:\SP`.
3. Once `sp20031` has extracted itself, look in the directory that `sp20031` created, `C:\SP`, to find a directory named `C:\SP\I386\update`. In there you'll find a program named `update.exe`.
4. Run `update.exe` with the `-s` option and point it at the drive containing I386, *not* the I386 directory itself. For example, if you put I386 on C:, then type `c:\sp\i386 update -s:c:\` to put the service pack files into `C:\I386`.

Microsoft says that the `-s` stands for "slipstream," but I tend to think that it stands for "aSsimilate," as that's what the service pack does—assimilates itself into the I386. Notice that, because the

service pack will only take the name of the directory *above* I386 as an input, you really *must* store the data from the CD's I386 folder in a folder also named I386. This isn't a great hardship—most distribution shares I've ever seen are named I386—but now there's a reason that you really *have* to call the directory I386.

**TIP** Now that you've seen how to automatically install a service pack, you're probably wondering how to automatically add the latest hotfixes. I'll show you how to do that in the upcoming section "Tell Setup to Run Commands with cmdlines.txt."

### **\$OEM\$: MORE I386 POWER**

Look back at my example script and you'll see, in the [Unattended] section, a command OEM-Preinstall=No. Let's change that No to Yes and unlock a bunch of convenient unattended setup features:

- ◆ You can tell Setup to create directories and files on the newly installed machine.
- ◆ You can tell Setup to run any number of commands at the end of setup—for example, commands to tell Setup to install other applications.
- ◆ You can supply Setup with newer device drivers than the ones that ship with Server 2003, or device drivers for hardware that didn't even exist when Server 2003 shipped.
- ◆ You can specify that you want to install a particular Hardware Abstraction Layer (HAL). You wouldn't do this very often (so I'm not going to cover the topic any further), but once in a while you'll try to build a setup script for a system that needs a custom HAL, and this is the only way to tell Setup to use it while unattended.

Here's how to use the power of \$OEM\$. Inside an I386 directory, create a directory named \$OEM\$. For example, suppose you'd copied the I386 directory to the E: drive and then perhaps slipstreamed a service pack onto it. Before starting to do installs from that E:\I386 directory, create a directory named E:\I386\\$OEM\$. We'll do our work in the following sections in that directory.

### **Setup Bitmaps and Logos**

While the Setup program runs on a user's machine, you might want to include instructions or information on the screen. You can do that with the [OEM\_Ads] section. Create a section in your script with a logo= and a background= command, like so:

```
[OEM_Ads]
logo=ourlogo.bmp
background=backgrnd.bmp
```

Place the files ourlogo.bmp and backgrnd.bmp in the \I386\\$OEM\$ directory. They must be simple Windows-type bitmap files—you can't use GIF or JPEG files. The background file will display as the background, centered on the Setup screen. Don't use a bitmap larger than 640×480, as that's the resolution that Setup runs in.

And by the way, here's an important tip: Try out the bitmap and logo before using it for a user's system install. Setup puts a couple of big dialog boxes up that obscure most of the background, so if you actually want to pass along some information, then you'll have to be careful about where you place the info on the bitmap or logo; otherwise, the information won't be readable.

### Create Directories and Copy Files

If you create a directory inside `$OEM$` with a one-letter name, like `I386\OEM$E` or `I386\OEM$D`, then Setup will copy any file (or directory) in that directory to the drive letter of the same name on the newly installed computer. For example, suppose I want my computers to all have a directory on C: called `Data`, which will contain a file named `basic.txt`. Let's assume that I've got the `I386` distribution share on a server, on its D: drive, so I've got the setup files in `D:\I386`. To ensure that every new system created from this share has a directory named `C:\Data` and containing the `basic.txt` file, all I need do is this:

- ◆ Create a directory named `D:\I386\OEM$C`.
- ◆ Create a directory inside *that* directory named `Data` -`D:\I386\OEM$C\Data`.
- ◆ Place the `basic.txt` file inside the `D:\I386\OEM$C\Data` directory.

`$OEM$` also has a few “magic” directory names that you can exploit to place files into the system folders. First, there's the `$$` directory. Anything in `I386\OEM$$$` goes to `winnt`. What's the value of that? Well, when you're writing an installation script, you might not know beforehand which drive `winnt` will go on. Rather than having to create a directory named `I386\OEM$C\winnt` and then accidentally try to use that to put files in `winnt` on a system that puts its operating system on the D: drive, putting files in `I386\OEM$$$` will ensure that those files will end up in `winnt` on the drive that contains the operating system.

So, for example, if you liked the idea of including support information on your system, then recall that you store the support and branding information in a file named `oeminfo.ini`, which must sit in `\winnt\system32`. You could create an `oeminfo.ini` file and then place it in a distribution share at `I386\OEM$$$\system32`, and the file would then automatically get copied to the `system32` directory of any newly installed systems. You'd be ensuring that every new system gets the support information without requiring any extra work on your part.

### Including Updated Drivers

Every version of Server includes a pretty large collection of drivers in its initial offering. But from the minute they ship a version of server, boatloads of new hardware appear, so as a version of Server gets older, it'll be more and more likely that either you have a piece of hardware that didn't exist at the time of that version's birth (and therefore that version lacks a driver for it), or the hardware's manufacturer has created a newer and better driver—and Server 2003 is no exception. You can automate the process of telling Server 2003 to use a new or updated driver, using the `OEMPNPDrivers` command.

Create the directories for new or updated drivers in `$OEM$\1\`, then specify them in `OEMPNPDriversPath`. For example, suppose I've got some new video and audio drivers, and I place the new video drivers into a directory named `I386\OEM$\1\newvid`. Then I put the new audio drivers in `I386\OEM$\1\newaud`. I can then tell Setup to look for them by adding this line to the [Unattended] section of my setup script:

```
OEMPNPDriversPath="newvid; newaud"
```

Notice that we describe directories by their path below `$OEM$\1`. Don't include `I386\OEM$\1` in the path.

**WARNING** Note that you should keep the list of directories to 40 or fewer characters. This is a limitation of OEMPnP-DriversPath. But don't make them single-character directory names, or Setup will try to create files on drive C:, D:, E:, etc., on the target machine!

### **Tell Setup to Run Commands with cmdlines.txt**

Once your system is set up, you might want to install some applications beyond the basic operating system, or you might want to delete some little-used files that Setup leaves behind, or you might want to accomplish any number of other small tasks. You can do that with a file named `cmdlines.txt`, which must be located in the `$OEM$` directory.

`cmdlines.txt` is just a list of command-line commands that you want Setup to execute. That may sound to you as if I'm suggesting that `cmdlines.txt` is an old DOS-style batch file, but it isn't. For some reason, it needs a specific format. The first line must be `[Commands]` on a line all by itself. Then, you list the commands that you want Setup to run—but you must surround the commands with double quotes. For example, consider this example `cmdlines.txt` file:

```
[Commands]
"msiexec /i \\server\share\somefile.msi"
"regedit /s myhacks.reg"
```

As you see, the first line is just `[Commands]`. Then, the second line is the first command that you want Setup to run. If you've never heard of `MSIEXEC`, then let me introduce you—it's a command that you'll use a lot when building `cmdlines.txt` files. You see, under Windows 2000, XP, and Server 2003, you install an application using a service called the Windows Installer service. Instead of installing programs with a traditional `setup.exe` program, you install programs by handing a "package" to the Installer. This package is the collection of files that you need to run the program, as well as a set of instructions about how to install the program—"this file goes here, this icon goes on the Start menu, create these Registry entries"—and the Installer looks at the instruction file (which, by convention, has the extension `.msi`) and carries out its instructions. (You'll learn more about this in the chapter on software deployment; I'm just giving you the barest of sketches about how it works here.)

Normally you deploy an MSI-type package using Active Directory, as you'll learn a bit later in this book. But if you want to install an application from the command line, then you'll use a program called `msiexec.exe`. The `/i` option says to install the program from its MSI, silently. Again, you'll learn more about where you get MSI files from a bit later in the book—I just thought that an `msiexec /i` example would be useful.

**TIP** In order to make this work, `msiexec.exe` must be in the `$OEM$` directory; copy it from a functioning Windows 2000 or later OS.

The second command may be familiar to experts in any NT version from 4 on. Sometimes the easiest way to set up NT, 2000, or Server 2003 to work *exactly* the way you want is to apply a bunch of Registry hacks. The `REGEDIT` command offers a pretty neat command-line way to modify the Registry.

For example, I find the AutoRun feature of CD-ROMs *really* annoying. I don't want Server 2003 offering to install every time I pop the Server 2003 CD into a drive just to get a file or two. Now, I *could*

shut off AutoRun by opening up a Registry Editor, navigating down to HKEY\_LOCAL\_MACHINE\SYSTEM\CurrentControlSet\Services\Cdrom, and then editing the entry labeled AutoRun, setting its value to 0. But I don't want to hand-edit the Registry—and that's where REGEDIT comes to the rescue. Just create a four-line ASCII file (call it `CDfix.reg`) with these contents:

```
REGEDIT4

[HKEY_LOCAL_MACHINE\SYSTEM\CurrentControlSet\Services\Cdrom]
"AutoRun"=dword:00000000
```

Note the blank line between REGEDIT4 and [HKEY; you need that. Now open up a command line and tell REGEDIT to apply this change by typing `regedit /s cdfix.reg`; the `/s` means, "Shut up and do it!" so you won't get a message. But reboot your NT or later machine and you'll find that AutoRun is now disabled. Notice how what I could call the REGEDIT "command language" works: the first line is REGEDIT4, then a blank line, then you indicate what key you want to work with, in brackets, and then the value entry. And that line starting with [HKEY\_LOCAL\_MACHINE is just one line when typed, no matter how long. You can put a whole bunch of changes into a single file, or create different .reg files and apply them sequentially.

As with `msiexec.exe`, be sure to put `regedit.exe` in the `$OEM$` folder, or this won't work. And you may be wondering, how did I figure out how to create a file in "REGEDIT format?" Simple. I just highlighted a key that I wanted to apply and then exported it. The exported file turned out to be a simple ASCII format—and an import showed that REGEDIT imports files in the same format as it exports.

### **Using CMDLINES.TXT to Install the Latest Hotfixes**

Here's an even more valuable use for `cmdlines.txt`: preinstalling hotfixes. Hotfixes are files that fix some critical problem in NT 4 or later, things that will eventually make their way into the next service pack but that Microsoft felt were important enough that they couldn't wait for the next service pack. You can find them by going to [www.microsoft.com/security](http://www.microsoft.com/security) and then clicking the Security Bulletins link. Now, that works as of the time that I am writing this, but Microsoft is fond of rearranging their Web site, so if that doesn't work, then just do a search for "security bulletins" on their site and you'll find them. For step 1, download them and collect them into the `$OEM$` directory. They'll have names like `q329834_WXP_SP2_ENU.exe`, which tells you

- ◆ that you can find out about what this fixes in Knowledge Base article 329834,
- ◆ that you apply this to Windows XP Pro (WXP),
- ◆ that it is post-Service Pack 2, and
- ◆ that it works on the version of the operating system that is localized for English.

If you've ever applied a hotfix, then you know that you just run it as a program, which is nice and simple. But what's *not* so simple is that every time you install a hotfix, the stupid hotfix insists that you reboot the computer. Let's see, 16 hotfixes in the post-SP2 world (to use XP as an example)... figure a minute a reboot... I've only got 1000 computers to do this on. Naaah. But there's good news. Fortunately, most hotfixes written since mid-2002 have two options, `-q` and `-z`, that tell the hotfixes to install quietly and not to force a reboot.

Now, if you ever did this with Windows 2000, then you may be expecting me to next talk about a utility called `qchain.exe`, which arranges hotfixes on your system. But I've got some good news for you... QCHAIN is no longer necessary on Windows XP or Server 2003. So just apply the hotfixes and you'll be up to date.

Make sure that all of the hotfixes are in the `$OEM$` directory. Then modify `cmdlines.txt` to invoke each of the hotfixes with the `-q -z` options, and finally run `qchain.exe`. A simplified `cmdlines.txt` with four imaginary hotfixes—I'll spare you the 16-liner that I actually use—might look like this:

```
[Commands]
"msiexec /i \\server\share\somefile.msi"
"regedit /s myhacks.reg"
"q302755_w2k_sp3_x86_en.exe -q -z"
"q303984_w2k_sp3_x86_en.exe -q -z"
"q301625_w2k_sp3_x86_en.exe -q -z"
```

Notice, as I've said before, that you must surround the commands in quotes.

Pretty nifty, eh? I used to roll out test machines without hotfixes mostly because I felt that it took too much time, but too many of those machines fell prey to the Worm of the Week. Now I'm (relatively) secure from the first power-up.

I hope I've convinced you that `$OEM$` holds some pretty powerful capabilities. If you use it and the `OEMPreinstall=Yes` command, then you can extend the power of an unattended installation pretty far.

### GUIRUNONCE

I haven't included this section in my example scripts yet, but I should mention that you can include a section, `[GUIRunOnce]`, in a setup script. It tells Server 2003 to finish installing and then to reboot. Once Server 2003 reboots, it then lets you log in. Once you've logged in, Setup runs the commands in `GUIRunOnce`—typically these are setup commands for applications. They run under whatever user account you logged in as, so if you're installing something that requires Administrator-level privileges, then be sure to log in with a powerful-enough account.

Items in the `[GUIRunOnce]` section must be surrounded by quotes. One example that I've seen of `GUIRunOnce`'s power is the automatic starting and running of `DCPROMO`, the program that creates domain controllers. You'll learn more about `DCPROMO` in Chapter 8.

So you can see that you can do pretty neat things with scripts and the `OEMPreinstall` features. But don't let me oversell this; let's remember that there's still that chicken-and-egg problem of "how do I get on the network to get to the network share in the first place?" We'll solve that problem next, with Remote Installation Services, or RIS.

## Installing Server 2003 with Remote Installation Services

Well, by now, you've probably tried shoving the CD-ROM into some computer's drive and installing Server 2003. You may well have had some luck at it and found that after a bit of twiddling, you could make it work quite well. "Cool," you might have thought, "Installing Server 2003 will be a snap."

But then, you probably realized that you'd have to do it for *several hundred machines*. Let's see now, doing the exact same set of twiddling several hundred times would take...well, more patience and time than many of us have. It would be nice to be able to spend a fair amount of time on just one computer, getting it just right, and then to "photocopy" that configuration onto dozens or hundreds of other computers.

And for years, many of us did just that. Back when I worked in training labs teaching Windows 3 running atop DOS 5, it was a simple matter to just boot up a workstation with a floppy containing the Novell client software, format the workstation's C: drive, and then XCOPY an entire drive image from a Novell shared volume onto the workstation. The whole process was completely automated once I got it started, and took no more than about 20 minutes.

Later on, with the advent of bigger operating systems like Windows 95, drive copier programs like Ghost and Drive Image Pro came out. These drive copiers didn't care what files were on a computer; they'd just copy a physical hard disk or partitions from that hard disk to a network folder for you. Then you could set up a new computer to look just like the prototypic computer by booting the new computer from a floppy and then pulling down the Ghost or Ghost-like (would that be "Ghostly"? ) image.

That worked fine for Windows, but not for NT, as NT is secure, and so each computer with NT installed on it has long and machine-specific strings of numbers embedded in it, numbers called security IDs, or SIDs. Cloning one machine's NT image onto thousands of machines would lead to thousands of machines with identical SIDs. While that might not *sound* terrible, it could have some very bizarre side effects.

For example, suppose you start up a new PC with a cloned copy of NT Workstation or Windows 2000 Professional on it, logging in the first time as the default administrator. The first order of business is then to create a local user account for yourself. But inside NT, that account would get an SID. As this is the first account created besides the built-in Administrator and Guest accounts, that account's SID will be the first available in the range of SIDs on this machine.

Now imagine that Janice down the hall, who has a machine containing the exact same cloned image on her system, also logs in to her new machine as its default administrator and creates herself an account. It'll have a different name than your account—but that won't matter. NT doesn't really care what your name is; it cares what your SID is. And what value SID does Janice have? Well, as it's the first created account, you guessed it—her account now has the same SID as yours.

What does that mean? Well, suppose you made your local account an Administrator account. That means that when she's logged in to her own machine with her own account, she can use Windows 2000's remote control tools to do administrator-like things to your system over the network. That's not a good thing, unless you and Janice are really good buddies.

As a result, disk-cloning vendors have come up with "SID scrambler" programs. You copy the cloned image onto a new machine and then run the SID scrambler. It creates a unique set of SIDs on the newly cloned machine and all should be well. Microsoft, however, says that the SID scramblers from the two big players, Symantec's Ghost and PowerQuest's Drive Image Pro, won't do the whole job. I honestly don't know if this true or if it's just Microsoft... well, being Microsoft. In any case, now Microsoft has a method for rolling out a single workstation image to dozens, hundreds, or thousands of machines while simultaneously ensuring that each machine has a unique SID. It's a tool called the Remote Installation Services (RIS). In this section, you'll learn how to set it up and how to get those images out to all of those PCs hungering for an operating system.

RIS solves the other big rollout problem, as well: the “how do I get a computer with nothing on its hard disk connected to the network so that I can do a network-based install?” problem. You’ll see how to do that in this section, but before I go further, let me offer this warning:

**WARNING** *I’ve included RIS in this chapter because it’s a rollout and deployment tool, but RIS won’t work unless you have an Active Directory infrastructure in place and some knowledge of another infrastructure tool called the Dynamic Host Configuration Protocol (DHCP) and are also comfortable with file and directory permissions on NTFS disk drives. If any of that sounds a bit scary, then just skip this RIS section and go on to the Sysprep section. Then, once you’ve gotten through the TCP/IP and Active Directory chapters, come revisit this section.*

## RIS Overview

RIS lets you designate a server or a set of servers as *RIS servers*. A RIS server contains the files necessary to install Windows 2000, XP, or Server 2003 onto a computer from across the network. RIS can deliver an operating system to a waiting PC in one of three formats:

**Simple I386-based Installation** In this simplest form, RIS is just a place to store the installation files for various versions of NT from Win2K on. How is it different from just putting I386 onto a directory on any old file server and then sharing that directory? Not very much, except in one important way: it solves the “how do I get to the network in the first place?” problem. You can go to the PC that you intend to put 2000, XP, or Server 2003 on and boot it with just one floppy, and you’ll be off and running, no messing around with the DOS Client for Networks or the like. Of course, once this installation starts up, you must sit at the computer and answer all of Setup’s questions, baby-sitting the computer while Setup runs.

**Scripted I386 Install** This installation is like the preceding situation, with the added benefit of unattended installation. You just go out to the target PC, boot the floppy, and away it goes. These first two options are called *flat image format* images. (If you’ve been using this since Windows 2000 then you’ll recall that they were called “CD images” in 2000.)

**Complete System Image with Minimal Setup Interaction** This option is really the more interesting option for many people. You build an entire prototypical machine running Windows 2000 Pro or Server, XP, or Server 2003, complete with applications. Then you use RIS to create an image of that machine on a RIS server. You then boot the target PC with a RIS-built floppy again, and RIS transfers the entire disk image, complete with operating system and applications, to the target PC. It’s not entirely hands-off, however, as it needs a bit of machine-specific customization: you need to punch in a unique machine name, for example. This kind of image is called a *RIPrep image format* image.

## New-to-Server 2003 RIS Goodies

RIS was neat under Windows 2000, but Windows Server 2003 offers several bits of good news. First, as I’ve mentioned already, 2000 only deployed Windows 2000 Professional images. Server 2003’s RIS will roll out Windows 2000 Server, Windows 2000 Professional, Windows XP Professional, Windows XP Home, or Windows Server 2003 images. Great news (and it’s about time)!

Second, as you’ve already learned, RIS is a neat way to roll out operating systems to computers. But getting those computers to talk to a RIS server requires that the computers (call them “RIS

clients”) be built in a particular way. Without this RIS client support, also called PXE support, you can’t use RIS to put an OS on a computer. But RIS has always had a workaround in that it will create a floppy disk that will support network cards for client systems that aren’t set up to get the benefits of RIS. That floppy has been revised for Server 2003 to support a wider range of systems.

Finally, RIS under Windows 2000 always had the annoying feature of sending your password *in cleartext* over the network cable when you first logged on. It only happened once, but it was still a bad idea security-wise. RIS for Server 2003 and its revised clients now encrypt passwords before putting them on the wire.

## RIS Limitations

Before getting too excited about RIS—it’s nice, but the Ghost guys needn’t worry about being put out of business—let’s look at what it *can’t* do.

### RIS CLIENTS MUST HAVE PARTICULAR PCI NETWORK CARDS; SOME LAPTOPS WON’T WORK

I’ll cover this later, but you can only get a RIS system image onto a computer that knows how to ask for one, and the only way that a system knows how to ask is if the system supports something called the Preboot Execution Environment (PXE) protocol, version 0.99C or later. If you’ve seen computers that can be “network managed,” then there’s a good chance that the computer has PXE support in its BIOS. In addition to PXE support, you’ll need a NIC that works with PXE. No ISA NIC that I know of supports PXE, and I’ve only heard rumor of PCMCIA/PC Card/CardBus laptop NICs that support PXE. Most PXE-compatible NICs are PCI cards. Laptops aren’t completely shut out, as some laptops now ship with an integrated NIC built to the “mini PCI” specification—I’ve seen some IBM ThinkPads that fit in this category. Such a laptop might be RIS-compatible. (And believe me, RIS’s convenience is sufficiently great that PXE/mini-PCI compliance will be a “must-have” characteristic of all of my future laptops!)

In Server 2003 and later, you’ll find that many laptops come with an integrated Ethernet card; again, take a moment and ask the vendor two questions: first, is it mini-PCI (rather than PCMCIA) and, second, does it support “network boot?” If so, the chances are good that such a machine will work with RIS.

What if your computer doesn’t support PXE? RIS comes with a program called **RBFGEN.exe**, the Remote Disk Boot Generator (RDBG). (It *was* Remote Boot Floppy Generator in 2000 but Microsoft renamed the program without renaming its file, so the program’s abbreviation is RDBG but its file name is **rbfg.exe**.) It’s a program that lets your computer support PXE, so long as your computer has one of the particular 32 NICs that **RBFGEN.exe** supports. It’s annoying that RIS doesn’t really support pre-year 2000 laptops and most pre-1998 desktops, but truthfully that’s often the case with Windows technologies: the coolest features of any version of Windows often require some new technology. I often find myself telling audiences that “the latest version of NT will solve many of your existing problems; all you have to do to get those benefits is to replace all of your hardware and software!”

### CERTAIN SERVICES KEEP RIS FROM WORKING

It’s great that Server 2003 lets us use RIS on both servers and workstations—2000’s RIS didn’t—but you can’t use RIS on *every* kind of server. You can’t, as far as I can see, use RIS on a server that is acting as a DHCP or RIS server, or on a server that acts as a domain controller.

### RIS CAN ONLY IMAGE THE C: DRIVE

When you build a prototype computer whose image you will then propagate all over the enterprise, you'd better build a computer with just one hard-disk partition C:. RIS will merely copy the C: drive and whatever's on it.

### RIS HAS A FAIRLY SPARSE ADMINISTRATIVE UI

While RIS doesn't require a *lot* of administration, there are few tasks that you'll do frequently, and RIS doesn't provide a very good way to do them. For example, if you had a RIS server that contained many system images, but you didn't want every user to see every possible image (which is very likely—odds are that you'd have one image for the accounting folks, another for the programmers, and so on), then the only way to restrict the choice of images that a user sees is through NTFS permissions rather than via some simple administrative interface.

### RIS SEEMS NOT TO WORK ON MULTIHOMED SYSTEMS

I've been using RIS on Windows 2000 for years and Server 2003 for a while and in both cases I have found that putting RIS on a system with more than one NIC is simply asking for trouble. I have no idea why this is, but I've run into far too many situations where I've got an up-and-running (in theory) RIS server that simply cannot see any clients. Other things work fine on the server, but RIS is just plain deaf on multihomed systems. I may simply be doing something wrong, but in my experience multihomed RIS servers are not reliable, so I don't recommend them.

## Steps to Making RIS Work

The first time you set up a RIS server, it can seem a bit complicated if you're not ready for it, as RIS is a bit different from other Server 2003 services. What I'm referring to is that to install most Server 2003 network services, like IIS or WINS, you just install them on a server, reboot the server (and many times you needn't even reboot), and you're done. Setting up RIS on a server, however, requires fiddling a bit with Active Directory.

**TIP** *Before you can use RIS, you must have Active Directory running. It seems to work fine with either a 2000-based or Server 2003-based AD, but you need AD. As you'll learn later or you might already know, you can't have AD without a functioning DNS server that supports RFC 2782 SRV records and RFC 2136 dynamic updates, as described in Chapter 8.*

**WARNING** *In order to explain how to set up RIS, I'll need to assume that you already know what a DHCP server is. If, however, you have not worked with previous versions of NT and so probably don't know DHCP, then don't worry about it—just skip this section until you've learned about TCP/IP, DHCP, and Active Directory in the next few chapters, then return to this section. (And in that case, please accept my apologies for making you jump around the book.)*

To get a RIS server working, follow these steps:

1. Set up a Server 2003 system and make it a member of an Active Directory domain. The server must have a fairly large NTFS drive available, and that drive can't be the boot drive or the drive containing the operating system. (When I say "drive" here I mean "partition." You needn't have two physical hard disks for a RIS server, but you *do* need to have at least two logical drives.)
2. Authorize the soon-to-be-RIS server in the Active Directory as a Dynamic Host Configuration Protocol (DHCP) server, even though it's *not* a DHCP server.

3. Add the Remote Installation Services service to the server and reboot it.
4. Run RISetup, the Remote Installation Setup Wizard, to prepare the large drive for receiving RIS images and to put an initial image on the drive—it's just a simple copy of I386.
5. At that point, the RIS server is ready. You can add new images to it with a wizard called RIPrep.

We'll examine each of these steps in the following pages.

## Getting Ready for RIS

RIS's job is to let you take a PC with an empty hard disk, attach the PC to your enterprise network, put a RIS-created floppy disk into the PC's A: drive, and boot the PC. The small program on the floppy disk is just smart enough to get an IP address for the PC, then locate an Active Directory domain controller and ask the Active Directory domain controller where to find a RIS server. Once the PC finds the RIS server, it can then start the process of pulling down a particular system image so that the PC becomes useful.

### NECESSARY INFRASTRUCTURE

But RIS needs some infrastructure to make all of this work right. The PC gets an IP address from a DHCP server, so you'll need at least one DHCP server running in your enterprise to make RIS work. (In case you've never worked with an IP-based NT network before, DHCP's job is to automatically assign unique network addresses to each server and workstation on the network. TCP/IP *requires* that every machine have a unique IP address, or the network software just doesn't work.) Once it has an IP address, the PC finds an Active Directory server by looking it up in DNS—so you'll need a DNS server. And the PC can't query an Active Directory domain controller for the location of a RIS server unless you've got an Active Directory domain controller—so you'll need an Active Directory–based domain (as opposed to a bunch of Server 2003s in a domain built out of NT 4 domain controllers). Of course, if you're running an Active Directory–based domain, then you've *got* to have DNS running, so the simplified list of things you'll need before RIS will work is an Active Directory–based domain and at least one DHCP server.

### A DRIVE FOR SIS

Furthermore, the RIS server needs a partition to store the RIS images. For some reason, RIS will not store images on the boot partition—which is usually drive C:—or the system partition, which is the drive that contains \windows and the other NT system files.

**NOTE** Please, *don't write me letters explaining to me that Microsoft's definition of "boot drive" is the one that contains \winnt or \windows, and their definition of "system drive" is the drive that you boot from. I know that's what they call it, but it makes no sense, so I'm going to tend to say "system drive" for the one with the operating system, and "boot drive" for the drive that you boot from. I know, that's not what Microsoft told you, but to quote John Candy from the movie Planes, Trains, and Automobiles, "If they told you that wolverines made great pets, would you believe that too?"*

I found this you-need-a-drive-that-is-neither-system-nor-boot thing kind of frustrating the first time I went to set up RIS, as the server that I intended to put RIS on had only two drive letters and Windows 2000 (this was back when I first tried RIS, under Win2K) installed on the D: drive. C: was the boot, D: the system, and so RIS wouldn't install. I reinstalled Windows 2000 on the C: drive, freeing

up D:, and RIS worked fine. You can have other things on RIS's drive, like files of other types; you just can't have the system files on the drive. Remember that while RIS will make an image of whatever filesystem is on the original workstation, it must be placed onto an NTFS partition on the server.

While it's not entirely clear to me why RIS is allergic to system files, there's a very good reason why it wants a drive pretty much to itself. Imagine a RIS server that contained 20 system images—how much space would that need? Well, Windows 2000 Professional (to use the example of one OS that RIS supports) takes up about 450MB on a hard disk, so let's be generous and say that the applications added to the image only total 50MB, leading to a 500MB image; it's just easier to calculate this way. Ten half-gigabyte images totals 5 gigabytes. But now let's look more closely at those 10 images. The vast majority of the files in the images are identical: For example, each image contains a file named `Drivers.cab` that's nearly 50MB in size, and the file is exactly the same for each of the 10 images. That's a terrible waste of space—500MB to store 10 identical copies of a 50MB file!

RIS solves that problem with a service called the Single Instance Store, or SIS. SIS is a service called the SIS Space Groveler (is that a great service name, or what?) that runs in the background and searches the directory that RIS uses to store system images looking for duplicate files. It then frees up space by deleting the duplicate files, putting in their place a directory entry that makes it appear as if the duplicate is still in place. In actuality, however, the duplicate is no more than a sort of pointer to the complete copy of the file. Clearly a trick like this will require a bit of magic, and that magic comes from a combination of the NTFS of SIS and Windows 2000 and later—that dedicated-to-RIS drive must be an NTFS volume.

#### EXTENDING SIS: SIDE NOTES

It's a shame that SIS only loads as part of RIS; I could easily imagine many cases wherein recovering space from duplicate files could be beneficial, such as in the case of a server containing hundreds of users' home directories—there's likely to be *plenty* of duplication there.

Actually, if you're feeling a bit brave, then you actually *can* get SIS to run on other drives, according to Knowledge Base article 226545. It says that SIS identifies which drives to do its magic on by looking for three things:

- ◆ First, the drive must be an NTFS drive.
- ◆ Second, the drive must contain a hidden folder in its root named `SIS Common Store`.
- ◆ Finally, that `SIS Common Store` folder must contain a file named `MaxIndex`.

I honestly have not tried this myself, but I pass along the information in case it's of help. So, for example, to apply SIS to any given file server, just install the RIS service on that system (even if you do not intend to make the server a RIS server), place a hidden folder named `SIS Common Store` in the root of whatever drive you want SIS to work on, and don't forget `MaxIndex`.

While I'm on the subject of advanced SIS maintenance, here's another tidbit from the Knowledge Base, article 272149. You can, if you want to, tell SIS to ignore a particular directory in this way:

1. Start up a Registry-editing tool.
2. Navigate to the key named `HKEY_LOCAL_MACHINE\SOFTWARE\Microsoft\Windows NT\CurrentVersion\Groveler\ExcludedPaths`.
3. Create a new value entry with any name that you like, of type `REG_SZ`.
4. In the data for that value entry, include the name of the directory without the drive letter.

For example, suppose I wanted SIS to ignore a directory named `mystuff` on a SIS volume. I'd just go to the key named above and create a new value entry. I could call that value entry `NoMyStuff`. I'd make it of type `REG_SZ`, and in the entry I would place the string `"\mystuff."` Then either I'd have to reboot to see the changes take effect, or I'd have to stop and start the SIS Space Groveler service.

**WARNING** *Be aware, however, that I'm told that unless you back up this drive with a backup program that is SIS-aware, then SIS drives aren't backed up properly. Sometimes the backup program thinks that it's backing up a file, but it actually just backs up SIS's pointer to a drive. Restoring that pointer without the file is usually not helpful.*

## Authorizing RIS in Active Directory

Microsoft figured—probably rightly—that you wouldn't want just *anybody* putting a RIS server on the network. So before you can get the RIS service working on a server, that server must be authorized in the Active Directory. For some reason, however, you don't authorize it as a RIS server; you authorize it as a DHCP server.

To do that, find a DHCP server and log in to it with an account that is a member of the Enterprise Administrators domain group. Click Start/Programs/Administrative Tools/DHCP. Click Action on the menu bar, and you'll see the option Manage Authorized Servers; click that and you'll see an option.

Manage Authorized Servers. You then see the list of currently authorized DHCP servers like the one in Figure 5.13.

**FIGURE 5.13**

List of current authorized servers

Here, you see that I've already got a server authorized named `dun.win2ktest.com`. Click `Authorize` and you'll get a dialog box like the one in Figure 5.14, letting you punch in the IP address of the server that you're going to make into a RIS server.

**FIGURE 5.14**

Entering IP address of RIS server

Click `OK`, and it'll confirm your choice, as Figure 5.15 shows.

**FIGURE 5.15**

Confirming the new server

**NOTE** If you don't know the IP address of the soon-to-be RIS server, go over to that server and log in to it. Then open a command prompt (Start/Programs/Command Prompt), type **ipconfig**, and press Enter. It will report the IP address; if you have several IP addresses, take the one in the section labeled *Ethernet Adapter Local Area Connection* rather than *PPP Adapter*.

Now that Active Directory is ready for RIS, let's get RIS ready.

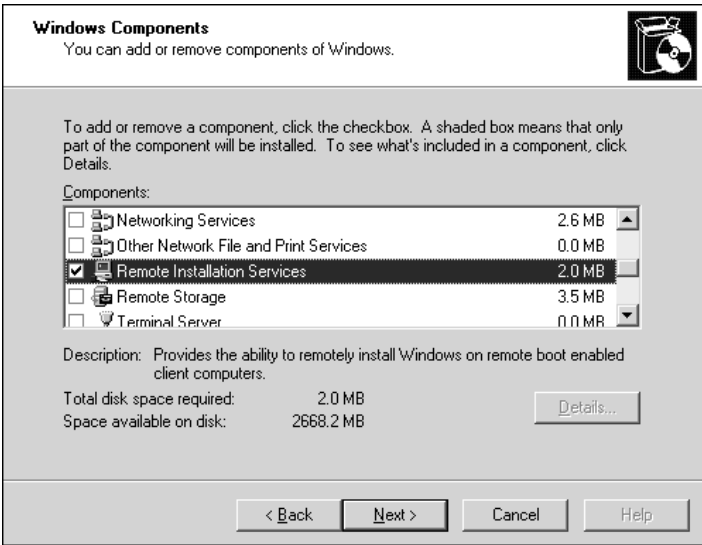

### Installing RIS

Next, you'll put the RIS service on the server:

1. Log in to the server that you want to add RIS to, using an Administrator account, and open the Control Panel (Start/Settings/Control Panel).
2. Start the Add/Remove Programs applet.
3. Choose the Add/Remove Windows Components icon.
4. A wizard screen labeled Welcome to the Windows Components Wizard will appear; click Next and it will show you the optional server components, as you see in Figure 5.16.

**FIGURE 5.16**

Windows Components screen

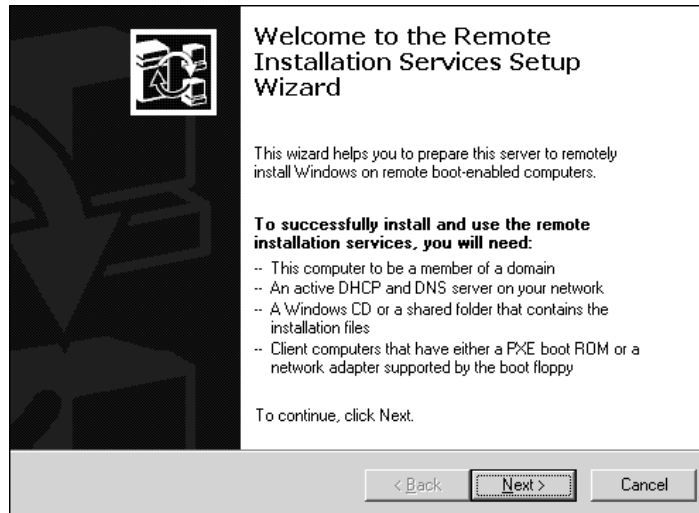

5. Scroll down and check the box labeled Remote Installation Services. Then click Next and Finish.
6. You'll be prompted to reboot, so reboot the server.

## Running RSETUP

When installing most Server 2003 services, you just choose the option in Windows Components, wait for the Control Panel to pull the new service off I386, reboot the computer, and it's up and running. RIS is a bit more work than that, however, as RIS must claim its drive and set up SIS. For good measure, RIS also creates a first image. That first image is the simplest one possible—it's just a copy of the I386 directory from the Windows Server 2003 CD-ROM, Standard Edition. (You could alternatively offer it XP Pro, XP Home, 2000 Server, or Professional. For that matter, you could offer it any version of Server 2003 as well.)

Log in to the would-be RIS server with an administrative account and run RSETUP (either from a command prompt or click Start/Run, fill in **rsetup**, and press Enter) and the Remote Installation Services Setup Wizard starts. The initial screen is shown in Figure 5.17.

**FIGURE 5.17**  
RISetup initial  
screen

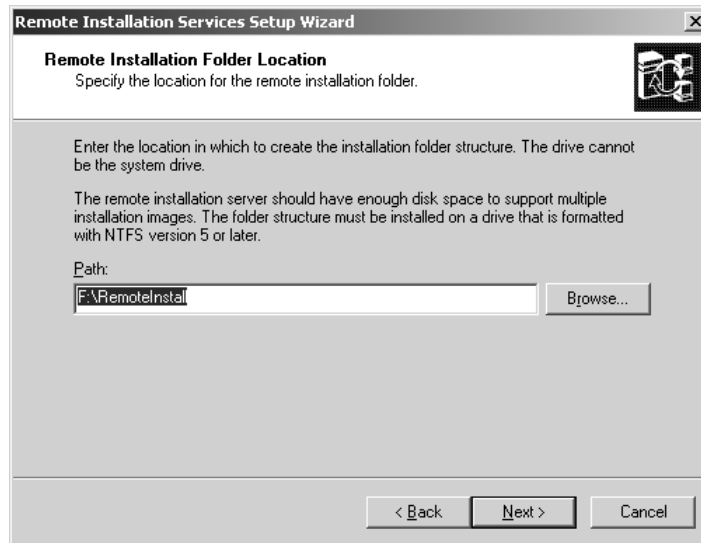

Click Next and the wizard will quickly scan your drives looking for a likely place to keep RIS's files. In my case, it found drive F:. It wants to create a directory named **RemoteInstall**, as you can see in Figure 5.18.

After you click Next, RSETup will ask you if you want the server to respond to requests from PCs for operating systems, as shown in Figure 5.19. Inasmuch as you don't have any useful images on the RIS server at the moment, tell the server not to respond to those requests.

**FIGURE 5.18**

Suggested location  
for RIS images

**FIGURE 5.19**

Telling RIS to ignore  
requests until we're  
done configuring it

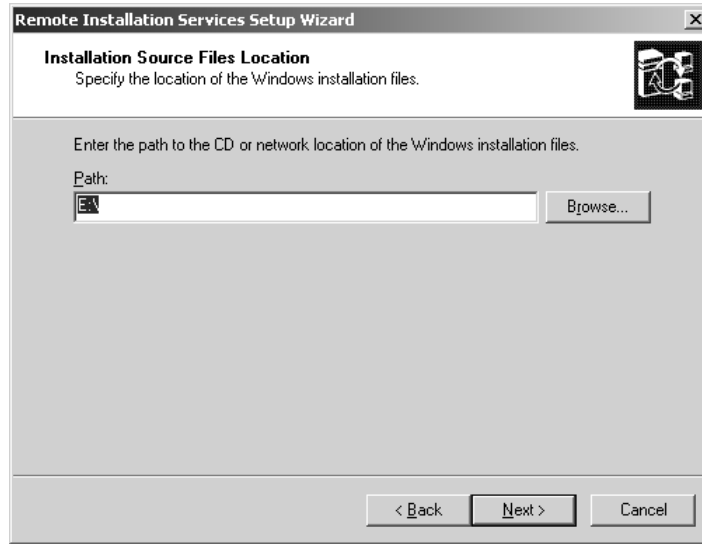

Click Next and, as you can see in Figure 5.20, RIS will ask where to find an I386 of some type.

Now's a good time to pop the Windows 2000 Professional, Server 2003, XP Pro, or whatever kind of disc you like into your CD-ROM drive. Alternatively, if you have some operating system's I386 directory on one of your hard disks, you can point RISetup there. (Think how useful this

is—you can pre-load a service pack onto an I386 on a hard disk and RIS then rolls your pre-SPed images!) Click Next and you'll get the screen you see in Figure 5.21.

**FIGURE 5.20**

Looking for a set of installation files

**FIGURE 5.21**

Folder name for the simple I386 option

Recall that a RIS server can have many images on it. Each image gets a folder within the `RemoteInstall` folder. This first, simple I386 image needs a name too, and RISetup suggests just `Windows`, which is probably fine for our needs. Click Next to continue and you'll see a screen in which you can describe the image, as shown in Figure 5.22.

**FIGURE 5.22**

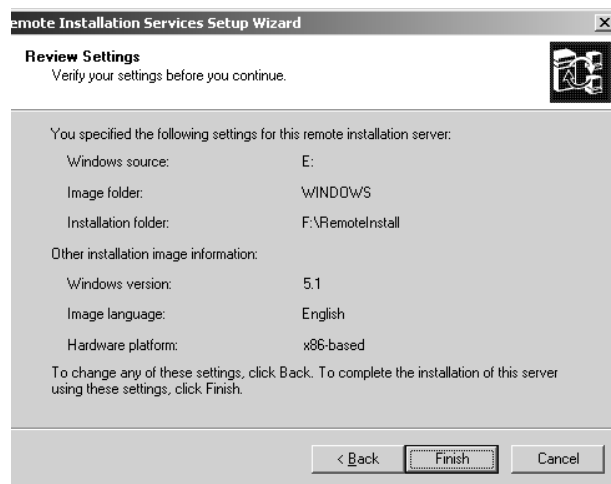

Describing the simple image

When someone plugs a new machine into the network and boots from the RIS-prepared boot floppy, he may be offered several choices of OS images to download. (After all, one of the things that RIS is supposed to offer is the ability to keep a bunch of images around for different uses.) This screen lets you add some descriptive text. Click Next and you'll get a summary "this-is-your-last-chance" screen like the one in Figure 5.23.

**FIGURE 5.23**

Checking on the settings

Click Finish and go away for a while. A screen like Figure 5.24 will appear.

As you see from the screen, RISetup has a lot to do. It copies the **I386** files over to its local folder, starts SIS, and does other housekeeping. Expect it to take 10 minutes or so at least.

**FIGURE 5.24**

Progress indication  
screen

## Checking That RIS Is Running

RIS is a mite sparse on administrative interfaces, as you'll see, so it can be hard to be 100 percent sure whether it's up or not. The best way to see if RIS is running is to go to the Services snap-in (Start/Run and type `services.msc` or look under Services in Computer Management) and look to see that these services are running:

- ◆ Remote Installation
- ◆ Single Instance Storage Groveler
- ◆ Trivial FTP Daemon

You'll also see a number of events in the Event Viewer's Application log:

- ◆ An Information event ID 4096 from Groveler
- ◆ An Information event ID 100 from ESENT
- ◆ An Information event ID 1003 from BINLSVC
- ◆ An Information event ID 1024 from BINLSVC
- ◆ Finally, an Information event ID 4097 from Groveler

Now, to look at these events, you'd think that everything is hunky-dory with RIS, and perhaps indeed it is. But remember that you have to approve RIS in Active Directory as if it were a DHCP server. If you don't do that, you still get all of those comforting-looking events in the Application log. To see if RIS is actually *not* running because it's not approved as a DHCP server in AD, flip over to the System log, where you'll see an event ID 1046 from DhcpServer like this:

The DHCP/BINL service on the local machine, belonging  
↳ to the WindowsAdministrative domain win2ktest.com,  
↳ has determined that it is not authorized to start.

↳ It has stopped servicing clients. The following  
 ↳ are some possible reasons for this...

And it then goes on to enumerate some possible reasons, but basically it's time to ensure that your RIS server can contact the AD and that it's approved as a DHCP server. After authorizing a RIS server in DHCP, then in theory all you need do is to restart the Remote Installation Service on the RIS server, but in my experience it's best to reboot the RIS server.

## Enabling RIS for Clients

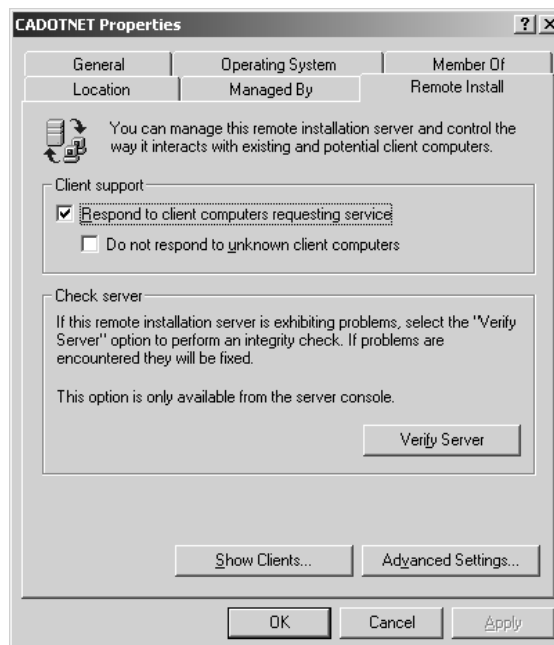

Amazingly, after RISetup does its work, the RIS server does not reboot! But it's time to put the RIS server to work, or at least to respond to requests for I386 installs. Make sure you are logged in as a domain administrator at the RIS server, then click Start/Run, fill in DSA.MSC, and press Enter. If the RIS server happens to be a domain controller, then it's even easier—just click Start/Programs/Administrative Tools/Active Directory Users and Computers. (Notice that you've got to start the DSA from Start/Run because for some reason Setup *installs* the Active Directory tools on all servers, but only puts entries for those tools on the Start/Programs menus of domain controllers.)

In the left pane of the window, you'll see an icon depicting several computers, intended to represent your domain. Open it (double-click or click the plus sign) and it'll open to some folders, including one named **Computers**. It's likely that your RIS server is there. Right-click the RIS computer's icon and choose Properties. You'll then see a properties page.

On the property page, you'll see several tabs, with one labeled Remote Install. Click that and you'll see a page like the one in Figure 5.25. There's not much in the way of an administrative and management interface for RIS, just this page and a few tabs on the Advanced screen, which you'll see a bit later.

**FIGURE 5.25**

Remote Install tab of the properties page for RIS server

On this screen, there's not all that much to do except to turn it on. Check Respond to Client Computers Requesting Service, and it's ready to go!

## Installing an OS on a Workstation from the RIS Server

It's working; let's give it a try. The RIS server is up on the network and the Active Directory knows about it. Suppose I have a computer that I want to put some RIS-compatible OS on (call it the target computer); these are the steps.

The target computer gets the attention of the RIS server through something called the Preboot Execution Environment protocol, abbreviated PXE and pronounced "pixie." Some computer vendors sell PCs with PXE in the BIOS. To connect a PXE-equipped PC to a RIS server, you don't even need a floppy disk; you just plug it into the network, turn it on, and you'll eventually get a prompt like "boot from the network y/n?" If you let it boot from the network, it'll first seek out a DHCP server, then find an Active Directory server with DNS, and kick off RIS—all the code for doing that is in the PC's BIOS ROM.

**NOTE** *You may have to adjust your system's CMOS settings in order to tell it to try to boot from PXE rather than the hard disk, floppy, or CD-ROM. Exactly how you do that depends on your system. On my IBM T21 ThinkPad, I press F12 when I turn on the computer to tell it to choose to boot from the Intel Boot Agent. I've seen Dells where you tell it to boot "fromMBA." Basically, though, here's the approach: start up your system's BIOS setup routine. You'll usually (sorry for the weasel words, but this does vary from system to system, and not every system even allows you to do a PXE boot) see an option to arrange the boot order. On my T21, I get the five options for devices to boot from: the floppy, the hard disk, the CD-ROM, the Intel Boot Agent, and Network Boot, which I haven't found a use for yet. I can then rearrange the boot order, so as to tell my system, "First try to boot from the Intel Boot Agent, and if that's not available then try the CD-ROM, and if that doesn't work then boot from the hard disk, and if that doesn't work then boot from the floppy, and never try to boot from Network Boot."*

What's that you say, your system isn't PXE compliant? Well, you're not barred from the RIS fun; you've got two ways to make your system a possible RIS client.

First, you could buy a PCI NIC that has a ROM on it that contains a PXE client. Believe it or not, I've got a bunch of five-year-old test machines that run 400MHz Pentiums and they're all PXE-bootable. How do I accomplish this? I just bought the "managed" versions of the Intel and 3Com Ethernet cards and replaced my old NICs with the new "managed" NICs. "Managed" usually means there's a PXE-compatible boot ROM on the board, so I'm instantly PXE-friendly.

But if you don't feel like buying a new NIC, all's not lost. Microsoft includes a utility with RIS that will generate bootable floppy disks that replace the PXE BIOS for the PXE-deaf among us. It's called `RBFGE.exe`, and you'll find it on any RIS server in the `\RemoteInstall\Admin\I386` directory. Run it and you'll see a screen like Figure 5.26.

Running it is pretty simple—just put a floppy into A: and click the Create Disk button. A great improvement over its older cousin, the Network Client Administrator, the Remote Boot Disk Generator (RBDG) doesn't require that you provide it with blank floppies. That's the good news.

The *bad* news is that this will only work if your computer has PCI expansion slots and one of the 32 supported PCI network cards. (The good news is that under 2000 it was only 25 network cards.) Fifteen years' experience with network software has made me conservative enough that almost all of my NICs are made by 3Com—not because I think 3Com makes a better card, but because I don't

want to have to search after drivers—and so RBDG supports all of my machines. But that might not be the case for all of your systems.

**FIGURE 5.26**

Remote Boot Disk  
Generator dialog box

Actually, let me take that back. Not *all* of my systems will work with an RBDG floppy—my older laptops won't. As I mentioned earlier, only systems with mini-PCI type integrated network cards have a prayer of being supported. The Server 2003 flavor of RBDG has, however, a mini-PCI driver for 3Com NICs, which is good if your laptop has that kind of NIC. My newer laptops, however, have either the Intel mini-PCI or the Realtek mini-PCI. Does that leave me out? No, because fortunately my laptops not only have mini-PCI cards in them, they also have PXE clients in their ROMs, so, again, all's not lost if your system doesn't have one of the Magic 32 NICs in it.

There's some more bad news about RBDG. What about the fact that new network cards appear all of the time? It's not unreasonable at all to suggest that a year after Server 2003's release you might find yourself trying to install an OS on a system with a brand-spanking-new network card that RBDG simply doesn't know how to handle. How do you introduce RBDG to a new set of drivers?

Unfortunately, you can't. Microsoft promised back in the Windows 2000 days that they would "periodically" update RBDG.exe, but the fact is that they never did. So let me say again that you may never need a PXE boot disk if you're buying new computers. Any computer with a PXE BIOS and an integrated NIC can use RIS without any floppies at all—these computers have been *designed* to support RIS, so to speak, and so won't need a floppy. As time goes on, it's reasonable to hope that more and more computers will be "net-bootable."

In any case, if you generate a PXE boot disk, stick it into the target machine and boot the machine. You'll see a screen with something like the following text:

```
Microsoft Windows Remote Installation Boot Floppy
Copyright 2001 Lanworks Technologies Co. a subsidiary of 3Com Corporation
All rights reserved.
3Com 3C90XB / 3C90XC EtherLink PC
Node: 00105AE2859F
DHCP...
TFTP.....
Press F12 for network service boot
```

Press F12, and a text screen appears that says:

```
Welcome to the Client Installation wizard. This wizard helps
↳you quickly and easily set up a new operating system
↳on your computer. You can also use this wizard to keep
↳your computer up-to-date and to troubleshoot computer
↳hardware problems.
In the wizard, you are asked to use a valid user name, password,
↳and domain name to log in to the network. If you do not
↳have this information, contact your network administrator
↳before continuing.
Press Enter to continue
```

You are looking here at some client software downloaded from the RIS server called the Client Install Wizard. Look back to the first screen and notice the TFTP with all the periods after it—that was the Trivial File Transfer Protocol transferring a very simple text-based operating system to your computer.

***TIP** But what if you don't get a response from PXE? If your system just searches and searches for DHCP but gets no response, then check your network switches. I once worked at a site where we couldn't get a PXE boot to work to save our lives. Then someone noticed that the Ethernet switches had a feature called "minimal spanning tree" enabled. Apparently it filtered or slowed down the DHCPDISCOVER broadcasts that the workstation did to find a DHCP server, and so the workstation never got an IP address from DHCP. So check your network infrastructure before you assume that a RIS client has bad hardware. And if it still doesn't work, then think about putting a network packet analyzer on the network segment so that you can watch the DHCP/TFTP process. Also check the NIC. I had one RIS server that worked perfectly for 90 percent of my workstations, but 10 percent just plain couldn't see it. The problem? It had a 10-megabit NIC and they had a 100-megabit NIC. Why that should trouble some 100Mb NICs and not others is a mystery to me, but you might want to be careful about matching 100Mb client NICs with 100Mb NICs on RIS servers. As I've said earlier, avoid multi-NIC systems for RIS servers.*

What's kind of interesting about this initial RIS setup screen is that the introductory screen, and all of the other text screens that you'll see from the Client Install Wizard, are built on a slightly modified version of HTML. You can see the "source code" for that first screen by looking on the RIS server in \RemoteInstall\OSChooser\English directory and examining the file named `welcome.osc`. It looks like the following:

```
<OSCM>
<META KEY=ENTER HREF="LOGIN">
<META KEY=F3 ACTION="REBOOT">
<META KEY=ESC HREF="LOGIN">
<META KEY=F1 HREF="LOGIN">
<TITLE> Client Installation Wizard
  Welcome</TITLE>
<FOOTER> [ENTER] continue </FOOTER>
<BODY left=5 right=75>
<BR>
<BR>
<BR>
```

```
Welcome to the Client Installation wizard. This wizard helps
↳you quickly and easily set up a new operating system
↳on your computer. You can also use this wizard to keep
↳your computer up-to-date and to troubleshoot computer
↳hardware problems.
```

```
<BR>
```

```
<BR>
```

```
In the wizard, you are asked to use a valid user name, password,
↳and domain name to log in to the network. If you do not
↳have this information, contact your network administrator
↳before continuing.
```

```
</BODY>
```

```
</OSCM1>
```

If you've got any familiarity with HTML, then understanding this is simple—things surrounded by angle brackets `<>` are *tags*, commands to the computer. They're often in pairs like right and left parentheses—`<oscm1>` starts the “program,” `</oscm1>` ends it. That forward slash ( / ) indicates that it's the end of a command—for example, `<TITLE> Client Installation Wizard</TITLE>` indicates that there's a command, `<TITLE>` (which, as you can guess, puts a title in the screen), then there's the text that's supposed to go into the title, and then `</TITLE>`, which says, “That's the end of the title text.” Again, they're like left and right parentheses. The `<META KEY>` commands tell the wizard what to do when you press particular keys. `<META KEY=ENTER HREF="LOGIN">` means, “When the user presses the Enter key, run the program `login.osc`.” `<META KEY=F3 ACTION="REBOOT">` means that if the user presses the F3 key, then just reboot the system.

My intent here isn't to document the entire programming language—Microsoft hasn't completely documented it yet, to my knowledge—but to point out that you could *easily* change the generic welcome text to something customized to your particular company.

Anyway, once you press Enter, you're prompted for a username, password, and domain. The account that you log in with must have the ability to create new computer accounts. You'll next be advised that the process will delete any data on the existing hard disk:

```
The following settings will be applied to this computer installation.
```

```
Verify these settings before continuing.
```

```
Computer account: ADMINMARK1
```

```
Global Unique ID: 00000000000000000000000000000000105AE2859F
```

```
Server supporting this computer: CADOTNET
```

```
To begin Setup, press Enter. If you are using the Remote
```

```
↳Installation Services boot floppy, remove the floppy
```

```
↳diskette from the drive and press Enter to continue.
```

Here, the RIS client software has chosen a name for the computer, ADMINMARK1, that it constructed by taking my login name—ADMINMARK was the account I used at the time—and adding a number to it. The Global Unique ID, or GUID (pronounced “gwid”), is just an ID number that RIS assigned to that computer. PXE-capable machines all have a GUID built right into them, but machines using RIS boot floppies get a GUID constructed for them consisting of 20 hex zeros followed by their NIC's MAC address. Finally, the Client Install Wizard tells you the name of the RIS server that it's getting its image from. Once you press Enter to confirm, pop the floppy out of

the A: drive and walk away for a half hour or so. When you return, whatever OS you chose will be installed completely hands-off on the machine.

RIS sets the system up like so:

- ◆ The new machine joins the RIS server's domain.
- ◆ RIS repartitions the machine's hard disk into just one large partition and formats that partition as NTFS, no matter how the drive was previously partitioned.
- ◆ The new system has all of the settings you'd find in a typical install.

Want to change any of that? Then you'll need to create some system images.

## Creating a System Image with RIPrep

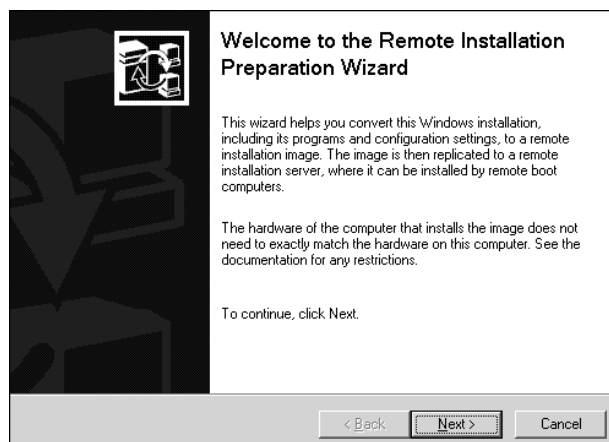

Even doing a no-frills installation on a new system with RIS is pretty nice. But it would be nicer to provide not only a vanilla operating system but perhaps a few settings and certainly an application or two—now, *that* would make the Ghost guys sweat! (But not sweat all *that* much, as you'll see. Ghost is still better than RIS. But Ghost costs money, and RIS comes free with Server from the 2000 edition onward.) You can do such a thing, creating what's called a *RIPrep image format* image. Here's how you do it:

1. Set up a prototypical Win2K, XP, or Server 2003 system as you'd like it. Make sure that all of the code and data are on drive C:—no other drives will be copied by RIS.
2. Run the Remote Installation Preparation Wizard (RIPrep), which strips the SIDs off the prototypical machine.
3. Once the image is on the RIS server, it's available to new systems for installation.

For my example, I've installed Office 2000 onto an XP Professional workstation. To create the RIPrep image, I log in to that prototypical machine with a domain administrator account. I then open up My Network Places and navigate over to my RIS server, the machine named CADOTNET. RIS creates a share called REMINST on every RIS server. I open REMINST, then I open up the folder inside labeled **Admin**, and then I open the folder inside that labeled **I386**. Inside is a file named **riprep.exe**. I double-click it and see the opening screen, as shown in Figure 5.27. Click Next to see the screen shown in Figure 5.28.

**FIGURE 5.27**

Opening screen  
of RIPrep

**FIGURE 5.28**

Choosing the destination RIS server

You can send the resulting image to any RIS server; I'll choose the one I've been working with, the server named *cadotnet*, and click *Next*, which leads to the screen in Figure 5.29.

**FIGURE 5.29**

Naming the new folder

As with the CD image that RISetup insisted upon, this new image will need a folder name. Once I name the folder and click *Next*, a screen in which I add a description appears, as shown in Figure 5.30.

Now, for RIS 2000 veterans, the next screen or two might be a surprise. RIPrep checks over the system looking for any showstoppers or warnings. For example, you can't use RIS on a server acting as a domain controller, RIS server, or DHCP server. Because RIS will remove all existing local security information, you probably won't be able to do much with local profiles, as you'll see in Figure 5.31.

Then RIPrep spends a few screens telling you that it's going to shut down a few services and suggesting that you shut down any programs that you're running, and finally, it confirms your choices, as you see in Figure 5.32.

## Reconfiguring the Prototype

After transferring the system image to the RIS server, you're directed to reboot the prototype. You'll then see something odd—it looks as if the prototype is running Setup all over again! In order to make the prototype's image usable to RIS, RIPrep scrubs all of the user-specific settings and SIDs off the machine. Once you reboot, your system runs a kind of “mini-setup” to restore that information. Once the system reboots, you'll be prompted to do the following:

- ◆ Agree to the license agreement.
- ◆ In a move designed to irritate even the calmest administrator, you must re-enter the 25-digit product key (on those versions of Server that require a product key); you will also have to re-activate your copy of Server.
- ◆ Choose a keyboard and localization.
- ◆ Fill in a username and organization.
- ◆ Specify a computer name and password for the default Administrator account.
- ◆ Pick a time zone.
- ◆ Decide whether to do typical or custom network settings.
- ◆ Join either a workgroup or domain.

The mini-setup doesn't take nearly as long as Setup did, however, as it's not necessary to run Plug and Play. Nevertheless, it *is* a real time-waster.

## Creating a “Flat” or “CD-ROM” Image

Using RIS's Ghost-like way of putting a complete system image on ice is useful, but I'm kind of partial to doing simple scripted installs, and RIS can do it my way as well. All I need do is to place an I386 for whatever OS I want to deploy on the RIS server, and then any RIS client will see an option to install from that I386.

This is useful for two reasons. First, as I've said, it's a nice way to be able to kick off installs from a central server (the RIS server), allowing me to store all of my installation files and scripts on one box. Second, being able to store I386es on my RIS server lets me store I386es that have already had a service pack slipstreamed onto them, as I've suggested before.

Let's see how to put an I386 from XP Professional onto my RIS server. I'll slipstream Service Pack 1 onto it.

First, let's get the slipstreamed copy of XP's I386 onto the RIS server's hard disk. I've already talked about how to do this in this chapter, but here's a reminder. First, copy the I386 from an XP Pro installation CD onto the RIS server's hard disk; call it `C:\XPPro\I386`. Then expand XP's Service Pack 1 and use the `update.exe` program to slipstream the service pack onto that I386:

```
update -s:c:\xppro\
```

Next, get the I386 image in `C:\XPPro\` into the RIS server:

1. Start up Active Directory Users and Computers (it's either on your Start menu as Start/Programs/Administrative Tools/Active Directory Users and Computers, or click Start, then Run, type `DSA.MSC`, and press Enter).

2. Open the folder labeled **Computers** and find the RIS server. Right-click its icon and choose **Properties**, then click the tab labeled **Remote Install**.
3. At the bottom of that tab, you'll see a button labeled **Advanced Settings**; click it. You'll see another properties page with three tabs labeled **New Clients**, **Images**, and **Tools**. Click the **Images** tab and you'll see something like Figure 5.33.

**FIGURE 5.33**

Listing of images on your RIS server

4. You'll see a listing of the images that your RIS server has. If you've just installed it, then you'll probably only have one image, with a name like **Windows .NET Standard Server**. Click the **Add** button at the bottom of the page and you'll see a screen like Figure 5.34.

**FIGURE 5.34**

Adding a new image

5. Notice that RIS lets you create an “image” simply by writing a script and associating that with an existing I386 directory, or it’ll let you introduce a whole new I386 directory, as I’ve checked. Choose Add a New Installation Image and click Next.
6. This starts off a wizard that basically just asks you where to find the image (C:\Xppro\I386, in this example); click Next and it’ll ask you what to call the new folder, as you see in Figure 5.35.

**FIGURE 5.35**

What to call the new folder

7. Here, I’ve called it XP-SP1. That means that the I386 files will go on my RIS server’s SIS drive into a folder named \RemoteInstall\Setup\English\Images\XP-SP1. Click Next and RIS will want a “friendly name” for this image, as you saw when you created other RIS images. Click Next from that and you’ll see a question about the “client installation screens,” as you see in Figure 5.36.

**FIGURE 5.36**

What to do with the client installation screens

8. The client installation screens are the HTML-like files that control what the user sees when first connecting to the RIS server. I'd just leave them as is, as you see on the screen. Click Next a couple more times and RIS will copy the I386 into the `\RemoteInstall\Setup\English\Images\XP-SP1` directory (or whatever you named it) and add that image to its list of images.

## Creating a Scripted Image

One subtype of “flat” images is a scripted image. By default when you install an I386 image like the one you just did, then RIS installs it hands-off, with no user intervention. How, you might wonder, does it do that? Well, it turns out that RIS has a prebuilt answer file like the `winnt.sif` that we built earlier in this chapter. That basic script installs the defaults and joins a system to the domain.

But where *is* that script? I just told you that XP-SP1 got its own folder on the RIS server in `\RemoteInstall\Setup\English\Images\XP-SP1` folder. Inside *that* folder is a folder named `\RemoteInstall\Setup\English\Images\XP-SP1\I386\Templates`, which contains a file named `RISTNDRD.SIF`. It's a script like the ones that you've seen so far, although not exactly the same; you may recall that Setup Manager offered as one of its options the ability to create a RIS script.

But you may not want to go with the no-frills `RISTNDRD.SIF` script. You may make your own customized one; but how to introduce it to RIS? Very simply; RIS sees a script as an image all itself. Just start up the wizard to add a new image, as you just read how to do. But instead of choosing Add a New Installation Image, choose Associate a New Answer File to an Existing Image when in the wizard panel shown back in Figure 5.34.

## Delivering a RIPrep Image to a Target PC

Now that you know how to create a system image, a flat image consisting of a new I386, or a flat image consisting of a new script, how do you deliver that image to a target PC? In exactly the same way that you got the first one onto a target PC. Either press F12 when the PXE ROM tells you to or boot from an RBDG-generated floppy.

**NOTE** *You do not need to build a separate RBDG-generated floppy for each system. You can build just one and carry it with you, using it to start as many different RIS image transfers as you'd like. Or, as you've already read, your newer systems may already have PXE boot abilities in their BIOS, and you therefore don't need a floppy to get a RIS install started.*

Now that you've got more than one image on your server, the Client Installation Wizard will offer you one more screen. After you log in, it'll list the available images and their descriptions, allowing you to choose one. Then, as before, it'll remind you that it's about to destroy any data on the hard disk and, from there, all you need do is to pop that RBDG floppy out of the floppy drive, walk away, and come back in a half-hour—the entire install is hands-off.

**WARNING** *Once again, don't take the “this will zap the hard disk” warning lightly. If (for example) your RIPrep image is based on a system with a 1500MB C: drive formatted as FAT32, then RIS will repartition and reformat the C: drive of the target PC to 1500MB and FAT32 no matter how the drive was partitioned on the target PC before. RIS will leave any remaining space unpartitioned.*

## Authorizing Users to Let RIS Create New Computer Accounts

The idea, then, with RIS is this: Joe comes into your office and tells you that his computer's hosed, and would you reinstall his operating systems and applications when you get a chance? You reply that

you've got an even better idea and hand him an RBDG floppy. You tell him to boot it, press F12 when prompted, then log in to the Client Installation Wizard and choose the Standard Productivity Desktop option, an image that you've built with all of the company's standard desktop software—Office, Palm's HotSync software, and Lotus Organizer.

Now, if Joe goes back and tries this, he'll see an error message like this:

```
The user Joe currently logged in to this computer does not
↳ have the permissions needed to create a computer account
↳ or modify the computer account NEWPC (NEWPC$) within
↳ the domain apex.com.
This error may also indicate that the server CADOTNET supporting
↳ this client cannot contact the directory service to perform
↳ the operation.
Restart this computer and try again. If the problem persists,
↳ contact your network administrator for assistance.
```

What's going on here is that, in the process of installing the RIS image on Joe's machine, RIS must also create a *machine account*—remember, in domains, machines have accounts just as people do—and not just any old user can create machine accounts. By the way, he also has to be able to delete machine accounts, as there's probably already a machine account floating around that has the same name as the one he's about to create, as well as a few other machine permissions.

But what permissions does he need? Joining a machine to a domain is actually sort of complicated. Here's what's going on:

- ◆ First, not just anyone can tell a given workstation that it's going to join a domain. Only someone with a local administrator account can tell a machine to join a domain. Therefore, if you've got a machine that's already installed and you want to join it to a domain, you should first log on as someone who's a member of the machine's local Administrators group. And remember that just because you're an administrator on one machine, you may not be one on another.
- ◆ Second, it's one thing for a machine to want to join a domain; it's quite another for a domain to be willing to accept that machine as a member. Joining a machine to a domain, then, requires help from someone with a certain amount of administrative power not on the machine, but on the domain. That's why when you're joining a machine to a domain the machine will pop up a dialog box asking you to log in. What it's saying here is, "Okay, I [the machine] accept that you have the authority to tell me to join this domain, but this isn't going to work unless you have the authority to tell the domain to accept me; can you give me the name and password of a *domain* account that can do that?"

Those are the basics. But in many cases we're not just installing, we're *reinstalling*. That adds a subtle but important wrinkle.

Suppose you have a workstation named MYPC. It's gone south and you decide that just blowing up the system and reinstalling it is the way to go. You've got a RIS-bootable system, and so you kick off a RIS boot. Now, by default RIS comes up with some goofy machine name for you automatically, but you don't like that, and so you modify RIS's scripts (I'll show you how in a bit) to let you specify a particular machine name. Of course, you choose MYPC. The RIS install goes all right for a while, but then it stops and says that it can't join you to the domain. To make things even stranger, it occurs

to you that you first installed this system with RIS and gave your system the name MYPC at the time, and RIS took that without a complaint.

What's different?

What's different is that the first time, RIS only had to create a brand new machine account named "MYPC\$." (Remember that machines get account names equal to the machine name with a \$ tacked on the end.) That only required the power to create a new machine account. And, as it turns out, regular old nonadministrative users have the ability to create 10 machine accounts in their lifetime. (Don't ask me why Microsoft set it up that way, I have no idea.)

But they *don't* have the power to *delete* machine accounts. Or change the passwords on machine accounts. When you tried to reinstall an OS on MYPC and tried to join a domain as MYPC, then the domain looked around and said to itself, "Hmmm, that's not right... there's already a MYPC account. I don't want to overwrite some poor machine's account," and denied the request. What you were really asking the domain to do was to first delete the MYPC account (or simply change its password, depending on what OS you're using), and your regular old user account didn't have the power to do either of those things.

But you can change that. If you like, you can create a whole new group called Installers. Then we'll give the group the power to change machine passwords and delete machine accounts. Then, when Joe wants to reinstall his computer, all you have to do is to just put him in the Installers group for the day. When his system is reinstalled, just take him out of the Installers group.

Now, creating the Installers group will be a bit of a lengthy procedure, but you'll only have to do it once.

**NOTE** *This is a neat example of something that you're going to learn in an upcoming chapter about Active Directory. Active Directory lets you create groups of administrators with sets of powers that you can control very finely. It's part of a process called delegation, and we'll take it up in detail in the Active Directory chapter.*

## Creating the Installers Group

You'll find creating the Installers group easiest while sitting at a domain controller:

1. Log in using an account with domain administrator rights and then start the Directory Service Administrator DSA.MSC by clicking Start/Administrative Tools/Active Directory Users and Computers. In the left pane, you'll see an icon representing your domain with a plus sign next to it; click the plus sign to expand the domain.
2. Next, create the Installers group. Right-click the **Users** folder and choose New/Group.
3. That raises a dialog box called Create New Object—(Group). In the field Name of New Group, type in **Installers**. This will create a global group named Installers, which is what you want, so click OK and the dialog will close.
4. Back in the DSA's menu, click View/Advanced Features. That will show the Security tab on the properties page, which will be essential to give Installers the permissions that it needs.
5. Next, you're going to give the Installers group the ability to create new computer accounts and by default computer accounts go in a folder labeled **Computers**, so right-click the folder, icon labeled **Computers** and choose Properties. You'll get a dialog box named Computers Properties.

6. Click the Security tab in the properties page. Installers doesn't currently have any permissions, so you'll need to add a record for them. Click the Add button and you'll now see a dialog named Select Users, Computers, or Groups.
7. Type in **Installers** and then, just for good measure, click Check Names. It'll think about it for a second. Once it's checked that there is indeed a group called Installers, Installers will be underlined. Click OK.
8. Back in the Computer properties page, find Installers in the Name list box and click it, then click the Advanced button.
9. You'll see a dialog box labeled Advanced Security Settings for Computers. Again, locate Installers—this part of the operating system isn't intended for regular old users, so the UI's a bit convoluted here—to indicate the Installers record that you created. It'll currently have some very basic permission like Read or the like. Click the Edit button.
10. Now you'll see a dialog named Permission Entry for Computers. Scroll down in the list box labeled Permissions to find the Create Computer Objects permission. You'll see two columns of check boxes, one labeled Allow and the other Deny. Check the Allow box. Click OK to clear the Permission Entry for Computer Objects dialog box.
11. That permission made the folders accept the new machine objects. But once created, Installers have very limited control over the machine accounts themselves. They can delete or modify machine accounts, but only the ones that they created. Now, if you only want users to have the power to reset machine accounts that they created, you can stop here and skip down to step 14. But if you want Installers to be able to reset even machine accounts that they did *not* install, then let's keep going. From the Access Control Settings for Computers dialog box, click Add, choose Installers again, and click OK. The Permission Entry for Computers dialog box then appears.
12. Click the Apply Onto drop-down list box and choose Computer Objects. Check the Allow box next to the Write All Properties, Change Password, and Reset Password permissions. In the lower left corner of the page, check the box that says Apply These Permissions to Objects and/or Containers within This Container Only. Click OK and you'll return to the Advanced Security Settings for Computers dialog box.
13. Scroll down in the Permission Entries list box and you'll see that there are now two or five new entries for Installers, depending on how much power you decided to give Installers.
14. Click OK to dismiss the Advanced Security Settings dialog box.
15. Click OK to dismiss the Computers properties page.

Now that that's done, you can put Joe into the Installers group:

1. Open the Users folder and locate the Installers group.
2. Right-click Installers and choose Properties.
3. Click the Members tab.
4. Click the Add button.
5. Find Joe's account, click Joe, click OK, and then click OK again.

Finally done. Yes, that was a bit of work, but worth it in the end, I think.

## Restricting RIS Image Choices

Once you turn Joe loose with that floppy, you might not want him accidentally loading the wrong image. He might just decide that he'd *love* to download the Programmer's Workstation image, complete with the C++ and Java compilers, interactive debuggers, and the like—none of which he has any use for. You can, as it turns out, keep him from seeing all of the images on the RIS server. But you'd never guess how you do it.

The RIS server has a set of directories that exist in `\RemoteInstall\Setup\English\Images`. If you've got a simple I386 installation called `Windows`, then its image is in `\RemoteInstall\Setup\English\Images\Windows`. Each RIS image, then, has a directory inside `\RemoteInstall\Setup\English\Images`; remember that.

Each image contains a folder named `I386`, which contains yet *another* folder named `Templates`. *That* folder contains a file named with the extension `.sif`. It's an answer file that RIS uses to be able to do the installation without any user intervention. So, for example, if you have an image called `Programmers`, there's an SIF file in `\RemoteInstall\Setup\English\Images\I386\Templates`.

The way that you keep Joe out of the `Programmers` image is to set the NTFS permissions on the SIF file so that he's denied Read access. Once RIS sees that he's not supposed to see the file, the `Programmers` image won't even be offered to him.

## Advanced RIS

Those are the basics about Remote Installation Services. But before you go running off to take advantage of them, you should know about some fine points.

### ADVANCED RIS I: USING \$OEM\$

Once you start getting a bit fancy with your RIS-based installs, you'll soon pine for the power of the `$OEM$` folder. So you might tunnel down into your `\RemoteInstall\Setup\English\Images\whateveryoucalledit\I386` folder and place an `$OEM$` folder inside that `I386` folder, hoping to see some of `$OEM$`'s power transferred to RIS.

But it won't work.

The problem? For some bizarre reason, RIS installs need the `$OEM$` folder *at the same directory level* as `I386`, not inside it. So, for example, if I created an image folder just called `serverinst`, then I'd place the `$OEM$` folder at `\RemoteInstall\Setup\English\Images\serverinst\OEM$`, not `\RemoteInstall\Setup\English\Images\serverinst\I386\OEM$`.

### ADVANCED RIS II: BUILDING RIS SCRIPTS

If you've built a few RIS flat images, then you know that by default RIS will wipe the first physical hard disk on a target computer, make that first drive one big NTFS volume, and do a mainly unattended installation of your OS—"mainly" because it'll prompt you for a product key.

Unattended is good; *mainly* unattended isn't. So let's see how to script a RIS install. As with the `winnt.sif`-style scripts, you can use the Setup Manager to create RIS scripts. But I find that the Setup Manager isn't much help here. I pretty much use Setup Manager to create a basic script, then I hand-adjust it, as you saw earlier in this chapter.

But there's no need to have Setup Manager create a basic script for RIS—you see, every RIS install gets its own basic script, called `ristndrd.sif`. Look in the `I386` directory of any RIS image directory and you'll see a directory named `Templates`. Inside *that* is a file named `ristndrd.sif`. Mine looks like the following.

```
[data]
floppyless = "1"
msdosinitiated = "1"
OriSrc = "\\%SERVERNAME%\RemInst\%INSTALLPATH%\%MACHINETYPE%"
OriTyp = "4"
LocalSourceOnCD = 1
DisableAdminAccountOnDomainJoin = 1

[SetupData]
OsLoadOptions = "/noguiboot /fastdetect"
SetupSourceDevice = "\\Device\LanmanRedirector\%SERVERNAME%\RemInst\%INSTALLPATH%"

[Unattended]
OemPreinstall = no
FileSystem = LeaveAlone
ExtendOEMPartition = 0
TargetPath = \WINDOWS
OemSkipEula = yes
InstallFilesPath = "\\%SERVERNAME%\RemInst\%INSTALLPATH%\%MACHINETYPE%"
LegacyNIC = 1

[UserData]
FullName = "%USERFIRSTNAME% %USERLASTNAME%"
OrgName = "%ORGNAME%"

[OSChooser]
Description = "Microsoft Windows .NET Standard Server"
Help = "Automatically installs Microsoft Windows .NET Standard Server
↳without prompting the user for input."
LaunchFile = "%INSTALLPATH%\%MACHINETYPE%\templates\startrom.com"
ImageType = Flat
Version = "5.1 (0)"

```

This won't need all that much in the way of changes because, after all, it's already able to direct an almost-unattended installation. But here are a few changes that I made to make my Server-installing RIS image more useful for me.

First, I added a `ProductKey=` line to the `[UserData]` section. That kept it from stopping to prompt me for a product key.

Next, I changed `OEMPreinstall=No` to `OEMPreinstall=Yes`, so I could then set up an `$OEM$` directory (at the same directory level as `I386`, recall, not *inside* `I386`) and get the benefits of `$OEM$—cmdlines.txt`, preloaded files and directories, extra driver directories, and so on. That also let me include an `[OEM_Ads]` section to specify background and logo bitmaps for the install—not necessary items, but I like them and clients like when I set them up, as it makes an install look like a “company brand” install rather than a Microsoft commercial.

Then I changed the `[Identification]` section. RIS normally uses some command that refers to an “oldstyledomainjoin” that seems to work fine if you let RIS pick the machine name, but if you want to pick your own, then it seems not to work unless you do it by specifying a user account and password that can create and destroy machine accounts. Again, it needn't be an actual domain administrator—just someone from the Installers group will do fine.

Then I changed the `[Display]` section so that the systems come up on 1024×768 resolution rather than the unwieldy 640×480. I used `[Components]`, as before, to remove the games and to enable Terminal Services, and `[FavoritesEx]` to preconfigure defaults for Internet Explorer. I ended up with a script that looks like this; I have highlighted the lines that I added or modified:

```

[data]
floppyless = "1"
msdosinitiated = "1"
OriSrc = "\\%SERVERNAME%\RemInst%\INSTALLPATH%\%MACHINETYPE%"
OriTyp = "4"
LocalSourceOnCD = 1
DisableAdminAccountOnDomainJoin = 1

```

```

[OEM_Ads]
background=backg.bmp
logo=logo.bmp

[SetupData]
OsLoadOptions = "/noguiboot /fastdetect"
SetupSourceDevice = "\\Device\LanmanRedirector\%SERVERNAME%\RemInst\%INSTALLPATH%"

[Unattended]
OemPreinstall = yes
FileSystem = LeaveAlone
ExtendOEMPartition = 0
TargetPath = \WINDOWS
OemSkipEula = yes
InstallFilesPath = "\\%SERVERNAME%\RemInst\%INSTALLPATH%\%MACHINETYPE%"
LegacyNIC = 1

[UserData]
FullName = "%USERFIRSTNAME% %USERLASTNAME%"

```

Now, how did I make that change take effect? Simple—I made the changes to the `ristndrd.sif` file and just resaved `ristndrd.sif` to its original location. Alternatively, I could have written another script and then gone to the Advanced button of the RIS page on Active Directory Users and Computers, as you saw me do a few pages back. If I wanted to, I could have any number of scripts all doing unattended installs from the same Server I386 directory.

### ADVANCED RIS III: MODIFYING THE CLIENT WIZARD

If you implemented something like the preceding script, then you might have noticed a sort of annoying thing about RIS: machine names. By default—and it takes a bit of doing to defeat the default, so to speak—RIS names the first machine that you install *yourusername1*, the second *yourusername2*, and so on. For example, I just started a RIS install of a server and, when the Client Installation Wizard asked me to log in, I logged in as ADMINMARK so RIS named the server ADMINMARK1. I'd much prefer it if the Client Installation Wizard would just *ask* me what to call the server. Look back to the line in the `ristndrd.sif` script that names the server:

```
ComputerName = %MACHINENAME%
```

So, clearly some kind of environment variable is set by RIS, and the value in the environment variable is then used to name the machine. As a matter of fact, a close look at `ristndrd.sif` shows *several* of these environment variables—`%MACHINEDOMAIN%`, `%TIMEZONE%`, `%ORGNAME%` and the like—that RIS somehow constructs and then passes to the Setup routine on a computer that RIS installs.

Is there a way for us to *directly* control those variables, and therefore to have greater control over how RIS installs the server? Yes. As a matter of fact, you can even create new environment

variables—but to see how that works, let’s go back and reexamine all of those .osc files. On your RIS server, there’s a directory named \RemoteInstall\Oschooser\English. In that directory, you’ll find (on my system, anyway) 45 text files with the extension .osc. I don’t pretend to understand entirely how they work, but here’s what I’ve pieced together from a variety of sources.

When you first connect to a RIS server, you get a screen driven by the file `welcome.osc`. Let’s revisit that file:

```
<OSCML>
<META KEY=ENTER HREF="LOGIN">
<META KEY=F3 ACTION="REBOOT">
<META KEY=ESC HREF="LOGIN">
<META KEY=F1 HREF="LOGIN">
<TITLE> Client Installation Wizard                               Welcome</TITLE>
<FOOTER> [ENTER] continue </FOOTER>
<BODY left=5 right=75>
<BR>
<BR>
<BR>
Welcome to the Client Installation wizard. This wizard helps
  you quickly and easily set up a new operating system
  on your computer. You can also use this wizard to
  keep your computer
up-to-date and to troubleshoot computer hardware problems.
<BR>
<BR>
In the wizard, you are asked to use a valid user name,
  password, and domain name to log on to the network.
  If you do not have this information, contact your
  network administrator before continuing.
</BODY>
</OSCML>
```

First, notice the `<META>` commands. They define what happens when you press one key or another. I’ve seen two variations on the `<META>` command—the `HREF` and the `ACTION` variations. For example,

```
<META KEY=ENTER HREF="LOGIN">
```

This tells the Client Installation Wizard that if the user presses the Enter key, then the wizard should next find and load the file `login.osc`. Like an HTML “`<A>`” tag, it provides a link to another OSC file. But now consider this `<META>` command:

```
<META KEY=F3 ACTION="REBOOT">
```

This time, pressing F3 doesn’t take you to a file `reboot.osc`. Instead, “REBOOT” means just what it sounds like—it tells the wizard to reboot the computer. Other `ACTION=` values that I’ve seen include

**LOGIN** Takes the information on the screen (this shows up in the wizard panel that asks you to log in) and tries to log in to an Active Directory domain.

<FORM> command is doing: first, it collects values for USERNAME, PASSWORD, and USER-DOMAIN. Then, once you press Enter to indicate that you're done entering those values, the form moves you along to "CHOICE." But what is CHOICE? Well, apparently the "ACTION=" parameter means something a little different in a <FORM> than it does in a <META>, as it just takes you to the screen defined by choice.osc.

But here's where things get a bit weird. Here's what's in choice.osc:

```
<OSCML>
<META KEY=F3 ACTION="REBOOT">
<META KEY=F1 HREF="CHOICHLP">
<META SERVER ACTION="DNRESET">
<META SERVER ACTION="FILTER CHOICE">
<TITLE>Client Installation Wizard
    Main Menu</TITLE>
<FOOTER>[ENTER] continue    [F1] help    [F3] restart computer</FOOTER>
<BODY left=5 right=75>
<BR>
<BR>
Use the arrow keys to select one of the following options:<BR>
<P left=8>
<FORM>
<SELECT SIZE=10>
<OPTION VALUE="OSAUTO" TIP="This is the easiest way to install
↳an operating system on your computer. Most installation
↳options are already configured by your network administrator.">
Automatic Setup
<OPTION VALUE="CUSTOM" TIP="With this option, you can define a
↳unique name for this computer and specify where the computer
↳account will be created within the directory service. Select
↳this option if you are setting up this computer for someone
↳else within your company.">
Custom Setup
<OPTION VALUE="RESTART" TIP="A previous remote installation attempt
↳has been detected on this computer. Select this option to
↳restart a previously started installation.">
Restart a Previous Setup Attempt
<OPTION VALUE="TOOLS" TIP="This option gives you access to tools
↳for keeping your computer up-to-date and for troubleshooting
↳problems.">
Maintenance and Troubleshooting
</SELECT>
</FORM>
</P>
<BR>
<BOLD>Description:</BOLD>&nbsp;&nbsp; 
<TIPAREA>
</BODY>
</OSCML>
```

```

<META KEY=ENTER ACTION="REBOOT">
<TITLE> Client Installation Wizard           Installation Information</TITLE>
<FOOTER> [ENTER] continue</FOOTER>
<BODY left=5 right=75>
<BR>
<BR>
The following settings will be applied to this computer installation.
↳Verify these settings before continuing.
<BR>
<BR>
Computer account:                        %MACHINENAME%
<BR>
<BR>
Global Unique ID:                        %GUID%
<BR>
<BR>
Server supporting this computer: %SERVERNAME%
<BR>
<BR>
<BR>
To begin Setup, press ENTER. If you are using the Remote
↳Installation Services boot floppy, remove the floppy
↳diskette from the drive and press ENTER to continue.
</BODY>
</OSCMML>

```

This panel also basically just displays some information. But notice something odd about the <META> commands—they say that no matter whether you press ESC or Enter, you’ll reboot. But you’d *think* that “reboot” would, well, reboot the computer—which would sort of abort the whole RIS process. But no—on this particular panel, “reboot” means “full speed ahead!” for the RIS install. So, we’ve seen that a standard RIS install progresses from `welcome.osc` to `login.osc` to `choice.osc` (in “stealth” mode) to `osauto.osc` (also “stealthed”) to `oschoice.osc` to `warning.osc` and then finally to `install.osc`. Here’s where I’m going to make use of this to control the machine name: I’ll add an extra panel between `oschoice.osc` and `warning.osc` and include a form that gives the user the ability to enter a machine name.

Looking back at `oschoice.osc`, you recall that we *got* from `oschoice.osc` to `warning.osc` by way of the form in `oschoice.osc`: the <FORM ACTION=“WARNING”> command. *That’s* where I’ll break the chain from `oschoice.osc` to `warning.osc`, by modifying that one item in `oschoice.osc` from <FORM ACTION=“WARNING”> to <FORM ACTION=“PICKNAME”>. Using the other .osc files as a model, I then come up with this file, which I name `pickname.osc`:

```

<OSCMML>
<META KEY=ESC ACTION="REBOOT">
<META KEY=F3 HREF="OSCHOICE">
<TITLE>Client Installation Wizard
    Choosing Names</TITLE>
<FOOTER>[ENTER] continue    [ESC] Reboot F3 Pick Install</FOOTER>
<BODY>

```

```
<FORM ACTION="WARNING">
Machine Name: <input NAME="MACHINENAME" VALUE=%MACHINENAME% maxLength=20><br>
%OPTIONS%
</SELECT>
</FORM>
</BODY>
</OSCMML>
```

This file starts off by defining ESC as “reboot” and F3 as “return to `oschoice.osc`.” Then it defines title and footer text for the screen. Then it defines a form that will progress to the `warning.osc` panel, once you press Enter for this form. Inside the form is just one field—an input field that lets you type a machine name of up to 30 characters. The `NAME=“MACHINENAME”` means that whatever you type will go into the environmental variable named `MACHINENAME`. The `VALUE=%MACHINENAME%` tells the Client Installation Wizard to offer as default text the name that RIS *wants* to use, like `ADMINMARK1`.

Still not sure this would be useful? Then consider this: Suppose you had to roll out hundreds of servers, each with static IP addresses—as a large international Web-hosting ISP had to recently. They built themselves some RIS Client Installation Wizard panels that let them type in IP addresses and subnet masks, then pass that information to the `ristndrd.sif` file. Now, in my example, I used the built-in environment variable named `MACHINENAME`, but there’s nothing keeping you from making up your own environment variable. For example, what if I’d added these two `<input>` commands to my `pickname.osc` file:

```
IP address:<input name="IPADR"><br>
Subnet mask:<input name="SUBMSK">
```

Then, inside `ristndrd.sif`, I just adjust the script so that it doesn’t get IP addresses from DHCP, but instead assigns static IP addresses. Part of the revised `ristndrd.sif`, then, would include these lines:

```
IPAddress=%IPADR%
SubnetMast=%SUBMSK%
```

You can create as many new environmental variables you like—IP address is just one example. RIS offers a lot of flexibility—so much so that it’s changed my PC hardware buying habits. From now on, it’s all PXE machines for me.

#### **ADVANCED RIS IV: NEW NIC DRIVERS**

Now, all of this will work fine, *unless* your computer requires a NIC driver that’s not on the I386 for the OS that you’re installing. For example, suppose you wanted to use Server 2003’s RIS to roll out Windows 2000 Professional installs but your computers had a NIC that made its market debut after February 2000, when 2000 Pro shipped. Supposing that this new computer can PXE boot, then it’ll boot to the RIS server all right and Setup will start. But just a few minutes into the text mode Setup, you may see this message:

```
The network server does not support booting Windows 2000.
↳Setup cannot continue. Press any key to exit.
```

You see, once Setup kicks in, it does a quick check to see if it can fire up your network card; for some reason, it won't use the TFTP transfer ability built into PXE to copy the Setup files. As the NIC is newer than the drivers that Setup knows about, Setup can't initialize the card, and stops.

But wait—what about that OEMPnPDrivers command? If you put the drivers for the new NIC into \$OEM\$ and pointed to them with OEMPnPDrivers, then Setup ought to be able to use those drivers, right? Well, not exactly. Windows 2000, XP, and Server 2003 like their drivers digitally signed, and many sets of drivers don't come with digital signatures. You can work around that by adding this line to the `ristndrd.sif` script:

```
DriverSigningPolicy = Ignore
```

Put that in the [Unattended] section. Then put the NIC drivers on the RIS server in \$OEM\$ as before, but Microsoft recommends a more specific procedure. Create a directory `\$OEM$\$1\Drivers\NIC` and put the NIC drivers there. Create an OEMPnPDrivers command that looks like `OemPnpDriversPath=\Drivers\Nic` in the `ristndrd.sif` file, and then you ought to be able to get RIS started on a system with a new NIC. (And yes, I *did* recommend that you keep the names of driver directories short due to the 40-character limit on the `OemPnpDriversPath` command, but I wanted this text to be clear, so I used a longer name. You'd do fine with a directory named `\$OEM$\$1\DR\NIC` instead of `\$OEM$\$1\Drivers\NIC`.)

Apparently a driver has to be in the I386 directory for the text mode portion of Setup to see it, so Microsoft says in Knowledge Base article 246184 that you've got to put the INF and SYS files from the network driver into the I386 directory on the RIS server. You may have to do a bit of experimenting to find out exactly which SYS and INF files you actually need in the I386 directory, because you don't want to *have* to put `oeminfo.inf` in I386—after all, it seems like every board comes with an `oeminfo.inf`.

Microsoft *also* advised in the KB article that you restart the BINL service in the Services applet of Manage Computer. (Right-click My Computer, choose Manage Computer, open Services and Applications, and then click Services. In the right pane you'll see a service named Remote Installation. Right-click it and choose Restart.) Using this process, I have successfully set up RIS for several computers with very recent—post-2000—NICs.

## Ghost's Little Helper: Sysprep

RIS and scripting are cool, but the fastest way to blast an image onto a new system continues to be Ghost or something like it. The idea is to first create a server or workstation just the way you like it, as you would before RIPrepping a system. Then use a disk-copying tool like Symantec's Ghost or PowerQuest's Drive Image Pro to essentially "photocopy" the drive—these tools don't look at files, they just copy an entire partition from one drive right atop another. (Or, for about \$1000, you can forgo buying Ghost or Drive Image and buy a drive-to-drive copier. These are pretty neat—you plug the source hard disk into one side, pop some empty drives into the "receiver" receptacles, push the Start button, and walk away. I'm told that some of these can copy a gigabyte a minute!)

This drive-copying method works great for Windows 9x, but it's a terrible idea for NT and 2000, as each NT or 2000 system has a unique set of numbers embedded into it called its security identifiers or SIDs. Copying a drive copies the SIDs, making the network unable to tell the difference between the two drives. Unfortunately, the consequences of having systems with identical SIDs wasn't severe

enough to warn people off from cloning drives, so many firms do drive cloning. In response to the need to handle the duplicate SID problem, the Ghost and Drive Image folks have written “SID scramblers,” which create a unique set of SIDs on every computer. And while that ought to solve the duplicate SID problem, Microsoft won’t support a computer that’s been cloned, even with an SID scrambler.

I once asked a Microsoft techie why they wouldn’t support a cloned system, even if it had its SIDs scrambled. Does it actually cause a repeatable problem, I asked, or was Microsoft refusing to support cloned systems just to play it safe? The Microsoft support person said, “Well, we can’t prove any problems with cloning—but we’ve seen cloned systems that had problems that went away when we wiped their hard disks and did a fresh install.” I looked at him with one eyebrow raised and said, “You do realize that wiping and reinstalling is a technique that we use all of the time, on systems both cloned and noncloned, don’t you?” He had nothing to say.

## Using Sysprep: Overview

In any case, Microsoft knows that many people use cloning products and that they’d do well to help their customers use those cloning products. So Server 2003 comes with a “SID scrubber” called System Preparation Tool (**Sysprep.exe**). Sysprep’s simple to use—here are the basic steps.

1. Put **Sysprep.exe** and **setupcl.exe** on a directory named **\Sysprep** on whatever drive the operating system is on. You can then script it, and if you do, put the script in **\Sysprep**, calling the script **sysprep.inf**.
2. While you were acting as the administrator and setting the system up, you probably created some default software settings that would be convenient for others to have. Copy the local Administrator’s profile to the Default Users profile so that anyone who gets a clone of this system gets those software settings.
3. Run Sysprep. It strips the SIDs off your computer and shuts down your machine.
4. *Do not boot your computer from the hard disk.* Instead, boot from a floppy (probably to DOS) and run your disk-cloning program—Ghost, Drive Image Pro, or whatever. You do not want to let the computer boot up because when it does, it will realize that it is SID-less and will generate a new set of SIDs—which is what you ran Sysprep to get rid of in the first place.

Let’s look at this in more detail. Before we do, one more quick point: Sysprep won’t prepare a server that’s acting as a domain controller, a certificate server, or a cluster member. Other than that, it’ll prepare just about any system running Windows 2000 or later.

## Set Up the Computer

Start off by creating a computer—whether a server or a workstation—and get it just the way that you want it. Don’t bother joining a domain—Sysprep will just unjoin you. As Sysprep removes all existing security-related information, any domain membership info will just be redundant.

Add whatever applications you’ll need, configuring the software settings as you think they should be. For example, I hate all that Web content in the Explorer folders and turn it off immediately. But it’d be nice to *always* have it turned off, and I can do that. The idea is this: while I’ve been logged in as an administrator, I’ve been making changes to the OS, and the OS remembers those changes—but only while I’m logged in as administrator! If I create a second user account and

log in as that person, then I won't keep any of my settings, and have to reteach the computer how I like it to work.

## Create a New Administrative User

Once you've got the computer the way you want it, you'll want to copy the administrator's profile to **Default User**, so you need another user account to do that, because an administrator can copy any profile in the system *except* his/her own. You need a second admin account in order to be able to copy the first admin account. Here's how to create an admin account.

1. Click Start\Run, and fill in **compmgmt.msc**, then press Enter to start the Computer Management snap-in.
2. In the left pane, you'll see an icon labeled Local Users and Groups with a plus sign next to it. Click the plus sign to expand it to two folders named, not surprisingly, **Users** and **Groups**. Right-click the **Users** folder and choose **New User**.
3. That'll give you a dialog box that will let you create a user account that is only recognized by this computer. Let's call it **ADMIN2**. Fill in the rest of the dialog box and the password, however you like. Click **Create**, then **Close**.
4. Click the **Users** folder to show the users in the right pane. Right-click **ADMIN2** and choose **Properties**.
5. In the resulting properties page, click the tab labeled **Member Of** (which shows the groups that **ADMIN2** is a member of) and then the **Add** button.
6. That will display the list of local groups on this computer. Choose **Administrators**, then **Add**, then **OK**, then **OK** again.
7. Close the Computer Management snap-in.

## Log In as the New User

Now log out of the default Administrator account and log back in as **ADMIN2**.

Locate the folder named **Documents and Settings**—it's probably on the same drive as the operating system—and open it. You'll see a folder or two in there—these folders store the user profiles (i.e., the settings and preferences) for the people who've used this computer. You'll probably see one for the Administrator. You want to copy this to a profile called **Default User**—but there are two things standing in your way. First, **Default User**'s profile folder is hidden by default, so unless you've told Server 2003 to show you hidden folders, then you won't see the folder. Second, you can't copy one profile to another just by copying the folder contents—you have to use a Control Panel tool.

First, let's see that **Default User** folder. If you haven't done it yet, open the **Documents and Settings** folder. Click **Tools**, then **Folder Options**, and then, on the resulting properties page, click **View**. Click the radio button labeled **Show Hidden Files and Folders**, then **OK**, and **Default User** should pop into view. Next, let's copy the Administrator profile to the Default User profile.

Open the Control Panel (Start/Settings/Control Panel) and then the System applet. The System applet will show five tabs: **General**, **Network Identification**, **Hardware**, **User Profiles**, and **Advanced**. Click **User Profiles** and you'll see a list of profiles stored on this computer. Locate the one named *machinename\Administrator* of Type "Local," and click the **Copy To** button; you'll see something like Figure 5.37.

**FIGURE 5.37**

Copying the Administrator's profile

That's a Windows 2000 screen shot, and it's what you'd see if you were Sysprepping a 2K box. XP and Server 2003's dialogs are similar. First, click the button labeled **Change** in the group labeled **Permitted to Use**. Right now, only the Administrator account can use this profile—let's change that so that anyone can use it. You'll get a list of possible groups and users, one of which is called, appropriately, **Everyone**. Choose **Everyone** and click **OK**.

Next, copy the profile to `\Documents and Settings\Default User`. Either type in the whole path name (including whichever drive letter you have **Documents and Settings** on), or use the **Browse** button and navigate to the folder. Once you've got `\Documents and Settings\Default User` in your sights, click **OK** and the deed is done!

### Copy Sysprep to C:\Sysprep

Now your system's ready for Sysprepping. Just open a command line and type

```
cd \sysprep
sysprep -reseal -quiet -mini -pnp
```

Or, alternatively,

```
sysprep -reseal -quiet
```

The difference is whether or not you want the Plug-and-Play information reset. With the `-mini -pnp` options, you create a Sysprep image that you can take from a computer with one set of hardware and get it to work on a system with very different hardware. But there's a price: the `-mini -pnp` settings slow down a cloned system's first startup, as the Plug-and-Play hardware detection can take another 10 or 15 minutes.

With either option, Sysprep will then strip the SIDs off of your system and shut the computer down. Now copy its hard disk in whatever way you prefer—with a hardware copier or by booting from a floppy or CD-ROM and running Ghost, Drive Image Pro, or something like that.

Now, whenever you copy that disk image to a new hard disk and boot a computer from that hard disk, then the copy of whatever OS you Sysprepped will recognize that it lacks SIDs, and so it'll generate some. In the process, it has to rejoin the domain, ask for a product ID, and so on. Don't want to have to babysit the cloned systems every time they're first Ghosted? No problem. You can make a Sysprep setup script, which is actually just a minor variation on the scripts we've been doing all chapter. Even better, Setup Manager will make a basic Sysprep script for you, and then you can tweak it for your particular needs. Here's the only thing you've got to do in order to make the Sysprep script work. First, you must name the script `sysprep.inf`. Second, you must include the `sysprep.inf` file in the `C:\Sysprep` directory before

Sysprepping your model machine. As before, you've got to add the ProductID entry if your copy of Windows 2000 requires product IDs, and you can use "computername=\*" as you've already seen to have the computer create its own unique, random name. If it's XP or Server 2003, don't use ProductID, use ProductKey—Microsoft changed the command for some reason. Here's an example `sysprep.inf`:

```
;SetupMgrTag
[Unattended]
    OemSkipEula=Yes
    InstallFilesPath=C:\sysprep\i386

[GuiUnattended]
    AdminPassword=43e140893084ea91cd85dddec2cd0905daf4d42d86df9ebd57b0641c94aa4c438
    EncryptedAdminPassword=Yes
    OEMSkipRegional=1
    OEMDuplicatorstring="Test Sysprep image"
    TimeZone=35
    OemSkipWelcome=1

[UserData]
    ProductKey=11111-22222-33333-44444-55555
    FullName="Mark Minasi "
    OrgName=" "
    ComputerName=CCXP

[Display]
    BitsPerPel=16
    Xresolution=1024
    YResolution=768
    Vrefresh=70

[SetupMgr]
    DistFolder=C:\sysprep\i386
    DistShare=windist

[Identification]
    JoinDomain=bigfirm.biz
    DomainAdmin=administrator
    DomainAdminPassword=swordfish

[Networking]
    InstallDefaultComponents=Yes
```

That's all there is to it—and it's well worth looking into Sysprep, as many people are finding that the absolutely fastest way to get a 2000 or later image on a system is to take a Sysprepped and Ghosted image that's been burned onto a CD, boot the new computer from that CD, and then Ghost the image to the computer's hard disk.

If you've made it with me this far, then you've probably seen that Windows Server 2003 offers us a considerably improved set of rollout tools than the ones we had with NT 4. Start playing around with scripting, RIS, \$OEM\$, and Sysprep, and you may find that deployment's not so bad after all!

## Chapter 6

# Understanding and Using TCP/IP in Server 2003

WHEN NT FIRST APPEARED, TCP/IP was the mildly scary, obscure, complex protocol used by just a few—those “oddballs” in research, education, and government who were attached to that large but still-private club called “the Internet.” Most of us chose either NetBEUI in small networks for its simplicity or IPX for its partial interoperability with Novell NetWare.

Since the early '90s, however, IPX has been dethroned as the corporate protocol of choice and TCP/IP has replaced it. Where NetBEUI was once Microsoft's “home protocol,” so to speak, the one protocol that you could be sure that *everything* worked on, Server 2003 doesn't even offer it as an option by default—you can find it on the CD, but when you tell 2003 that you want to add a protocol, the only major protocols that you'll see are IP and IPX. Ever since Windows 2000, the Microsoft networking world has required TCP/IP to get the most out of Redmond OSes. For example, to use Active Directory and Group Policies—two of the big pluses of Windows 2000, XP, and Server 2003—you must use TCP/IP. In a very large sense, TCP/IP is *the* mandatory protocol for Server 2003.

TCP/IP is a big subject, so the book takes three chapters to cover it. In this, the first of those, I'll explain what TCP/IP is and how its networks—both the worldwide Internet and your firm's intranet—work. In this first TCP/IP chapter, you'll see how to build a basic intranet and you'll understand some of the vexing-but-necessary parts of putting one together—in particular, you'll learn about IP addresses, subnet masks, and IP routing. I'd like to be able to tell you, “You needn't worry about any of that—just run the Intranet Creation Wizard” or some other mythical tool, but sadly such tools are just that—mythical. However, things like subnet masks sound scarier than they actually are, which is why I'm going to take you through the ugly details.

In the next chapter, we'll look at three very basic and essential TCP-related technologies that allow you to create an infrastructure for your network: the Dynamic Host Configuration Protocol (DHCP), the Domain Name System (DNS), and the Windows Internet Name Service (WINS).

Then, in Chapter 17, you'll see how to set up the server service that is perhaps the most popular type of server on TCP/IP-based networks—a Web server, with the built-in Internet Information Server (IIS) shipped with Server 2003.

## A Brief History of TCP/IP

Let's start off by asking, "What *is* TCP/IP?" TCP/IP is a collection of software created over the years, much of it with the help of large infusions of government research money. Originally, TCP/IP was intended for the Department of Defense (DoD). You see, the DoD tends to buy a *lot* of equipment, and much of that equipment is incompatible with other equipment. For example, back in the late '70s when the work that led to TCP/IP was first begun, it was nearly impossible to get an IBM mainframe to talk to a Burroughs mainframe. That was because the two computers were designed with entirely different *protocols*—something like Figure 6.1.

**FIGURE 6.1**

Compatible hardware, incompatible protocols

To get some idea of what the DoD was facing, imagine picking up the phone in the U.S. and calling someone in Spain. You have a perfectly good hardware connection, as the Spanish phone system is compatible with the American phone system. But despite the *hardware* compatibility, you face a *software* incompatibility. The person on the other end of the phone is expecting a different protocol, a different language. It's not that one language is better or worse than the other, but the English speaker cannot understand the Spanish speaker and vice versa. Rather than force the Spanish speaker to learn English or the English speaker to learn Spanish, we can teach them both a universal language such as Esperanto, the universal language designed in 1888. If Esperanto were used in my telephone example, neither speaker would use it at home, but they would use it to communicate with each other. With time, however, Esperanto might become so flexible and expressive that more and more people might find themselves using it both at home and in public, and English and Spanish might fall into disuse. That's what happened with TCP/IP.

TCP/IP began as a simple *alternative* communications language, an Esperanto for networks. But in time, however, TCP/IP evolved into a mature, well-understood, robust set of protocols, and more and more of the networking world has tossed aside their home-grown, "native" network language in favor of TCP/IP. Let's first look at a little bit of the history of how that happened before we get into the specifics of TCP/IP on Server.

### Origins of TCP/IP: From the ARPANET to the Internet

The original DoD network wouldn't just hook up military sites, although that was an important goal of the first defense internetwork, a network called the ARPANET. Much of the basic research in the U.S. was funded by an arm of the Defense Department called the Advanced Research Projects

Agency, or ARPA. ARPA gave, and still gives, a lot of money to university researchers to study all kinds of things. ARPA thought it would be useful for these researchers to be able to communicate with one another, as well as with the Pentagon. Figures 6.2 and 6.3 demonstrate networking both before and after ARPANET implementation.

**FIGURE 6.2**

Researchers before  
ARPANET

**FIGURE 6.3**

Researchers after  
ARPANET

The new network, dubbed ARPANET, was designed and put in place by a private contractor called Bolt, Beranek, and Newman. (They're still around at [www.bbn.com](http://www.bbn.com).) For the first time, it linked university professors both to each other and to their military and civilian project leaders around the country. Because ARPANET was a network that linked separate private university networks and the separate military networks, it was a "network of networks."

ARPANET ran atop a protocol called the Network Control Protocol (NCP). NCP was later refined into two components, the Internet Protocol (IP) and the Transmission Control Protocol (TCP). The change from NCP to TCP/IP is the technical difference between ARPANET and the Internet. On January 1, 1983, ARPANET packet-switching devices stopped accepting NCP packets and only passed TCP/IP packets, so in a sense, January 1, 1983 is the “official” birthday of the Internet.

ARPANET became the Internet after a few evolutions. (Well, that’s a “few evolutions” unless you happen to believe that Al Gore invented it in his spare time while a senator.) Probably the first major development step occurred in 1974, when Vinton Cerf and Robert Kahn proposed the protocols that would become TCP and IP. (I say *probably* because the Internet didn’t grow through a centralized effort, but rather through the largely disconnected efforts of several researchers, university professors, and graduate students, most of whom are still alive—and almost *all* of whom have a different perspective on what the “defining” aspects of Internet development were. And all of whom have a Web site on Internet history...) Over its more than 20-year history, the Internet and its predecessors have gone through several stages of growth and adjustment. In 1987, the Internet could only claim a few thousand users. By 1993 it had grown to about 20 million. In 2002, there were nearly 600 million users, according to a study at [www.nua.ie/surveys/how\\_many\\_online/index.html](http://www.nua.ie/surveys/how_many_online/index.html). *All* of those numbers should be taken with a pound of salt, but no matter what numbers you believe, it’s clear that the Internet’s still growing pretty quickly.

Internet growth is fueled not by an esoteric interest in seeing how large a network the world can build, but rather by just a few applications that require the Internet to run. Perhaps most important is Internet e-mail, followed closely by the World Wide Web, and then the File Transfer Protocol (FTP), but more on those later in Chapter 17. (And okay, let’s tell the truth—if we took the pornography and the stolen MP3 files off the Net, then the Internet’s free bandwidth would probably grow by a factor of 20.)

Originally, the Internet protocols were intended to support connections between mainframe-based networks, which were basically the only ones that existed through most of the 1970s. But the 1980s saw the growth of Unix workstations, microcomputers, and minicomputers. The Berkeley version of Unix was built largely with government money, and the government said, “Put the TCP/IP protocol in that thing.” Adding IP as a built-in part of Berkeley Unix has helped both Unix and the Internet grow. The IP protocol was used on many of the Unix-based Ethernet networks that appeared in the ’80s and still exist to this day—I know very few Linux boxes that run anything but TCP/IP, for example. In fact, you’ll find that most ISPs mainly run Unix—something you’ll discover when you try to connect your Microsoft-based network to the Internet and hear the derision in the voice of the (Unix-oriented) tech support guy at the ISP. (For example, my ISP recently needed me to reconfigure my router to reflect a change in their system software. When the tech support guy on the phone asked me what I did for a living, I told him that I wrote books about Windows networking. “You have my sympathies,” he said.)

In the mid-1980s, the National Science Foundation created five supercomputing centers and put them on the Internet. This served two purposes: It made supercomputers available to NSF grantees around the country, and it provided a major “backbone” for the Internet. The National Science Foundation portion of the network, called NSFnet, was for a long time the largest part of the Internet. It is now being superseded by the National Research and Education Network (NREN). For many years, commercial users were pretty much kept off the Internet, as most of the funding was governmental;

you had to be invited to join the Net. But those restrictions have vanished, and now the vast majority of Internet traffic is routed over commercial lines rather than government-run lines. In fact, commercial and private users dominate the Internet these days, so much so that the government and educational institutions are now working on a faster “Internet 2.”

It’s customary to refer to the Internet as the information superhighway. I can understand why people say that; after all, it’s a long-haul trucking service for data. But I think of it more as “Information Main Street.” The Internet is growing because businesses are using it to get things done and to sell their wares. All of this book was shipped back and forth on the Internet as it was being written. Heck, that sounds more like Main Street than a highway.

The network protocol wars are over. We’re not running NetBEUI, or IPX, or X.25, or HDLC, or DDCMP—the TCP/IP based Internet is *it*, and has been at least since 1995. It seems like there can’t be more than one person left on the *planet* without an e-mail address...and I’m still working on my mother.

Let me not leave this section without defining a few terms: internet, Internet, and intranet.

- ◆ An *internet* is any network that uses TCP/IP.
- ◆ *The Internet*—capital *I*—is the informal term that I’ll use to describe the public Internet, the one that connects networks the world over.
- ◆ An *intranet* is a term that popped up in the mid ’90s because people found it confusing to have to say “THE Internet” when speaking of the world-wide public Internet rather than “AN internet” when referring to a private network that uses TCP/IP. *Intranet*, then, usually means basically the same thing as *internet*—little *i*—perhaps refined to mean “your internal network that not only uses TCP/IP but is also separated from the public Internet in some fashion, perhaps by a firewall.”

## Goals of TCP/IP’s Design

But let’s delve into some of the techie aspects of the Internet’s main protocols. When the DoD started building this set of network protocols, they had a few design goals. Understanding those design goals helps in understanding why it was worth making the effort to use TCP/IP in the first place. Its intended characteristics include:

- ◆ Good failure recovery
- ◆ Ability to plug in new networks without disrupting services
- ◆ Ability to handle high error rates
- ◆ Independence from a particular vendor or type of network
- ◆ Very little data overhead

I’m sure no one had any idea how central those design goals would be to the amazing success of TCP/IP both in private intranets and in *the* Internet. Let’s take a look at those design goals in more detail.

### GOOD FAILURE RECOVERY

Remember, this was to be a *defense* network, so it had to work even if portions of the network hardware suddenly and without warning went offline. That’s kind of a nice way of saying the network had to work even if big pieces got nuked.

### **CAN PLUG IN NEW SUBNETWORKS “ON-THE-FLY”**

This second goal is related to the first one. It says that it should be possible to bring entire new networks into an intranet—and here, again, *intranet* can mean your company’s private intranet or *the* Internet—without interrupting existing network service.

This seems kind of basic nowadays, doesn’t it? But a lot of the old network protocols were *really* fragile. Trust me, if we’d all stayed with some of the early PC networking protocols, then I’m only exaggerating a little bit when I say that we’d all have to reboot the Internet every time someone connected.

### **CAN HANDLE HIGH ERROR RATES**

The next goal was that an intranet should be able to tolerate high or unpredictable error rates and yet still provide a 100-percent reliable end-to-end service. If you’re transferring data from Washington, D.C., to Portland, Oregon, and the links that you’re currently using through Oklahoma get destroyed by a tornado, then any data lost in the storm will be resent and rerouted via some other lines.

### **HOST INDEPENDENCE**

As I mentioned before, the new network architecture should work with any kind of network and not be dedicated or tied to any one vendor.

This is essential in the twenty-first century. The days of “We’re just an IBM shop” or “We only buy Novell stuff” are gone for many and going fast for others. (Let’s hope that it doesn’t give way to “We only buy Microsoft software.”) Companies must be able to live in a multivendor world.

In fact, the Internet has achieved this wonderfully. When you connect to CNN, IBM, the White House, or my Web site, do you have any idea whether those Web servers are running some Microsoft Server OS, Unix, Linux, VMS, MVS, or something else? Of course not. My Web server runs atop a Microsoft OS and my e-mail server runs on Linux, and they get along just fine.

### **VERY LITTLE DATA OVERHEAD**

The last goal was for the network protocols to have as little overhead as possible. To understand this, let’s compare TCP/IP to other protocols. While no one knows what protocol will end up being *the* world protocol 20 years from now—if any protocol *ever* gets that much acceptance—one of TCP/IP’s rivals is a set of protocols built by the International Organization for Standardization (ISO). ISO has some standards that are very similar to the kinds of things that TCP/IP does, standards named X.25 and TP4. But every protocol packages its data with an extra set of bytes, kind of like an envelope. The vast majority of data packets using the IP protocol (and I promise, I *will* explain soon how it is that TCP and IP are actually two very different protocols) have a simple, fixed-size 20-byte header. The maximum size that the header can be is 60 bytes if all possible options are enabled. The fixed 20 bytes always appear as the first 20 bytes of the packet. In contrast, X.25 uses dozens of possible headers, with no appreciable fixed portion to it. But why should *you* be concerned about overhead bytes? Really for one reason only: performance. Simpler protocols mean faster transmission and packet switching. We’ll take up packet switching a little later.

But enough about the Internet for now. Let’s stop and define something that I’ve been talking about—namely, just what *are* TCP and IP?

Originally, TCP/IP was just a set of protocols that could hook up dissimilar computers and transfer information between them. But it grew into a large number of protocols that have become collectively known as the *TCP/IP suite*.

## Getting There: The Internet Protocol (IP)

The most basic part of the Internet is the Internet Protocol, or IP. If you want to send data over an intranet, then that data must be packaged in an IP packet. That packet is then *routed* from one part of the intranet to another.

### A Simple Internet

IP is supposed to allow messages to travel from one part of a network to another. How does it do this?

An intranet is made of at least two *subnets*. The notion of a subnet is built upon the fact that most popular LAN architectures (Ethernet, Token Ring, and ARCNet) are based on something very much like a radio broadcast. Everyone on the same Ethernet segment hears all of the traffic on their segment, just as each device on a given ring in a Token Ring network must examine every message that goes through the network. The trick that makes an Ethernet or a Token Ring work is that, while each station *bears* everything, each station knows how to ignore all messages except the ones intended for it.

You may have never realized it, but that means that in a single Ethernet segment or a single Token Ring ring, there is *no routing*. If you've ever sat through one of those seemingly unending explanations of the ISO seven-layer network model, then you know that in network discussions, much is made of the *network layer*, which in ISO terms is merely the routing layer. And yet a simple Ethernet or Token Ring never has to route. There are no routing decisions to make; everything is heard by everybody. (Your network adapter filters out any traffic not destined for you, in case you're wondering.)

But now suppose you have *two* separate Ethernets connected to each other, as you see in Figure 6.4.

**FIGURE 6.4**  
Multisegment  
intranet

In Figure 6.4, you see two Ethernet segments, named Rome and Carthage. (I was getting tired of the “shipping” and “finance” examples that everyone uses.) There are three computers that reside solely in Rome. Each one has an Ethernet card built into it, and I’ve labeled those Ethernet cards A, B, and C. Three more computers reside in Carthage; I’ve labeled their Ethernet cards F, G, and H. One PC has *two* Ethernet cards—one labeled D that’s connected to Rome, and one labeled E that’s connected to Carthage.

### Subnets and Routers: “Should I Shout, or Should I Route?”

Much of intranet architecture is built around the observation that the PCs with Ethernet cards A, B, and C can communicate directly with each other, and the PCs with Ethernet cards F, G, and H can communicate directly with each other, but A, B, and C *cannot* communicate with F, G, and H without some help from the machine containing Ethernet cards D and E. That D/E machine will function as a *router*, a machine that allows communication between different network segments. A, B, C, and D could be described as being in each other’s “broadcast range,” as could E, F, G, and H. What I’ve

just called a broadcast range is called more correctly in intranet terminology a *subnet*, which is a collection of machines that can communicate with each other without the need for routing.

For example, F and H can communicate directly without having to ask the router (E, in their case) to forward the message, and so they're on the same subnet. A and C can communicate directly without having to ask the router (D, in their case) to forward the message, and so they're on the same subnet. But if B wanted to talk to G, it would have to first send the message to D, asking, "D, please get this to G," so they're not on the same subnet.

Now, this whole trick of somehow knowing that F and H are on the same subnet and so do not need to enlist the aid of a router—F can just "shout" the message and H will hear it—or knowing that A and F are on different subnets—so A would need the help of D to get to F and F would require E's assistance to get to A—is IP's main job. Essentially, IP's job is to figure out "should I shout, or should I route?" and then, if routing's the way to go, IP has to figure out which router to use, assuming there's a choice of routers.

## IP Addresses and Ethernet/MAC Addresses

Before continuing, let's briefly discuss the labels A, B, C, and so on and how those labels actually are manifested in an intranet. Each computer on this net is attached to the net via an Ethernet board, and each Ethernet board on an intranet has two addresses: an *IP address* and an *Ethernet or MAC address*. (There are, of course, other ways to get onto an intranet than via Ethernet, but let's stay with the Ethernet example as it's the most common one on TCP/IP intranets.)

### ETHERNET/MAC ADDRESSES

Each Ethernet board's Ethernet address is a unique 48-bit identification code. If it sounds unlikely that every Ethernet board in the world has its own unique address, then consider that 48 bits offers 280,000,000,000,000 possibilities. Ethernet itself only uses about one quarter of those possibilities (2 bits are set aside for administrative functions), but that's still a lot of possible addresses. In any case, the important thing to get here is that a board's Ethernet address is predetermined and hard-coded into the board. Ethernet addresses, which are also called Media Access Control (MAC) addresses (it's got nothing to do with Macintoshes), are expressed in 12 hex digits. (*MAC address* is synonymous with *Token Ring address* or *Ethernet address*.) For example, the Ethernet card on the computer I'm working at now has MAC (Ethernet) address 0020AFF8E771, or as it's sometimes written, 00-20-AF-F8-E7-71. The addresses are centrally administered, and Ethernet chip vendors must purchase blocks of addresses. In the example of my workstation, you know that it's got a 3Com Ethernet card because the Ethernet (MAC) address is 00-20-AF; that prefix is owned by 3Com.

**NOTE** To see a Server 2003 system's MAC address—or addresses, if it has more than one NIC—just open a command line and type **getmac**, then press Enter. The string of numbers and letters under the column *Physical Address* is the MAC address of your NIC.

### IP ADDRESSES AND QUAD FORMAT

In contrast to the 48 bits in a MAC address, an IP address is a 32-bit value. IP addresses are numbers set at a workstation (or server) by a network administrator—they're not a hard-coded hardware kind of address like the Ethernet address. That means that there are four billion distinct Internet addresses.

It's nice that there's room for lots of machines, but having to remember—or having to tell someone else—a 32-bit address is no fun. Imagine having to say to a network support person, “Just set up the machines on the subnet to use a default router address of 10101110100-101010010101100010111.” Hmm, doesn't sound like much fun—we need a more human-friendly way to express 32-bit numbers. That's where *dotted quad* notation comes from.

For simplicity's sake, IP addresses are usually represented as *w.x.y.z*, where *w*, *x*, *y*, and *z* are all decimal values from 0 to 255. For example, the IP address of the machine that I'm currently writing this at is 199.34.57.53. Each of the four numbers is called a *quad*; as they're connected by dots, it's called *dotted quad* notation.

Each of the numbers in the dotted quad corresponds to 8 bits of an Internet address. (*IP address* and *Internet address* are synonymous.) As the value for 8 bits can range from 0 to 255, each value in a dotted quad can be from 0 to 255. For example, to convert an IP address of 110010101000001111101010100000001 into dotted quad format, it would first be broken up into 8-bit groups:

11001010 00001111 10101010 00000001

And each of those 8-bit numbers would be converted to its decimal equivalent. (If you're not comfortable with binary-to-decimal conversion, don't worry about it: Just load the Server 2003 Calculator, click View, then Scientific, and then press the F8 key to put the Calculator in binary mode. Enter the binary number, press F6, and the number will be converted to decimal for you.) Our number converts as follows:

11001010 00001111 10101010 00000001  
202 15 170 1

which results in a dotted quad address of 202.15.170.1.

So, to recap: Each of these computers has at least one Ethernet card in it, and that Ethernet card has a predefined MAC address. The network administrator of this network has gone around and installed IP software on these PCs and, in the process, has assigned IP addresses to each of them. (Note, by the way, that the phrase “has assigned IP addresses to each of them” may not be true if you are using the Dynamic Host Configuration Protocol, or DHCP, which I'll describe in detail in the next chapter. For most of this chapter, however, I'm going to assume that you're not using DHCP and that someone must hand-assign an IP address to each Ethernet card.)

Let me redraw our intranet, adding totally arbitrary IP addresses and Ethernet addresses, as shown in Figure 6.5.

**FIGURE 6.5**

Two-subnet intranet with Ethernet and IP addresses

**NOTE** Remember, MAC addresses are burned into a network card; they come “out of the box,” so to speak. IP addresses, in contrast, are assigned by a network administrator or software configured by a network administrator. There isn’t any mathematical relationship between the two numbers; don’t try to see if there’s some connection between, say, the bottom 32 bits of a MAC address and the IP address—there won’t be one.

## IP Routers

Now let’s return to the computer in the middle. It is part of *both* segments, both subnets. How do I get one computer to be part of two networks? By putting two Ethernet cards in the computer in the middle. (A computer with more than one network card in it is called a *multibomed* computer. Don’t ask me why, the term has never made sense to me; I suppose it flows better than “multiNICced.”) One of the Ethernet cards is on the Rome subnet, and the other is on the Carthage subnet. (By the way, each computer on an intranet is called a *host* in TCP-ese.)

Now, each Ethernet card must get a separate IP address, so as a result, the computer in the middle has *two* IP addresses, D and E. If a message is transmitted in Rome, adapter D hears it and E doesn’t. Then, if a message is transmitted in Carthage, adapter E hears it but D doesn’t.

How would we build an intranet from these two subnets? How could the computer with Ethernet card A, for example, send a message to the computer with Ethernet card G? Obviously, the only way that message will get from A to G is if the message is received on the Ethernet adapter with address D and then re-sent out over the Ethernet adapter with address E. Once E resends the message, G will hear it, as it is on the same network as E.

In order for this to work, the machine containing boards D and E must be smart enough to perform this function whereby it resends data between D and E when necessary. Such a machine is, by definition, an *IP router*. A Server 2003 computer can act as an IP router, as you’ll learn later.

Under IP, the sending station (the one with Ethernet card A, in this case) examines the address of the destination (the PC with Ethernet card G, in this case) and realizes that it does not know how to get to G. (I’ll explain exactly *how* it comes to that realization in a minute.) Now, if A has to send something to an address that it doesn’t understand, then it uses a kind of “catchall” address called the *default router* or, for historical reasons, the *default gateway* address. A’s network administrator has already configured A’s default router as D, so A sends the message to D. Once D gets the message, it then sees that the message is not destined for itself, but rather for G, and so it resends the message from board E.

## Routing in More Detail

Now let’s look a little closer at how that message gets from A to G. Each computer, as you’ve already seen, has one *or more* IP addresses. It’s important to understand that there is no relation whatsoever between an Ethernet card’s address and the IP address associated with it: The Ethernet MAC address is hardwired into the card by the card’s manufacturer, and the IP addresses are assigned by a network administrator.

But now examine the IP addresses and you’ll see a pattern to them. Rome’s addresses all look like 199.34.57.*z*, where *z* is some number, and Carthage’s addresses all look like 156.40.10.*z*, where, again, *z* can be any number. The Ethernet addresses follow no rhyme or reason and are grouped by the board’s manufacturer. That similarity of IP addresses within Rome and Carthage will be important in understanding routing.

Now, let's reexamine how the message gets from A's computer to G's (for simplicity's sake, I'll say "A" instead of "the computer with the Ethernet card labeled A," and the same for G's computer and so on):

1. The IP software in A first says, "How do I get this message to G—can I just broadcast it, or must it be routed?" The way that it makes that decision is by finding out whether or not G is on the same *subnet* as A is. A subnet is simply a broadcast area. The host with Ethernet card A then, is asking, "Is G part of Rome, like me?"
2. A determines that it is on a different subnet from G by examining their addresses. A knows that it has address 199.34.57.10 and that it must send its message to 156.40.10.50. A's computer has a simple rule for this: If the destination address looks like 199.34.57.*z*, where, again, *z* can be any value, then the destination is in the same subnet and so requires no routing. On the other hand, 156.40.10.50 is clearly *not* in the same subnet.

If, alternatively, G *had* been on the same subnet, then A would have "shouted" the IP packet straight to G, referring specifically to its IP and Ethernet address.

3. So A can't directly send its IP packets to G. A then looks for another way. When A's network administrator set up A's IP software, she told A the IP address of A's *default router*. The default router is basically the address that says, "If you don't know where to send something, send it to me and I'll try to get it there." A's default router is D. So now A has a sort of sub-goal of getting a message to nearby D, with IP address 199.34.57.40. We're almost ready to hand this over to the Ethernet card—*except* that Ethernet cards don't understand IP addresses; they understand MAC addresses.

TCP/IP's got an answer for this: Address Resolution Protocol (ARP). A just sends a broadcast to the local segment, saying, "If there's a machine out there that goes by the IP address 199.34.57.40, please send me back your MAC address." D hears the request and responds that its MAC address is 100.

A then sends an Ethernet frame from itself to D. The Ethernet frame contains this information:

- ◆ Source Ethernet address: 14
  - ◆ Destination Ethernet address: 100
  - ◆ Source IP address: 199.34.57.10
  - ◆ Destination IP address: 156.40.10.50
4. Ethernet card D receives the frame and hands it to the IP software running in its PC. The PC sees that the IP destination address is not *its* IP address, so the PC knows that it must route this IP packet. Examining the subnet, the PC sees that the destination lies on the subnet that Ethernet adapter E is on, so it ARPs to get G's MAC address; G responds, "My MAC address is 115," and then E sends out a frame, with this information:
    - ◆ Source Ethernet address: 5
    - ◆ Destination Ethernet address: 115
    - ◆ Source IP address: 199.34.57.10 (note this is A's address, not E's)
    - ◆ Destination IP address: 156.40.10.50

5. G then gets the packet. By looking at the Ethernet and IP addresses, G can see that it got this frame from E, but the original message really came from another machine, the 199.34.57.10 machine.

That's a simple example of how IP routes, but its algorithms are powerful enough to serve as the backbone for a network as large as the Internet.

**TIP** *There are different kinds of routing algorithms in TCP/IP. Server 2003 supports the Routing Information Protocol (RIP) version 2, Open Shortest Path First (OSPF), and IGMP version 2. For other routing approaches, or for very high-capacity routing needs, you need either third-party software or a dedicated hardware router to build large, complex intranets with Server 2003. But Server 2003 can handle a considerably larger set of routing tasks than did its predecessors.*

## Class A, B, and C Networks, CIDR Blocks, Routable and Nonroutable Addresses, and Subnetting

Before leaving IP routing, let's take a more specific look at networks, subnets, and IP addresses.

The whole idea behind the 32-bit IP addresses is to make it relatively simple to segment the task of managing the Internet or, for that matter, *any* intranet.

To become part of the Internet, you'll need a block of IP addresses and a name (like `acme.com`) or a set of names. Find a local Internet service provider (ISP) for the block of addresses. ISPs may also handle registering names for you, but it's just as easy to register a name yourself with Network Solutions or another name registrar; surf over to [www.networksolutions.net](http://www.networksolutions.net) to find out how.

But how do the *ISPs* get their IP addresses? Originally, an organization named the Internet Assigned Numbers Authority (IANA) handed out addresses. In 1993, however, an Internet document RFC 1466 (the rules describing how things work in the Internet are called Requests for Comment, or RFCs) explained that it made more sense to distribute the job as the Internet became bigger. The IANA, which is now in the process of becoming the Internet Corporation for Assigned Names and Numbers (ICANN), divides its number-assigning authority among three Regional Internet Registries (RIRs, inevitably): RIPE (Reseaux IP Europeens, or European IP Networks) handles Europe, the Middle East, Africa, and the better part of Asia; APNIC (Asia Pacific Network Information Center) handles the rest of Asia and the South Pacific; and ARIN (American Registry for Internet Numbers) handles the Americas. Rather than say "The IANA/ICANN, RIPE, ARIN, APNIC, or one of their suborganizations," however, I hope you won't mind if I just say "IANA" when referring to the IP-allocating groups.

### A, B, and C Class Networks

The IANA or an ISP assigns a company a block of IP addresses according to the company's size. That block of addresses is called a *network*. (As you'll soon see, a subnet is just a subdivision of that set of assigned addresses, hence *subnet*.) Big companies get class A networks (there are none left; they've all been given out), medium-sized companies get class B networks (they're still around but pretty scarce), and others get class C networks (they're still available). Although there are three network classes, there are five kinds of IP addresses, as you'll see in Figure 6.6.

**FIGURE 6.6**  
Internet network  
classes and reserved  
addresses

Because it seemed, in the early days of the Internet, that four billion addresses left plenty of space for growth, the original designers were a bit sloppy. They defined three classes of networks of the Internet: Large networks, medium-sized networks, and small networks. The creators of the Internet used 8-bit sections of the 32-bit addresses to delineate the difference between different classes of networks:

**Class A Networks** A large network would have its first 8 bits set by the NIC, and the network’s internal administrators could set the remaining 24 bits. The leftmost 8 bits could have values from 0 to 126, allowing for 127 class A networks. Companies like IBM get these, and there are only 127 of these addresses. As only 8 bits have been taken, 24 remain; that means that class A networks can contain up to 2 to the 24th power, or about 16 million, hosts. Examples of class A nets include General Electric (3.x.y.z), BBN (4), IBM (9), Xerox (13), Hewlett-Packard (15), DEC (16), Apple (17), MIT (18), Ford (19), Eli Lilly (40), DuPont (52), Merck (54), Boeing (55), the U.S. Postal Service (56), various defense groups—remember who built this—and some unexpected ones: Network+Interop, which has the 45.x.y.z network set aside for its use (not bad, an A network for two week-long conferences a year!), the U.K. Department of Social Security (51), and Norsk Informasjonsteknologi (32).

**Class B Networks** Medium-sized networks have the leftmost 16 bits preassigned to them, leaving 16 bits for local use. Class B addresses always have the values 128 through 191 in their first quad, then a value from 0 to 255 in their second quad. There are then 16,384 possible class B

networks. Each of them can have up to 65,536 hosts. Microsoft and Exxon are examples of companies with class B networks. (So Apple and IBM have class A networks and Microsoft only has a class B. What do you want to bet that this kind of thing keeps Bill up late nights?)

**Class C Networks** Small networks have the leftmost 24 bits preassigned to them, leaving only 8 bits for local administration (which is bad, as it means that class C networks can't have more than 254 hosts), but as the NIC has 24 bits to work with, it can easily give out class C network addresses (which is good). Class C addresses start off with a value from 192 to 223. As the second and third quads can be any value from 0 to 255, that means that there can potentially be 2,097,152 class C networks. (That's what my network, minasi.com, is.) The last C network, when it's assigned, will be 223.255.255.z; remember that the owner of that network will be able to control only z.

**Reserved Addresses** Some addresses are reserved for multicast purposes and for experimental purposes, so they can't be assigned for networks. In particular, address 224.0.0.0 is set aside for *multicasts*, network transmissions to groups of computers.

## Routable and Nonroutable Addresses

Once upon a time, getting hold of a bunch of IP addresses was easy. But nowadays, they're scarcer and scarcer. Four billion possible addresses sounds like a lot, but the A/B/C class approach tends to waste addresses on large companies and those who just got in line at the right time: With all due respect to the organizations involved, it's hard to believe that certain universities, Apple, and the Network+Interop conference each really need 16 million unique IP addresses. Don't misunderstand me, I'm not suggesting that we change their address allocation—first come, first served in the IP land rush is a reasonable first approach to allocation. But big and small firms alike need IP addresses, and they're not as plentiful as they once were.

### RFC 1918'S NONROUTABLE ADDRESSES

We've heard for years that the Giant Brains of the IP world are working on promoting a replacement for IP called IPV6, a 128-bit-based addressing scheme that would allow more IP addresses than there are electrons in the universe (okay, I rechecked, it's only about the size of the square root of the number of electrons in the universe, but it's still a big number), but then I've been hearing about the "imminent" nature of IPV6 since about 1993. Until it's more widely accepted, we need some way to stretch our IP addresses. And there *is* a way that's been widely adopted.

In RFC 1918, the Internet folks defined three nonroutable ranges of IP addresses. They are

- ◆ 10.0.0.0–10.255.255.255
- ◆ 172.16.0.0–172.31.255.255
- ◆ 192.168.0.0–192.168.255.255

The original idea with the ranges of nonroutable addresses was to set aside some addresses that people could use to build "test" intranets without having to go to the IANA for a range of numbers—anyone can build an IP-based network using these addresses. Furthermore, even if networks based on the above addresses *were* attached to the Internet, then they couldn't cause any mischief, because Internet routers are programmed to *ignore* them! As messages sent from these ranges won't be routed on the public Internet, they are logically called the *nonroutable* ranges.

This means that literally millions of networks in the (for example) 192.168.1.0–192.168.1.255 range could exist, all at the same time, because they cannot communicate with the public Internet, and therefore can't cause any trouble. And that offers a kind of side benefit to companies choosing to use the nonroutable addresses: security. Clearly if my system has address 10.10.10.10, then I'm protected from outside hackers, because if they can't connect to me, then they can't cause trouble, right?

Because of this, most companies use at least two sets of IP addresses: Addresses used in their company's *internal* Internet (or "intranet," as we say nowadays) and a range of "official" Internet addresses obtained from an ISP or directly from a part of the IANA.

### ROUTING THE NONROUTABLE, PART I: NETWORK ADDRESS TRANSLATION

Now, from what I've said so far, it sounds like the folks whose machines have nonroutable addresses are sort of left out in the cold; they can route *inside* their company's network, but they're shut out of access to the public, *routable* Internet. But not any more. In fact, a little technological trick has made it possible for companies to offer public Internet access to their nonroutable addresses. You see, there is a class of routers called network address translation (NAT) routers that can perform a small bit of magic and let you use private, non-IANA-assigned IP addresses on your company's intranet and still be able to communicate with the Internet.

So, for example, suppose your firm had obtained a class C address range from the IANA or an ISP: 256 addresses. Although you have thousands of computers, the fact that there are only 256 addresses is no problem as the NAT router can handle communications with the Internet. NAT is kind of interesting in that it lets machines with nonroutable addresses *initiate* conversations with machines on the routable public Internet, but doesn't allow machines out on the Internet to initiate conversations in the other direction. For example, if I were sitting at a machine with IP address 192.168.1.17 behind a NAT router and tried to surf [www.microsoft.com](http://www.microsoft.com), then I'd get in, no problem. But if someone in the public Internet tried to connect to my system at 192.168.1.17, they'd be rebuffed, as *their* local router would know better than to pass a request to a nonroutable address.

You'll see a bit more about NAT (and an important partner, PAT, *port* address translation) later in the chapter. And in case you wondered, NAT and PAT have a *downside*: under the wrong circumstances, NAT and PAT *can* let the bad guys in.

### You Can't Use *All* of the Numbers

There are some special rules to IP addresses, however. There's a whole bunch of numbers that you can never give to any machine. They're the default route address, the loopback address, the network number, the broadcast address, and the default router address.

#### THE DEFAULT ROUTE ADDRESS

As you'll see later, the address 0.0.0.0 is another way of saying "the entire Internet." But as 0.x.y.z is in the class A range of addresses, all of 0.x.y.z must be set aside—all 16 million addresses.

#### THE LOOPBACK ADDRESS

The address 127.0.0.1 is reserved as a loopback. If you send a message to 127.0.0.1, then it should be returned to you unless there's something wrong on the IP software itself; messages to the loopback don't go out on the network, but instead stay within a particular machine's IP software. And so no network has an address 127.xxxxxxx.xxxxxxx.xxxxxxx, an unfortunate waste of 16 million addresses.

### THE NETWORK NUMBER

Sometimes you need to refer to an entire subnet with a single number. Thus far, I've said things like "My C network is 199.34.57.*z*, and I can make *z* range from 0 to 255." I was being a bit lazy; I didn't want to write "199.34.57.0 through 199.34.57.255," so I said "199.34.57.*z*."

It's not proper IP-ese to refer to a range of network addresses that way. And it's necessary to have an official way to refer to a range of addresses.

For example, to tell a router, "To get this message to the subnet that ranges from 100.100.100.0 through 100.100.100.255, first route to the router at 99.98.97.103," you've got to have some way to designate the range of addresses 100.100.100.0–100.100.100.255. We could have just used two addresses with a dash between them, but that's a bit cumbersome. Instead, the address that ends in all binary 0s is reserved as the *network number*, the TCP/IP name for the range of addresses in a subnet. In my 100.100.100.*z* example, the shorthand way to refer to 100.100.100.0 through 100.100.100.255 is 100.100.100.0.

Notice that this means you would never use the address 100.100.100.0—you never give that IP address to a machine under TCP/IP.

For example, to tell that router, "To get this message to the subnet that ranges from 100.100.100.0 through 100.100.100.255, first route to the router at 99.98.97.103," you would type something like **route add 100.100.100.0 99.98.97.103**. (Actually, you'd type a bit more information, and I'll get to that in the upcoming section on using your machine as a router, but this example gives you the idea.)

### IP BROADCAST ADDRESS

There's another reserved address, as well—the TCP/IP broadcast address. It looks like the address of one machine, but it isn't; it's the address you'd use to broadcast to each machine on a subnet. That address is all binary 1s.

For example, on a simple class C subnet, the broadcast address would be *w.x.y.255*. When would you need to know this? Some IP software needs this when you configure it; most routers require the broadcast address (as well as the network number). So if I just use my class C network 199.34.57.0 (see how convenient that .0 thing is?) as a single subnet, then the broadcast address for my network would be 199.34.57.255.

### DEFAULT ROUTER ADDRESS

Every subnet has at least one router; after all, if it didn't have a router, then the subnet couldn't talk to any other networks, and it wouldn't be an intranet.

By convention, the first address after the network number is the default gateway (router) address. For example, on a simple class C network, the address of the router should be *w.x.y.1*. This is not, by the way, a hard-and-fast rule like the network number and the IP broadcast address—it is, instead, a convention.

Suppose you have just been made the proud owner of a class C net, 222.210.34.0. You can put 253 computers on your network, as you must not use 222.210.34.0, which describes the entire network; 222.210.34.255, which will be your broadcast address; and 222.210.34.1, which will be used either by you or your Internet Service Provider for a router address between your network and the rest of the Internet.

## Subnet Masks

If you had a trivially small intranet, one with just one segment where everyone can just “shout” to one another, then no routing is required. But that wouldn’t be the case for most—routing is a great way to isolate parts of your network and is absolutely essential whenever connecting a wide area network to a local area network. Or you might simply have too large a number of IP addresses to fit on one segment even if you wanted to. Consider IBM’s situation, with a class A network that can theoretically support 16 million hosts. Managing *that* network cries out for routers. For this reason, it may be necessary for your IP software on your PC to route data over a router even if it’s staying within your company. Let’s ask again, and in more detail this time, “How does a machine know whether to route or not?”

That’s where subnets are important. Subnets make it possible, as you’ve seen, for a host (that is, a PC with an IP address) to determine whether it can just lob a message straight over to another host or if it must go through routers. You can tell a host’s IP software how to distinguish whether or not another host is in the same subnet through the *subnet mask*.

Recall that all of the IP addresses in Rome looked like 199.34.57.*z*, where *z* was a number between 1 and 255. You could then say that all co-members of the Rome subnet are defined as the hosts whose first three quads match. Now, on some subnets, it might be possible that the only requirement for membership in the same subnet would be that the first *two* quads be the same—a company that decided for some reason to make its entire class B network a single subnet would be one example of that. (Yes, they *do* exist: I’ve seen firms that make a single subnet out of a Class B network, with the help of some bizarre smart bridges. Imagine it—65,534 machines all able to broadcast to one another; yikes. And no, I don’t recommend it.)

When a computer is trying to figure out whether the IP address that it owns is on the same subnet as the place that it’s trying to communicate with, then a subnet mask answers the question, “Which bits must match for us to be on the same subnet?”

IP does that with a *mask*, a combination of 1s and 0s like so:

```
11111111 11111111 11111111 00000000
```

Here’s how a host would use this mask. The host with IP address 199.34.57.10 (station A in Figure 6.5) wants to know if it is on the same subnet as the host with IP address 199.34.57.20 (station B in Figure 6.5). 199.34.57.10, expressed in binary, is 11000111 00100010 00111001 00001010. The IP address for B is, in binary, 11000111 00100010 00111001 00010100. The IP software in A then compares its own IP address to B’s IP address. Look at them right next to each other:

```
11000111 00100010 00111001 00001010 A's address
11000111 00100010 00111001 00010100 B's address
```

The leftmost 27 bits match, as does the rightmost bit. Does that mean they’re in the same subnet? Again, for the two addresses to be in the same subnet, certain bits must match—the ones with 1s in the subnet mask. Let’s stack up the subnet mask, A’s address, and B’s address to make this clearer:

```
11111111 11111111 11111111 00000000 the subnet mask
11000111 00100010 00111001 00001010 A's address
11000111 00100010 00111001 00010100 B's address
```

Look down from each of the 1s on the subnet mask, and you see that A and B match at each of those positions. Under the 0s in the subnet mask, A and B match up sometimes but not all the time. In fact, it doesn't matter whether or not A and B match in the positions under the 0s in the subnet mask—the fact that there are 0s there means that whether they match is irrelevant.

Another way to think of the subnet mask is this. The IANA and friends give you a range of addresses, and you allocate them as you see fit. Of the 32 bits in your IP addresses, some are under your control and some are under the IANA & Co.'s control. In general, however, the bits that the IANA controls are to the left, and the ones that *you* control are to the right. For example, the IANA controls the leftmost 8 bits for a class A network, the 16 leftmost bits for a class B network, and the leftmost 24 bits for a class C network.

How do you know what value to use for a subnet mask? Well, if you have a class C number and all of your workstations are on a single subnet, then you have a case like the one we just saw: A subnet mask of 11111111 11111111 11111111 00000000, which, in dotted-quad terminology, is 255.255.255.0. Remember that, by definition, the fact that I have a C network means that the IANA has “nailed down” the leftmost or top three quads (24 bits), leaving me only the rightmost quad (8 bits). Since all of my addresses must match in the leftmost 24 bits and I can do anything I like with the bottom 8 bits, my subnet mask must be 11111111 11111111 11111111 00000000, or 255.255.255.0. Again, with subnet masks, the 1s are always on the left and the 0s on the right—you'll never see a subnet mask like “11111111 11110000 00001111 11111000” or “00000000 11111111 11111111 11111111.”

Getting back to my C network, however, that 11111111 11111111 11111111 00000000 mask assumes that I'll use my entire C network as one big subnet. Instead, I might decide to break one class C network into two subnets. I could decide that all the numbers from 1 to 127—00000001 to 01111111—are subnet 1 and the numbers from 128 to 255—10000000 to 11111111—are subnet 2. In that case, the values inside my subnets will only vary in the last 7 bits rather than (as in the previous example) varying in the last 8 bits. The subnet mask would be, then, 11111111 11111111 11111111 10000000, or 255.255.255.128.

The first subnet is a range of addresses from *w.x.y.0* through *w.x.y.127*, where *w.x.y* are the quads that the NIC assigned me. The second subnet is the range from *w.x.y.128* through *w.x.y.255*.

Now let's find the network number, default router address, and broadcast address. The network number is the first number in each range, so the first subnet's network number is *w.x.y.0* and the second's is *w.x.y.128*. The default router address is just the second address in the range, which is *w.x.y.1* and *w.x.y.129* for the two subnets. The broadcast address is then the *last* address in both cases, *w.x.y.127* and *w.x.y.255* respectively.

## Subnetting a Class C Network

If you're going to break down your subnets smaller than class C, then having to figure out the subnet mask, network number, broadcast address, and router address can get kind of confusing. Table 6.1 summarizes how you can break a class C network down into one, two, four, or eight smaller subnets with the attendant subnet masks, network numbers, broadcast addresses, and router addresses. I've assumed that you are starting from a class C address, so you'll only be working with the fourth quad. The first three quads I have simply designated *w.x.y*.

**TABLE 6.1: BREAKING A C CLASS NETWORK INTO SUBNETS**

NUMBER OF DESIRED SUBNETS	SUBNET MASK	NETWORK NUMBER	ROUTER ADDRESS	BROADCAST ADDRESS	REMAINING NUMBER OF IP ADDRESSES
1	255.255.255.0	w.x.y.0	w.x.y.1	w.x.y.255	253
2	255.255.255.128	w.x.y.0	w.x.y.1	w.x.y.127	125
	255.255.255.	w.x.y.128	w.x.y.129	w.x.y.255	125
4	255.255.255.192	w.x.y.0	w.x.y.1	w.x.y.63	61
	255.255.255.	w.x.y.64	w.x.y.65	w.x.y.127	61
	255.255.255.	w.x.y.128	w.x.y.129	w.x.y.191	61
	255.255.255.	w.x.y.192	w.x.y.193	w.x.y.255	61
8	255.255.255.224	w.x.y.0	w.x.y.1	w.x.y.31	29
	255.255.255.	w.x.y.32	w.x.y.33	w.x.y.63	29
	255.255.255.	w.x.y.64	w.x.y.65	w.x.y.95	29
	255.255.255.	w.x.y.96	w.x.y.97	w.x.y.127	29
	255.255.255.	w.x.y.128	w.x.y.129	w.x.y.159	29
	255.255.255.	w.x.y.160	w.x.y.161	w.x.y.191	29
	255.255.255.	w.x.y.192	w.x.y.193	w.x.y.223	29
	255.255.255.	w.x.y.224	w.x.y.225	w.x.y.255	29

For example, suppose you want to chop up a class C network, 200.211.192.z, into two subnets. As you see in the table, you'd use a subnet mask of 255.255.255.128 for each subnet. The first subnet would have network number 200.211.192.0, router address 200.211.192.1, and broadcast address 200.211.192.127. You could assign IP addresses 200.211.192.2 through 200.211.192.126, 125 different IP addresses. (Notice that heavily subnetting a network results in the loss of a greater and greater percentage of addresses to the network number, broadcast address, and router address.) The second subnet would have network number 200.211.192.128, router address 200.211.192.129, and broadcast address 200.211.192.255.

In case you're wondering, it is entirely possible to subnet further, into 16 subnets of 13 hosts apiece (remember that you always lose three numbers for the network number, router address, and broadcast address) or 32 subnets of 5 hosts apiece, but at that point, you're losing an awful lot of addresses to IP overhead.

## Subnetting a Class C Network the RFC/CCNA Way

Now, I *guarantee* that the previous page or so got the readers with a CCNA (Cisco Certified Network Administrator) certification all cranked up. I just told you that you could chop a C network into two

subnets of 126 addresses, or four subnets of 62 addresses, or eight of 30 addresses. That's a fact that will actually work in the real world. But if you do your routing by the book or, rather, by the RFC, then you'll get a different answer. The RFC point of view would say that you *cannot* chop a C network into 126-address subnets at all. The RFC would also say that you can indeed chop a C network into 62-address subnets, but that you only get two of them, or only six 30-address subnets. Here's why.

The RFC on subnetting is RFC 950; it says

*In certain contexts, it is useful to have fixed addresses with functional significance rather than as identifiers of specific hosts. When such usage is called for, the address zero is to be interpreted as meaning "this," as in "this network." The address of all ones are to be interpreted as meaning "all," as in "all hosts." For example, the address 128.9.255.255 could be interpreted as meaning "all hosts on the network 128.9." Or the address 0.0.0.37 could be interpreted as meaning "host 37 on this network." It is useful to preserve and extend the interpretation of these special addresses in subnetted networks. This means the values of all zeros and all ones in the subnet field should not be assigned to actual (physical) subnets. In the example above, the 6-bit wide subnet field may have any value except 0 and 63.*

What this means in English is this: RFC 950 says to use neither the first subnet nor the last subnet. Thus, if you're going to be completely RFC-compliant (which is never a bad idea), you would *not* be able to use subnets 199.34.57.0 and 199.34.57.192. And my earlier example of dividing 199.34.57.0 into two subnets by using subnet mask 255.255.255.128 would not work at all.

Should you care? If you're using modern routers or NT machines for routers, you won't run into trouble using all possible subnets. But if you've got some routers that are sticklers for the rules, you might cause trouble by using those other subnets. It's kind of a shame, as the 255.255.255.192 subnet for a C network yields four 62-address subnets, and staying strictly RFC compliant means you only get *two* 62-address subnets.

Oh, and one more reason to understand RFC 950's restrictions: If you take any exams, such as the Microsoft or Cisco certification exams about TCP/IP, the RFC 950 answer will be right—the practical answer will be "wrong," even if it *would* work in the real world.

## **Classless Inter-Domain Routing (CIDR)**

Now that we've gotten past some of the fine points of subnet masks, let me elaborate on what you see if you ever go to the IANA or an ISP looking for a domain of your own.

The shortage of IP addresses has led the IANA to curtail giving out class A, B, or C addresses. Many small companies need an Internet domain, but giving them a C network is overkill, as a C network contains 256 addresses and many small firms only have a dozen or so computers that they want on the Internet. Large companies may also want a similarly small presence on the Internet: For reasons of security, they may not want to put all of the PCs (or other computers) on the Internet but rather on an internal network not attached to the Internet. These companies *do* need a presence on the Internet, however—for their e-mail servers, FTP servers, Web servers, and the like—so they need a dozen or so addresses. But, again, giving them an entire 256-address C network is awfully wasteful. However, until 1994, it was the smallest block that an ISP could hand out.

Similarly, some companies need a few hundred addresses—more than 256, but not very many more. Such a firm is too big for a C network but a bit small for the 65,536 addresses of a B network. More flexibility here would be useful.

For that reason, the IANA now gives out addresses without the old A, B, or C class restrictions. This newer method that the IANA uses is called Classless Inter-Domain Routing, or CIDR, pronounced “cider.” CIDR networks are described as “slash *x*” networks, where the *x* is a number representing the number of bits in the IP address range that IANA controls.

If you had a class A network, then the IANA controlled the top 8 bits and you controlled the bottom 24. If you decided somehow to take your class A network and make it one big subnet, then what would be your subnet mask? Since all of your A network would be one subnet, you’d only have to look at the top quad to see if the source and destination addresses were on the same subnet. For example, if you had network 4.0.0.0, then addresses 4.55.22.81 and 4.99.63.88 would be on the same subnet. (Please note that I can’t actually imagine anyone doing this with a class A net; I’m just trying to make CIDR clearer.) Your subnet mask would be, then, 11111111 00000000 00000000 00000000, or 255.0.0.0. Reading from the left, you have eight 1s in the subnet mask before the 0s start. In CIDR terminology, you wouldn’t have a class A network; rather, you would have a *slash 8* network. It would be written “4.0.0.0/8” instead of “4.0.0.0 subnet mask 255.0.0.0.”

With a class B, the IANA controlled the top 16 bits, and you controlled the bottom 16. If you decided to take that class B network and make it a one-subnet network, then your subnet mask would be 11111111 11111111 00000000 00000000, or 255.255.0.0. Reading from the left, the subnet mask would have 16 1s. In CIDR terms, a B network is a *slash 16* network. So if your firm had a B network like 164.109.0.0 subnet mask 255.255.0.0, in slash format that would be 164.109.0.0/16.

With a C class, the IANA controlled the top 24 bits, and you controlled the bottom 8. By now, you’ve seen that the subnet mask for a C network if you treated it as one subnet is 11111111 11111111 11111111 00000000. Reading from the left, the subnet mask would have 24 1s. In CIDR terms, a C network is a *slash 24* network. Thus, one of my C networks (206.246.253.0, mask 255.255.255.0) can be written “206.246.253/24.” Grasping this /24 nomenclature is important because you’ll see it on some routers. My Ascend router never asks for subnet masks—just slashes.

Where the new flexibility of CIDR comes in is that the IANA can in theory now not only define the A-, B-, and C-type networks, it can offer networks with subnet masks in between the A, B, and C networks. For example, suppose I wanted a network for 50 PCs. Before, IANA would have to give me a C network, with 256 addresses. But now they can offer me a network with subnet mask 11111111 11111111 11111111 11000000 (255.255.255.192), giving me only 6 bits to play with. Two to the sixth power is 64, so I’d have 64 addresses to do with as I liked. This would be a *slash 26* (/26) network.

In summary, Table 6.2 shows how large each possible network type would be.

TABLE 6.2: CIDR NETWORK TYPES		
IANA NETWORK TYPE	“SUBNET MASK” FOR ENTIRE NETWORK	APPROXIMATE NUMBER OF IP ADDRESSES
slash 0	0.0.0.0	4 billion
slash 1	128.0.0.0	2 billion
slash 2	192.0.0.0	1 billion
slash 3	224.0.0.0	500 million
slash 4	240.0.0.0	250 million

Continued on next page

**TABLE 6.2:** CIDR NETWORK TYPES (*continued*)

IANA NETWORK TYPE	“SUBNET MASK” FOR ENTIRE NETWORK	APPROXIMATE NUMBER OF IP ADDRESSES
slash 5	248.0.0.0	128 million
slash 6	252.0.0.0	64 million
slash 7	254.0.0.0	32 million
slash 8	255.0.0.0	16 million
slash 9	255.128.0.0	8 million
slash 10	255.192.0.0	4 million
slash 11	255.224.0.0	2 million
slash 12	255.240.0.0	1 million
slash 13	255.248.0.0	524,288
slash 14	255.252.0.0	262,144
slash 15	255.254.0.0	131,072
slash 16	255.255.0.0	65,536
slash 17	255.255.128.0	32,768
slash 18	255.255.192.0	16,384
slash 19	255.255.224.0	8192
slash 20	255.255.240.0	4096
slash 21	255.255.248.0	2048
slash 22	255.255.252.0	1024
slash 23	255.255.254.0	512
slash 24	255.255.255.0	256
slash 25	255.255.255.128	128
slash 26	255.255.255.192	64
slash 27	255.255.255.224	32
slash 28	255.255.255.240	16
slash 29	255.255.255.248	8
slash 30	255.255.255.252	4
slash 31	255.255.255.254	2
slash 32	255.255.255.255	1

I hope it's obvious that I included all of those networks just for the sake of completeness, as some of them simply aren't available, like the slash 0, and some just don't make sense, like the slash 31—it only gives you two addresses, which would be immediately required for network number and broadcast address, leaving none behind for you to actually use. The smallest network that the American subgroup of the IANA, ARIN, will allocate to a network is a slash 20, a 4,094-address network.

CIDR is a fact of life if you're trying to get a network nowadays. With the information in this section, you'll more easily be able to understand what an ISP is talking about when it says it can get you a slash 26 network.

### What IP *Doesn't* Do: Error Checking

Whether you're on *an* intranet or *the* Internet, it looks like your data gets bounced around quite a bit. How can you prevent it from becoming damaged? Let's look briefly at that, and that'll segue to a short talk on TCP.

An IP packet contains a bit of data called a *checksum header*, which checks whether the header information was damaged on the way from sender to receiver.

Many data communications protocols use checksums that operate like this: I send you some data. You use the checksum to make sure the data wasn't damaged in transit, perhaps by line noise. Once you're satisfied that the data was not damaged, you send me a message that says, "Okay—I got it." If the checksum indicates that it did *not* get to you undamaged, then you send me a message that says, "That data was damaged—please resend it," and I resend it. Such messages are called ACKs and NAKs—positive or negative acknowledgments of data. Protocols that use this check-and-acknowledge approach are said to provide *reliable* service.

*But IP does not provide reliable service.* If an IP receiver gets a damaged packet, it just discards the packet and says nothing to the receiver. Surprised? I won't keep you in suspense: It's TCP that provides the reliability. The IP header checksum is used to see if a header is valid; if it isn't, then the datagram is discarded.

This underscores IP's job. IP is not built to provide end-to-end guaranteed transmission of data. IP exists mainly for one reason: routing. We'll revisit routing a bit later, when I describe the specifics of how to accomplish IP routing on a Microsoft OS-based machine.

But whose job *is* end-to-end integrity, if not IP's? The answer: its buddy's, TCP.

## TCP (Transmission Control Protocol)

I said earlier that IP handled routing and really didn't concern itself that much with whether the message got to its final destination or not. If there are seven IP hops from one point to the next, then each hop is an independent action—there's no coordination, no notion of whether a particular hop is hop number three out of seven. Each IP hop is totally unaware of the others. How, then, could we use IP to provide reliable service?

IP packets are like messages in a bottle. Drop the bottle in the ocean, and you have no guarantee that the message got to whomever you want to receive it. But suppose you hired a "message-in-the-bottle end-to-end manager." Such a person (let's call her Gloria) would take your message, put it in a bottle, and toss it in the ocean. That person would also have a partner on the other side of the ocean (let's call him Gaston), and when Gaston received a message in a bottle from Gloria, Gaston

would then pen a short message saying “Gloria, I got your message,” put *that* message in a bottle, and drop that bottle into the ocean.

If Gloria didn’t get an acknowledgment from Gaston within, say, three months, then she’d drop *another* bottle into the ocean with the original message in it. In data communications terms, we’d say that Gloria “timed out” on the transmission path and was *resending*.

Yeah, I know, this is a somewhat goofy analogy, but understand the main point: We hired Gloria and Gaston to ensure that our inherently unreliable message-in-a-bottle network became reliable. Gloria will keep sending and resending until she gets a response from Gaston. Notice that she doesn’t create a whole new transmission medium, like radio or telephone; she merely adds a layer of her own watchfulness to the existing transmission protocol.

Now think of IP as the message in the bottle. TCP, the Transmission Control Protocol, is just the Gloria/Gaston team. TCP provides reliable end-to-end service.

By the way, TCP provides some other services, most noticeably something called *sockets*, which I will discuss in a moment. As TCP has value besides its reliability feature, TCP also has a “cousin” protocol that acts very much like it but does *not* guarantee end-to-end integrity. That protocol is called UDP (User Datagram Protocol).

*That’s* basically the idea behind TCP. Its main job is the orderly transmission of data from one intranet host to another. Its main features include

- ◆ Handshake
- ◆ Packet sequencing
- ◆ Flow control
- ◆ Error handling

Where IP has no manners—it just shoves data at a computer whether that computer is ready for it or not—TCP makes sure that each side is properly introduced before attempting to transfer. TCP sets up the connection.

## Sequencing

As IP does not use a virtual circuit, different data packets may end up arriving at different times and, in fact, in a different order. Imagine a simple intranet transferring four segments of data across a network with multiple possible pathways. The first segment takes the high road, so to speak, and is delayed. The second, third, and fourth do not and so get to the destination more quickly. TCP’s job on the receiving side is to then reassemble things in order.

## Flow Control

Along with sequencing is flow control. What if 50 segments of data had been sent and they all arrived out of order? The receiver would have to hold them all in memory before sorting them out and writing them to disk. Part of what TCP worries about is *pacing* the data—not sending it to the receiver until the receiver is ready for it.

## Error Detection/Correction

And finally, TCP handles error detection and correction, as I’ve already said. Beyond that, TCP is very efficient in the way that it does error handling. Some protocols acknowledge each and every

block, generating a large overhead of blocks. TCP, in contrast, does not do that. It tells the other side, “I am capable of accepting and buffering some number of blocks. Don’t expect an acknowledgment until I’ve gotten that number of blocks. And if a block is received incorrectly, I will not acknowledge it, so if I don’t acknowledge as quickly as you expect me to, then just go ahead and resend the block.”

## Sockets, Ports, and the Winsock Interface

Just about anything that you want to do with the Internet or your company’s intranet involves two programs talking to each other. When you browse someone’s Web site, you have a program (your Web browser, a *client* program) communicating with their Web server (obviously, a *server* program). Using the File Transfer Protocol (FTP), which I’ll discuss later in this chapter, requires that one machine be running a program called an *FTP server* and that another computer be running an *FTP client*. Internet mail requires that a mail client program talk to a mail server program—and those are just a few examples.

Connecting a program in one machine to another program in another machine is kind of like placing a telephone call. The sender must know the phone number of the receiver, and the receiver must be around his or her phone, waiting to pick it up. In the TCP world, a phone number is called a *socket*. A socket is composed of three parts: the IP address of the receiver, which we’ve already discussed, the receiving program’s *port number*, which we *haven’t* yet discussed, and whether it’s a TCP port or a UDP port—each protocol has its own set.

Suppose the PC on your desk running XP wants to get a file from the FTP site, which is really the PC on *my* desk running Server 2003. Obviously, for this to happen, we have to know each other’s IP addresses. But that’s not all; after all, in my PC I have a whole bunch of programs running (my network connection, my word processor, my operating system, my personal organizer, the FTP server, and so on). So if TCP says, “Hey, Mark’s machine, I want to talk to you,” then my machine would reply, “Which *one* of us—the word processor, the e-mail program, or what?” So the TCP/IP world assigns a 16-bit number to each program that wants to send or receive TCP information, a number called the *port* of that program.

The most popular Internet applications have had particular port numbers assigned to them, and those port numbers are known as *well-known ports*. You can see some well-known ports in Table 6.3.

**TABLE 6.3: INTERNET PROTOCOLS AND PORT NUMBERS**

INTERNET PROTOCOL	PORT NUMBER
FTP	TCP 20/21
Telnet	TCP 23
Simple Mail Transport Protocol	TCP 25
DNS	UDP and TCP 53
Trivial FTP (TFTP)	UDP 69
Hypertext Transfer Protocol (Web)	TCP 80
Kerberos logons	UDP and TCP 88

*Continued on next page*

**TABLE 6.3:** INTERNET PROTOCOLS AND PORT NUMBERS (*continued*)

INTERNET PROTOCOL	PORT NUMBER
Post Office Protocol v3 (POP3)	TCP 110
Network News Transfer Protocol (NNTP)	TCP 119
Simple Network Time Protocol (SNTP)	UDP 123
NetBIOS	UDP and TCP 137, UDP 138, TCP 139
IMAP4	TCP 143
SNMP	UDP 161/162
LDAP	TCP 389
Secure HTTP (SSL)	TCP and UDP 443
SMB over sockets (CIFS)	TCP/UDP 445
ISAKMP (key exchange for IPsec)	UDP 500
SQL Server	UDP/TCP 1433

Specific programs may use their own particular ports, as in the case of Active Directory’s global catalog server, which uses port 3268. Someone in the Navy has put up a nice page collecting many more ports at [www.nswc.navy.mil/ISSEC/Docs/Ref/Networking/new\\_ports.html](http://www.nswc.navy.mil/ISSEC/Docs/Ref/Networking/new_ports.html).

**How Ports and Sockets Work**

So, for instance, suppose I’ve pointed my HTTP client (which you know as a Web browser, like Internet Explorer) to an HTTP server (which you know as a Web server, like a copy of Internet Information Server). Let’s also assume that I’m going to visit [www.acme.com](http://www.acme.com), that [acme.com](http://acme.com)’s Web server is at 123.124.55.67, and that my computer has IP address 200.200.200.10.

My Web browser tries to contact the machine at 123.124.55.67. But just knowing a machine’s IP address isn’t sufficient; we need also to know the port address of the program that we want to talk to because, for example, this computer might also be a mail server, and I want to surf its Web pages, not send or receive e-mail. My Web browser knows that by convention the Web server lives at port 80. So my Web browser essentially “places a call”—that is, sets up a TCP/IP session—with port 80 at address 123.124.55.67, sometimes written 123.124.55.67:80, with a colon between the IP address and the port number. That combination of an IP address and a port is called a *socket address*.

In order for the Web server computer to chat with my computer, the Web server computer must be *ready* to chat—there’s got to be someone at the Web browser “listening” when I “call.” That’s a lot of what a Web browser program does—it just sits and waits, “listening” on port 80. When the Web browser first starts up, it says, “If anyone calls on port 80, wake me up—I’m willing to take calls on that port.” That’s called a *passive open* on TCP.

So my Web browser talks to the Web server at the Web server’s port 80. But how does the Web server talk back—what port does it use on *my* computer, what port on my computer is now listening for the server’s response? Well, port 80 might seem the logical answer, at first—but it

can't be. Here's why: suppose I'm sitting at a computer that's *running* a Web server and I fire up Internet Explorer to surf a different Web site. Could that Web site talk back to my computer at port 80? No, because port 80 on my computer is *already* busy, as *my* Web server would be running there.

Instead, the Web server negotiates with my Web browser to pick a port that my system's not using. So the conversation might look like

1. (From my computer to the Web server): "Hi there, anyone home at port 80 on 123.124.55.67?"
2. (From the Web server to my computer): "Sure; how should we talk?"
3. (From my computer to the Web server): "Ummm, how about port 40000?"
4. (From the Web server to my computer): "Great, then, let's set up a connection to 40000."

So my questions to the Web server go to 123.124.55.67:80, and the answers come back on 200.200.200.10:40000. (And yes, I've left a few steps out, like "how did the Web server ask which port to use in the first place," but I'm trying not to turn this into a whole *book* on TCP/IP!) Here's the point that I want to make: Communications to a server employ a well-known port, like 80 on HTTP. In contrast, however, communications back to a client don't use any particular predefined port—the server and client just agree on one on-the-fly.

**NOTE** *And in case you're wondering, servers can carry on more than one conversation over a given port. If 500 people are all surfing a Web server, then the Web server can keep those conversations separate.*

## Routing the Nonroutable, Part II: PAT and NAT

Now that you know about ports, I can tell you how a bit of magic that you'll see a little later works. Server 2003 includes a couple of tools called Internet Connection Sharing (ICS) and port address translation (PAT) that let you share a single routable IP address with any number of computers, even though those computers all bear *nonroutable* addresses. Let's look at how the simpler one, ICS, works.

### INTERNET CONNECTION SHARING OVERVIEW

Suppose you have a bunch of computers in your home, all connected via an Ethernet network. Suppose also that you've got a high-speed Internet connection like a DSL or a cable modem connection. Those kinds of connections usually come with one—and one only—routable IP address, which you give to one of your computers.

But what about the other ones? How can you get all of your Windows 9x, NT 4, and Server 2003 boxes in the house *all* on the Internet at the same time? After all, only one computer can use a given IP address, so trying to put that one routable IP address on every computer in the house not only won't help, it'll hurt—the Internet connection will work fine as long as only one computer's using the DSL or cable modem vendor-supplied address, but put it on a second system and *neither* system will be able to get to the Internet. Instead, here's how to put everyone in the house on the Internet.

First, connect all of the computers to your home Ethernet. Do not give those computers an IP address; instead, tell their TCP/IP software to obtain IP addresses "automatically" (and I promise, we'll do that soon; I'm just explaining the outline of the method right now). Next, give the routable IP address (let's make it 200.200.200.10 for the sake of example) to a Server 2003 computer. Finally, turn on a Server 2003 feature called Internet Connection Sharing—there are specifics on this at the end of this chapter. Then reboot all of the computers except for the one with the routable IP address. Result: once rebooted, all of those computers will be able to access Internet resources.

### HOW ICS SHARES A ROUTABLE ADDRESS WITH NONROUTABLE MACHINES

What happened? Well, first of all, the routing computer—the one running ICS—distributes unique IP addresses to all of your other computers. But *what* IP addresses? Well, it's not kosher to start making up routable IP addresses and handing them out unless you actually *own* those addresses, so the routing computer hands out “safe” IP addresses from one of the nonroutable ranges specified in RFC 1918, the range from 192.168.0.2 through 192.168.0.254, and gives itself an extra IP address, 192.168.0.1. So far, so good—the computers in your home network can all “see” each other, even the routing computer.

Here's where the magic happens. Suppose one of your nonroutable computers (let's give it address 192.168.0.10) wants to surf my Web site at 206.246.253.200. That nonroutable computer says to the routing computer, the only one with a routable, acceptable-on-the-Internet address, “Please connect me to the Web server at 206.246.253.200.” Now, clearly, the 192.168.0.10 system can't directly talk to my Web server, as 192.168.0.10 is a nonroutable address and no router will pass any 192.168.y.z traffic over the Internet. But the routable computer can employ its 200.200.200.10 address to establish that connection to the Web server at 206.246.253.200. The routable computer at 200.200.200.10 acts as a kind of “relay” to forward the nonroutable computer's request to my Web server, passing messages back and forth. My Web server hasn't a clue that the *real* client is sitting on a nonroutable address; as far as my Web server's concerned, it's talking to 200.200.200.10.

But the 200.200.200.10 computer running ICS can go further than that, as it can simultaneously relay requests for every single computer in your nonroutable network. So could you have 15 machines in your nonroutable network all talking to my Web site at the same time? Sure. But my Web site would think that the machine at 200.200.200.10 was holding 15 simultaneous conversations with it—peculiar, perhaps, but not unallowable. But what if each of the 15 people sitting at the 15 computers were surfing *different* pages on my Web site—how would the routing computer on your network keep it all straight? With ports. It could be that the session between the first nonroutable computer and my Web site took place on 200.200.200.10:40000, the second on 200.200.200.10:40001, and so on. The routing computer is then using the incoming port number to figure out which of its local, nonroutable computers made a particular request, so that it can *translate* that incoming port into a nonroutable address, so to speak. That's why the process is called *port address translation* or PAT. ICS is a piece of PAT routing software built into Server 2003.

### PAT IS ALMOST A FIREWALL, BUT ONLY ALMOST

PAT is, then, a pretty neat bit of routing magic. Say your ISP only gives you one routable IP address—here's a way to stretch it across dozens of machines. Even better, PAT offers a simple, basic kind of anti-hacker security. Consider that your nonroutable computers can access e-mail, Web, and other services on the public Internet, but still remain basically invisible in the sense that your internal computers can *initiate* a conversation with a server on the Internet, but no computer on the public Internet can initiate a conversation with one of your nonroutable computers. It's harder, then, for jerks—oops, I mean hackers—to attack your internal machines.

*Harder*, yes, but not impossible, I should point out. Once one of your internal, nonroutable systems establishes contact with a computer on the public Internet through your PAT routing computer, then there's obviously a channel now open from that computer on the public Internet and your nonroutable computer. While I'm not a security expert by any means, I'm told by people that I trust that this “open port,” as they call it, can be a method for “e-bottom feeders” to potentially attack your

system. And no matter what sort of security you use, remember that once you've downloaded a program to one of your internal computers and run that program, then the program can have malicious intent. Remember also that many kinds of files can contain programs nowadays: Web pages can contain VBScript macros, Word files can contain programs, and you might end up downloading and installing a kind of program called an ActiveX object simply by viewing a Web page. (That's why I keep my security settings fairly paranoid in Word, Outlook, and Internet Explorer, and I recommend that you do also—look in Tools/Macro/Security in Word and Outlook, or Tools/Internet Options/Security in Internet Explorer.)

And by the way, I've cast my PAT example as a home-based one, but don't think that only homes and small businesses can use it. Most large organizations only assign their routable addresses to a small number of systems, and put nonroutable addresses on the vast majority of their machines. Then they use PAT or PAT-like routers to let their employees access the Internet.

### **NAT VERSUS PAT**

PAT's a nice piece of routing software built into Server 2003 (and in fact every Microsoft OS shipped since 1998), but not the only one. ICS is nice, but it's pretty inflexible. It's supplemented by a more powerful bit of routing software called network address translation (NAT). In fact, it's far more likely that you've heard of NAT than PAT, because many PAT routers are mistakenly called NAT routers. (And understand that while a purist might quibble about whether a router is a PAT or NAT router, the fact is that the definitions have blurred so much in popular usage that in actual fact you'll probably *only* hear the phrase "NAT" rather than "PAT." As you'll see later in this chapter, Server 2003 contains software that will do both NAT and PAT, but it calls the capability "NAT routing." So after this section, I'll surrender and just refer to NAT rather than PAT.)

A simple NAT router lets you connect a particular routable IP address with a particular nonroutable IP address. Thus, for example, if you had a Web server on a machine with the nonroutable address 10.10.10.50, then the outside world couldn't see or access that Web server. But suppose you had a few dozen routable addresses, including (for example) 100.50.40.10? You could put those addresses on a NAT router and tell the NAT router for example, "connect the routable 100.50.40.10 address with the nonroutable 10.10.10.50 address." When someone on the public Internet tried to surf the Web site at 100.50.40.7, then, the NAT router would transparently redirect all of that traffic to the system at the nonroutable address 10.10.10.50.

There's yet another permutation of port address translation that you'll see, built into Server 2003's NAT routing software. In NAT, as you saw, the router completely assigned an entire routable IP address to a machine with a nonroutable IP address. But Server 2003 also lets you assign a particular port on one system to a particular port on another system. So, for example, I could tell a Server 2003 system acting as a router, "Whenever traffic comes in for 100.50.40.7 on port 80, send it to the nonroutable 10.10.10.50 system, on port 5000." (I'm not saying you would *want* to do it, I'm just explaining that it's possible.) So, in that case, you would set up the Web server on the 10.10.10.50 system and reconfigure the Web server so that it didn't use the standard port 80, but rather port 5000—and yes, IIS lets you do that, as you'll see in Chapter 17.

### **Winsock Sockets**

Before moving on to the issue of Internet names (rather than all this IP address stuff that we've been working with), let me define a term that you'll hear in the Microsoft TCP/IP networking

business: *winsock* or “windows sockets.” The value of sockets is that they provide a uniform way to write programs that exploit the underlying Internet communications structure. If, for example, I want to write a networked version of the game Battleship, then I might want to be able to quickly turn out versions for Windows, OS/2, the Mac, and Unix machines. But maybe I don’t know much about communications, and don’t *want* to know much. (I’m probably supposed to note here that Battleship is a registered trademark of Milton Bradley or someone like that; consider it done.) I could just sit down with my C compiler and bang out a Battleship that runs on Unix machines. Just a few code changes, and *presto!* I have my PC version.

But the PC market requires some customization, and so a particular version of the sockets interface, called Winsock, was born. It’s essentially the sockets interface but modified a bit to work better in a PC environment.

The benefit of Winsock is that all vendors of TCP/IP software support an identical Winsock programming interface (well, identical in theory, anyway) and so TCP/IP-based programs should run as well atop FTP software’s TCP/IP stack as they would atop the TCP/IP stack that ships with NT and 2000, as well as Windows for Workgroups, Windows 9x, and Windows Me. That’s why you can plop your Netscape Web browser on just about any PC with TCP/IP and it should work without any trouble.

## Telling Software to Use TCP/IP Over Other Protocols: Network Binding

This discussion has covered a particular set of network protocols—TCP/IP—so far, and TCP/IP is a pretty flexible protocol. You can use it for just about anything that you’d need a network protocol for, and in fact many networks use only TCP/IP. But your network might include other protocols running alongside TCP/IP on your Ethernet cables; in particular, it’s not unusual to see Microsoft networks running IPX/SPX or NetBEUI in addition to TCP/IP. You might be running IPX/SPX because you’ve also got some Novell servers around, or you might be running NetBEUI because you still have some older Microsoft operating systems, either on clients or workstations. (Although you *really* have to work to get NetBEUI on a modern Microsoft operating system.) If either of those things are true, then you might have to run NetBEUI and/or IPX/SPX on your Windows Server 2003 systems as well. And that leads me to discuss network binding.

Suppose I have a workstation running TCP/IP, IPX/SPX, and NetBEUI protocols, trying to talk to a file server that runs only TCP/IP. The workstation and server employ several pieces of software to set up the workstation-to-file-server file sharing connection:

- ◆ There’s a piece of software on the workstation that knows how to ask the file server for data; technically, we could call it the *file-server-client software*, the client part of the file sharing client-server software. Microsoft calls it the Client for Microsoft Networks.
- ◆ The client software gets to the network by choosing a protocol to use to communicate over the wire to the server. If the workstation runs TCP/IP, IPX/SPX, and NetBEUI, then the Client for Microsoft Networks doesn’t know which to choose, so it uses them all, duplicating its request to the file server over all three.

- ◆ The protocols run over the network cables to the server. As we’ve seen, the server doesn’t respond to all of them, as it’s not running software to make it aware of IPX/SPX or NetBEUI. But it *does* understand TCP/IP.
- ◆ The server-side piece of the file sharing software connects to the one protocol running on the server, TCP/IP.

What’s wrong with this? Nothing really, except that it’s a bit inefficient. The workstation essentially makes the “server, please talk to me” request over one protocol, then another, and then, if there’s no response, finally the third protocol. So the order in which a piece of software tries different protocols can speed up or slow down a computer’s performance. You could probably pretty easily imagine some not-so-great scenarios here; for instance, suppose this three-protocol-using workstation lived in an environment with 20 file servers, and 19 of the 20 file servers used TCP/IP exclusively. Suppose also that this workstation always first tried IPX/SPX, then NetBEUI, and then TCP/IP whenever it wanted to contact a file server. Clearly that’d run terribly.

The word for the order in which a given piece of network client or server software—like the Client for Microsoft Networks—taps a protocol is called the *network binding order*. You can control that from a Windows Server 2003 system like this.

1. Right-click My Network Places.
2. Choose Properties.
3. You’ll see a Network Connections window that contains icons that represent your different ways of connecting to a network, whether a network adapter or a dial-up connection.
4. Do *not* right-click Local Area Connection—surprised you, eh? Instead, look at the Network and Dial-Up Connections window, and notice that it’s got an unusual item on its window menu—Advanced. Click Advanced and then Advanced Settings; *that* will raise another window, labeled Advanced Settings, with Adapters and Settings and Provider Order tabs. Click Adapters and Settings.
5. The resulting property page has an upper and lower part. The upper lets you choose which adapter you want to arrange bindings for; click it and you will see the applications that communicate through that adapter.

In the lower part of the dialog box, you’ll see the various network applications running on your computer. For example, most systems run Client for Microsoft Networks (the file sharing client software) and File and Printer Sharing for Microsoft Networks (the server piece of the file sharing software). Under each application, you’ll see the protocols that use it. Up- and down-arrow buttons then let you choose the order of the protocols to try—the *binding order* for that application. In my example where you’ve got a client computer in a network that incorporates 20 file servers, 19 of which use only TCP/IP, then, it’d make sense to adjust the bindings for the Client for Microsoft Networks to use TCP/IP before IPX/SPX or NetBEUI.

## Internet Host Names

Thus far, I’ve referred to a lot of numbers; hooking up to my Web server, then, seems to require that you point your Web browser to IP address 206.246.253.200, TCP port number 80, which is written “206.246.253.200:80” in socket terminology.

Of course, you don't actually do that. When you send e-mail to your friends, you don't send it to 199.45.23.17; you send it to something like `robbie@somefirm.com`. What's IP got to do with it?

IP addresses are useful because they're precise and because they're easy to subnet. But they're tough to remember, and people generally prefer more English-sounding names. So TCP/IP allows us to group one or more TCP/IP networks into groups called *domains*, groups that will share a common name like `microsoft.com`, `senate.gov`, `army.mil`, or `mit.edu`.

**NOTE** *Internet naming, and in particular the Domain Name System (DNS), is a big topic—in fact, it'll take up the majority of the next chapter; this section is just a brief summary. Stay tuned to Chapter 7 for the truly ugly (but necessary) details.*

Machines within a domain will have names that include the domain name; for example, within my `mmco.com` domain I have machines named `earth.mmco.com`, `narn.mmco.com`, `minbar.mmco.com`, `zhahadum.mmco.com`, and `vorlon.mmco.com`. Those specific machine names are called *host names*.

How does TCP/IP connect the English names—the *host names*—to the IP addresses? And how can I sit at my PC in `mmco.com` and get the information I need to be able to find another host called `archie.au` when `archie`'s all the way on the other side of the world in Australia?

Simple—with `HOSTS`, `DNS`, and (if you have a network that does not yet use Active Directory) `WINS`, which is covered in the next chapter. The process of converting a name to its corresponding IP address is called *name resolution*. Again, how does it work? Read on.

## Simple Naming Systems (HOSTS)

When you set up your subnet, you don't want to explicitly use IP addresses every time you want to run some TCP/IP utility and hook up with another computer in your subnet. So, instead, you create a file called `HOSTS` that looks like this:

```
199.34.57.50  keydata.mmco.com
199.34.57.129 serverted.mmco.com
```

This is just a simple ASCII text file. Each host goes on one line, and the line starts off with the host's IP address. Enter at least one space and the host's English name. Do this for each host. You can even give multiple names in the `HOSTS` file:

```
199.34.57.50  keydata.mmco.com markspc
199.34.57.129 serverted.mmco.com serverpc bigsv
```

You can even add comments, with the octothorp (`#`):

```
199.34.57.50  keydata.mmco.com markspc #The Big Dog's machine
199.34.57.129 serverted.mmco.com serverpc bigsv
```

Ah, but now comes the really rotten part.

You have to put one of these `HOSTS` files on *every single workstation*. That means that every single time you change anyone's `HOSTS` file, you have to go around and change *everybody's* `HOSTS` file. Every workstation must contain a copy of this file, which is basically a telephone directory of every machine in your subnet. It's a pain, yes, but it's simple. If you're thinking, "Why can't I just put a central `HOSTS` file on a server and do all my administration with *that* file?"—what you're really

asking for is a *name server*, and I'll show you two of them, the Domain Name System (DNS) and the Windows Internet Name Service (WINS), in this chapter.

You must place the HOSTS file in `\WINDOWS\SYSTEM32\DRIVERS\ETC` on an NT or Server 2003 system, in the `Windows` directory on a Windows for Workgroups or Windows 9x machine, and wherever the network software is installed on other kinds of machines (DOS or OS/2).

HOSTS is reread every time your system does a name resolution; you needn't reboot to see a change in HOSTS take effect.

## Domain Name System (DNS)

HOSTS is a pain, but it's a necessary pain if you want to communicate within your subnet. How does IP find a name outside of your subnet or outside of your domain?

Suppose someone at `exxon.com` wanted to send a file to a machine at `minasi.com`. Surely the `exxon.com` HOSTS files don't contain the IP address of my company, and vice versa?

Well, back when the Internet was small, HOSTS was sufficient—the `exxon.com` and `minasi.com` machines *would* have found each other in HOSTS back in 1980. The few dozen people on the early Internet just all used the same small HOSTS file. With the Internet's machine population in the hundreds of millions, however, that's just not practical; we needed something better.

The Internet community came up with an answer in 1984: Distribute the responsibility for names. That's done by the Domain Name System (DNS). There is a central naming clearinghouse for *the* Internet, the Internet Corporation for Assigned Names and Numbers (ICANN), which you met earlier in this chapter. (Obviously, if you're only running a private intranet that's not connected to the public Internet, then *you* perform the function of name manager.) ICANN is the overall boss of DNS naming, but it delegates particular domains to particular *name registrars*, as for example when it delegates keeping track of all of the `.com` domains to VeriSign's Network Solutions subsidiary.

Instead of trying to keep track of the name and IP address of every single machine in the Internet, ICANN and its delegated registrars require that every Internet domain have at least two machines (although some now only require one) running that contain a database of that domain's machines. These machines are called *DNS servers*.

ICANN then needs only to know the IP address of the domain's DNS servers, and when a request for a name resolution comes to ICANN's servers, ICANN's servers just refer the questioner to the domain in question's local DNS machines. (We'll see how this works in greater detail in the next chapter.)

Thus, if you wanted to visit my Web site at `www.minasi.com`, you'd start up your Web browser and point it at `www.minasi.com`. Before your browser could show you anything, however, it would need to *find* the machine named `www.minasi.com`. So it would fire off a DNS query, "What's the IP address of `www.minasi.com`?" to its local DNS server. The local DNS server probably wouldn't know, and so it would ask ICANN's DNS servers. ICANN's servers would know that the IP address for `minasi.com`'s DNS server is `206.246.253.111` and would tell your local DNS server that it could find `www.minasi.com`'s IP address by asking the question of the `206.246.253.111` machine. So your local DNS server would then re-ask the question, this time of my local DNS server, and would then get the answer "`206.246.253.200`." And most DNS servers remember past queries for a few hours or perhaps a day, so if you revisited my Web site the same day, when your Web browser asked your local DNS server for the IP address of `www.minasi.com`, your local DNS server would respond, "`206.246.253.200`," without hesitation.

You've no doubt noticed that many Internet domains end with `.com`, but there are other endings as well. Back in the pre-ICANN days, the InterNIC (ICANN's predecessor) started off with six initial naming domains: EDU was for educational institutions, NET was for network providers, COM for commercial users, MIL was for military users (remember who built this?), ORG was for organizations, and GOV was for civilian government. For example, there is a domain on the Internet called `whitehouse.gov`; you can send Internet e-mail to the President that way, at `president@whitehouse.gov`. There are more root domains these days, such as `.int`, `.museum`, `.name`, and a long list of two-letter codes for countries such as `.fi` for sites in Finland, `.uk` for sites in the United Kingdom, and so on.

What kind of computer do you need to run a DNS server? Just about any kind—there's DNS server software for IBM mainframes, DEC Vaxes, Unix and Linux, and of course, Server 2003—in fact, a DNS server module not only ships with Server 2003, you can't even run an Active Directory without a DNS server. You'll see how to set up a DNS server in the next chapter.

## E-Mail Names: A Note

If you've previously messed around with e-mail under TCP/IP, then you may be wondering something about these addresses. After all, you don't send mail to `minasi.com`, you'd send it to a name like `help@minasi.com`. `help@minasi.com` is an e-mail address. The way it works is this: A group of users in a TCP/IP domain decide to implement mail.

In order to receive mail, a machine must be up and running, ready to accept mail from the outside world (that is, some other subnet or domain). Now, mail can arrive at any time of day, so this machine must be up and running all of the time. That seems to indicate that it would be a dumb idea to get mail delivered straight to your desktop. So, instead, TCP mail dedicates a machine to the mail router task of receiving mail from the outside world, holding that mail until you want to read it, taking mail that you want to send somewhere else, and routing that mail to some other mail router. The name of the most common TCP/IP mail router program is *sendmail*. The name of the protocol used most commonly for routing e-mail on the Internet, by the way, is the Simple Mail Transfer Protocol (SMTP). Once e-mail is sitting on your local mail server, you then retrieve it via another mail protocol, the Post Office Protocol (POP3).

Windows Server 2003 can act as both POP3 and SMTP server, so if you're connected to the Internet 24/7, then your Server 2003 machine could be your e-mail server. Or you might be running Microsoft's Exchange Server, that is also a POP3/SMTP server. Or you might run any of dozens of different programs that could make a Linux, Unix, Novell, or NT/2000/Server 2003 into a POP3/SMTP server. You can see how mail works in Figure 6.7.

**FIGURE 6.7**

The interrelation of host names, e-mail names, and the Internet

In this small domain, we've got two users: Mark and Christa. Mark works on `keydata.mmco.com`, and Christa works on `ams.mmco.com`. Now, suppose Christa wants to send some mail to her friend Corky, executive director for Surfers of America; Corky's address is `corky@surferdudes.org`. She fires up a program on her workstation, which is called a *mail client*. The mail client allows her to create and send new messages as well as receive incoming messages. She sends the message and closes her mail client. Notice that her mail client software doesn't do routing—it just lets her create, send, and receive messages.

The mail client has been configured to send messages to an SMTP server, which is running in this subnet on `mailguy.mmco.com`. `mailguy` is kind of the post office (in Internet lingo, a *mail router*) for this group of users. The SMTP server on `mailguy.mmco.com` stores the message, and it then sends the message off to the machine with the DNS name `surferdudes.org`, trusting IP to route the message correctly to `surferdudes`. Hmmmm...there's no one machine named `surferdudes.org`; where should the mail go? As you'll learn in the next chapter, a DNS administrator can advertise that e-mail should go to a particular machine. Thus, `surferdudes.org` might have a machine named `po.surferdudes.org`; when `mailguy.mmco.com` tries to send the mail to `corky`, `mailguy` first asks DNS, "What machine is supposed to get mail for `surferdudes`?" and DNS replies, "`po.surferdudes.org`."

Additionally, the SMTP server knows the names Christa and Mark. It is the workstation that is the interface to the outside world vis-à-vis mail. Note, by the way, that *DNS* has no idea who Mark or Christa is; DNS is concerned with *host* names, not *e-mail* names. It's DNS that worries about how to find `mailguy.mmco.com`.

A bit later, Corky gets the message and sends a reply to Christa. The reply does *not* go to Christa's machine `ams.mmco.com`; instead, it goes to `mailguy.mmco.com` because Corky sent mail to `christa@mmco.com`. The mail system sends the messages to `mmco.com`, but what machine has the address `mmco.com`? Simple: DNS directs it to send mail for `mmco.com` to `mailguy.mmco.com`.

Eventually, Christa starts up the mail client program once again. The mail program uses POP3 to send a query to the local mail router `mailguy.mmco.com`, saying, "Any new mail for Christa?" There *is* mail, and Christa reads it.

## Attaching to an Internet

So far, I've talked quite a bit about how an internet works and what kinds of things there are that you can do with an internet. But I haven't told you enough yet to actually get *on* an internet, whether it's your company's private intranet or *the* Internet.

- ◆ You can connect to a multiuser system and appear to the Internet as a dumb terminal. This doesn't happen much any more, so it's unlikely that you'll do this.
- ◆ You can connect to an Internet provider via a serial port and a protocol called Point-to-Point Protocol (PPP) and appear to the Internet as a host. This is what you're doing when you dial up with a modem to an Internet service provider (ISP) such as AOL.
- ◆ You can connect to an Internet provider via either a modified cable television network ("cable modem") or via modified phone lines ("digital subscriber line" or DSL).
- ◆ You can be part of a local area network that is an Internet subnet and then load TCP/IP software on your system and appear to the Internet as a host. This is probably how most people get on the Internet—either when the computer on your desk connects to the Internet via your company's network, or if you connect at home via a cable modem or DSL.

Each of these options has pros and cons, as you'll see. The general rule is that in order to access the Internet, all you basically have to do is to connect up to a computer that is already on the Internet.

The essence of any internet is in *packet switching*, a kind of network game of hot potato whereby computers act communally to transfer each other's data around. Packet switching is what makes it possible to add subnetworks on-the-fly.

## Dumb Terminal Connection

This was once a common way to attach to the Internet. You'd dial up to a multiuser system of some kind—usually a Unix box of some stripe—and do simple terminal emulation. You'd then have a character-based session with typed commands only—no mouse, no graphics. Very macho, but not as much fun as surfing with a graphical Web browser. On the other hand, the distant multiuser machine did all the heavy lifting, computing-wise.

Unfortunately, this terminal access approach was kind of limited. Suppose, for example, that I live in Virginia (which is true) and I connect to the Internet via a host in Maine (which is not true). From the Internet's point of view, I'm not in an office in Virginia; instead, I'm wherever the host that I'm connected to is. I work in Virginia, but if I were dialing a host in Maine, then from the Internet's point of view I'd be in Maine. Any requests that I make for file transfers, for example, wouldn't go to Virginia—they'd go to my host in Maine.

Now, that can be a bit of a hassle. Say I'm at my Virginia location logged on to the Internet via the Maine host. I get onto Microsoft's FTP site—I'll cover FTP in Chapter 17, but basically FTP is just a means to provide a library of files to the outside world—and I grab a few files, perhaps an updated video driver. The FTP program says, "I got the file," but the file is now on the host in Maine. That means that I'm only half done, as I now have to run some other kind of file transfer program to move the file from the host in Maine to my computer in Virginia.

## PPP Serial Connection

If you've got one of those \$10/month or \$20/month dial-up Internet accounts, then you fit in this category. Instead of connecting to the Internet with an Ethernet card, you connect with a serial port connected to a modem, which in turn is connected to the ISP with phone lines.

To do this you will need software to support a protocol called the Point to Point Protocol or PPP. (Once upon a time PPP had a sibling protocol named the Serial Line Interface Protocol, or SLIP, but I've not seen anyone use it since 1997.) But you needn't look very far for PPP software—it's built into every version of Windows and NT since 1995. When setting up 2003 systems to dial up to an ISP, you're using PPP by default.

Nor is PPP only for use in dialing up to ISPs. Server 2003's Routing and Remote Access Server (RRAS) supports PPP, so if you dial into your company's servers, you do that with PPP.

## Cable Modem and DSL Connections

Cable modem and DSL are a sort of halfway step between the previous connection type, simple dial-up, and the next type, direct network connection. Where dial-up is pure WAN connection and networks are pure LAN connection, cable modem and DSL are half and half in that they employ devices called "cable modems" and "DSL modems" that communicate on one side to a wide area

network—the cable company’s television signal network or the phone network in the case of DSL—and on the other side to your local area network.

Cable modems connect to cable networks using the same kind of “F” type connector that you’d use to connect your TV to a cable antenna. Then they connect to your computer or your local area network with an RJ-45 connector using Ethernet signals. To connect just one PC to a cable modem, then, you would put an Ethernet card in the computer and plug a standard Cat5-type patch cable between the cable modem and the Ethernet card. To connect an entire home or small office network, you’d hook the cable modem’s RJ-45 port to an Internet sharing device like the roughly \$200 devices you can find from DLink, Linksys and others, or you could put a second NIC in your PC and then use the PC as an Internet sharing device—you’ll see how at the end of the chapter. Many cable modems also offer USB connections, although I strongly recommend against using them because of driver problems. If you connect to your cable modem using an Ethernet card then the only drivers that your computer needs are the drivers for the Ethernet card, and those are usually pretty reliable. But connecting to the Internet via the USB connector on the cable modem requires a USB driver for the cable modem, and I’ve seen a number of cases where cable modem drivers were flaky.

DSL “modems”—I hate the term because they are by no means modems, but are instead something called a control service unit/data service unit (CSU/DSU)—typically have a standard familiar telephone-type RJ-13 connector that you use to connect them to a phone line in your house—one that’s been specially tuned by the DSL provider—and then an RJ-45 jack that you use to make an Ethernet connection to a computer or a group of computers, in much the same way as you would with a cable modem. Some DSL modems have USB connections as well—my advice about cable modem USB connections also applies here.

## LAN Connection

The most common way to connect to an internet is simply by being a LAN workstation on a TCP/IP-using network. Again, this needn’t be *the* Internet—almost any LAN can use the TCP/IP protocol suite. This is the connection that most Server 2003 servers will use to provide TCP/IP services.

## Terminal Connections versus Other Connections

Before moving on to the next topic, I’d like to return to the difference between a terminal connection and a PPP or LAN connection. In Figure 6.8, you see three PCs on an Ethernet attached to two minicomputers, which in turn serve four dumb terminals.

The minicomputer-to-minicomputer link might be SLIP or PPP, or then again they might be LANed together. Notice that only the *computers* in this scenario have Internet Protocol (IP) addresses. Whenever you send mail to one of the people on the PCs at the top of the picture, it goes to that person’s PC. If you were to scrutinize the IP addresses—and most of the time, you will not—you’d see that everyone had the same IP address. In contrast, the people at the *bottom* of the picture get their mail sent to one of the minicomputers, and so in this example, each pair of terminals shares an IP address. If Shelly and George in your office access your company’s intranet through terminals connected to the same computer, then a close look at mail from them would show that they have the same IP address. But, if you think about it, you already knew that; if you send mail to `george@mailbox.acme.com` and to `shelly@mailbox.acme.com`, then the machine name to which the mail goes is the same; it’s just the usernames that vary.

**FIGURE 6.8**

When Internet connections involve IP numbers and when they don't

So, in summary: If you want to get onto *the* Internet from a remote location, then your best bet is to sign up with a service that will bill you monthly for connect charges, like Delphi. To attach to a private intranet, you need to dial up to a multiuser computer on that intranet, or you need a SLIP or PPP connection, or you have to be on a workstation on a LAN that's part of that intranet. You then need to talk to your local network guru about getting the software installed on your system that will allow your computer to speak TCP/IP so that it can be part of your intranet.

**NOTE** There is one case where Figure 6.8 isn't complete. If one of the terminals pictured is not simply a dumb ASCII terminal attached to a minicomputer but is instead a Windows Terminal—still a dumb terminal, but one built to work specifically with Server 2003 Terminal Services, Windows Terminal Server 4, or Citrix Metaframe—then that terminal will have its own IP address.

## So Where Do I Get My IP Addresses?

You can't get anywhere in the next section without some IP addresses. How does what you've read so far in this chapter relate to where you should go to get IP addresses?

- ◆ If you're part of a large corporation, there is almost certainly a group who manages (or doles out, in other words) the IP addresses; if so, go to them for the IP addresses you'll need.
- ◆ If you're just playing around with this, then you can use any addresses you like, provided you're not connected to the Internet. But it's a good idea to use one of the RFC 1918 ranges in any case—it's a good habit.

- ◆ If you're with a small firm and it's your job to get the firm on the Internet, then you have two tasks. First, you've got to figure out how you'll be connected. Do you need constant, 24/7 connection to the Internet? You will if you intend to run your own Web or mail servers on your site, and in that case, you'll probably need to get a frame relay connection to your ISP. On the other hand, does your firm just need periodic access to the Internet? Then you may be perfectly happy with the cheaper alternative of some kind of shared dial-on-demand system, either using analog modems or ISDN. Second, how many IP addresses do you need? If you put in a NAT router, by purchasing one from Cisco or some other router vendor, or if you use a Server 2003 machine as a NAT router (you'll read later how to do that), then you'll only need one dedicated IP address from your ISP. On the other hand, if you want all of your firm's computers to have their own routable IP addresses, then you should expect to have to pay your ISP a bit more for them than you would for just one IP address—but having all routable IP addresses keeps things simpler, in my experience.
- ◆ If you're a home user with an existing Internet connection, such as a dial-up modem, an ISDN dial connection, cable modem, or DSL, and you want to share that connection with other machines on a home network, then just use Internet Connection Sharing, which you'll read about later in this chapter.

## The Basics of Setting Up TCP/IP on Server 2003 with Static IP Addresses

Enough talking about TCP/IP internetworking; let's do it, and do it with Server 2003.

Traditionally, one of the burdens of IP administrators has been that they must assign separate IP numbers to each machine, a bit of a bookkeeping hassle. You can adopt this “static” IP address approach, and in fact you will *have* to assign static IP addresses to at least a few of your systems. In actual fact, however, you'll find that assigning a static IP address to every single IP-using computer in your enterprise soon palls, and you'll assign IP addresses to most systems automatically with the Dynamic Host Configuration Protocol, covered in the next chapter.

No network can completely avoid static IP addresses, however, so we'll start out with this older method of putting an IP address on a Server 2003 computer. In the next chapter, we'll take up dynamic IP addressing with DHCP.

Here's the most basic set of TCP/IP configuration tasks, and the first ones we'll tackle:

1. Set the IP address and subnet, default gateway, and DNS server.
2. Prepare the HOSTS file, if you're going to use one.
3. Test the connection with Ping.

Let's take a look at those steps, one by one.

### Configuring TCP/IP with a Static IP Address

First, let's apply an IP address to the network interface card on this system. Do that by getting to its property page: click Start/Control Panel/Network Connections and then, when your mouse is on Network Connections, *right-click* the mouse and choose Open. You'll see something like Figure 6.9.

**FIGURE 6.9**  
Network and Dial-Up Connections

This window describes each NIC in your system and also lists every item in your Dial-Up directory—so if you’ve got your system set up to be able to dial an ISP or perhaps a distant Windows 2000 network, then you’ll see a line for each of those DUN directory entries—as well as an icon that can start a wizard to add new Dial-Up entries. This computer hasn’t got a modem and therefore has never dialed up anywhere. If this machine had two NICs, then you’d see two Local Area Connection entries.

Bring up the properties for the NIC by right-clicking the NIC (Local Area Connection is the name of the NIC in Figure 6.9) and choosing Properties. That will give you something like Figure 6.10.

**FIGURE 6.10**  
LAN Connection properties page

Click Internet Protocol (TCP/IP) and then the Properties button. You’ll see a dialog box that looks like Figure 6.11, or anyway it will once we’re through with it.

**FIGURE 6.11**

IP properties page  
after modification

When you first see this dialog box, the Obtain an IP Address Automatically and Obtain DNS Server Address Automatically radio buttons will be selected. You should click the Use the Following IP Address and Use the Following DNS Server Addresses radio buttons. As mentioned earlier, you'll need to know four things to configure this screen: your IP address, the subnet mask, the IP address of your default gateway, and the IP addresses of one or more DNS server. In the case of the computer I'm configuring here, the IP address is 192.168.71.50, the subnet mask is 255.255.255.0, the default gateway is 192.168.71.2, and I've got a DNS server at 192.168.71.10.

**TIP** Do you recognize those IP addresses? They're in one of the RFC 1918 "nonroutable" ranges. It's safe to assume, then, that the router referred to at address 192.168.71.2 is a NAT router. (Notice that it's not the .1 address that you'd expect; that's a side effect of a particular network product that I'm using—remember that I told you that using .1 for the default gateway was a custom, not a rule!) But **please** do not—and I repeat, do **not**—simply type in numbers to make your dialog box match mine. You'll have to plan the layout of your IP-based network. Just making up IP addresses will, I can pretty much guarantee, not work.

Click OK to clear the IP and LAN properties pages, and you'll have your IP address configured. But does it work? Read on.

## Testing Your IP Configuration

There are three basic tools you'll use to verify that TCP/IP's working on your system: IPConfig, Ping, and netsh.

### IPCONFIG

First, check your IP configuration by opening a command prompt and typing **ipconfig /all**; you'll then see a screen like Figure 6.12.

**FIGURE 6.12**Output of  
`ipconfig /all`

```

C:\>ipconfig /all

Windows IP Configuration

Host Name . . . . . : ssdotnet
Primary Dns Suffix . . . . . :
Node Type . . . . . : Unknown
IP Routing Enabled. . . . . : Yes
WINS Proxy Enabled. . . . . : No

Ethernet adapter Local Area Connection:

   Connection-specific DNS Suffix  : 
   Description . . . . . : AMD PCNET Family PCI E
   Physical Address. . . . . : 00-50-56-69-D5-8E
   DHCP Enabled. . . . . : No
   IP Address. . . . . : 192.168.71.50
   Subnet Mask . . . . . : 255.255.255.0
   Default Gateway . . . . . : 192.168.71.2
   DNS Servers . . . . . : 192.168.71.10

C:\>

```

`ipconfig /all` should be your first step when checking a TCP/IP installation or when troubleshooting one. This particular IPConfig output starts out with some general information about this machine and then displays specific information about the Ethernet adapter. It's laid out like this because, in some cases, you may have two or more NICs in a system, and each NIC will have an IP address. Additionally, you may have a modem on your system and may be connected to the Internet via a dial-up connection. In that case, you'd again have more than one IP address—your Ethernet card would have an IP address (the one you just assigned it if you were following along with the previous text), and your modem would have an IP address that your ISP gave it when you dialed up.

In the IPConfig output, `ssdotnet` is the machine's name.

**WARNING** *In general, you should avoid underscores in your computer names. Microsoft's old-style NetBIOS-based networking doesn't mind it, but the Internet document on legal Internet names, RFC 1123, doesn't permit underscores. According to RFC 1123 in its "assumptions" section, each piece of an Internet name can be no more than 24 characters long—that is, each piece between the periods—and the only legal characters are a–z, 0–9, and the hyphen/minus sign. In fact, the earliest 32-bit Microsoft TCP/IP software, the code that shipped with Windows for Workgroups 3.11, would simply refuse to work on a machine with an underscore in its name. That's not true anymore, and in fact, the Active Directory uses a fair number of underscored names, but that's acceptable, as AD communications will mainly just go on amongst computers running Microsoft software. But avoid underscores in workstation names as it may potentially cause trouble when trying to use resources on the Internet, which may be running on computers that aren't running Microsoft software.*

Primary DNS Suffix is the end of the DNS name; if this computer had a full DNS name like `ssdotnet.bigfirm.biz`, then the primary DNS suffix would be "`bigfirm.biz`." (It *doesn't* have one because I've not told you how to configure one yet.) Node Type answers the question, "How does the system convert an old-style NetBIOS name like `\\SNOOPY` into an IP address?" That's a long and complicated story, and we'll take it up in the next chapter. IP Routing Enabled asks whether this computer is acting as an IP router. As you saw in the example in the beginning of the chapter with machines A through H, you've got to have two IP connections to do that, so this clearly isn't a potential router—I have no idea why 2003 decided to enable IP routing. I will show you before the end of the chapter, however, how to make a Server 2003 machine into an IP router. I'll explain WINS Proxy Enabled in the next chapter.

Looking at the specific information under Ethernet Adapter Local Area Connection, the first entry is Connection-Specific DNS Suffix. This refers not to a Server 2003 domain but to an Internet domain name, such as minasi.com, microsoft.com, or whitehouse.gov. Back in the NT 4 and earlier days, NT's TCP/IP software would only let you put a machine in just one Internet domain. That wasn't a big deal for most of us, but some people wanted their systems to be able to seem to be members of several domains, to have a sort of multiple citizenship in two or more domains. Such a machine might have a NIC in it that was connected to bigfirm.biz's network, and it might have another NIC in it connected to minasi.com's network. If the machine's name were tadpole, then it might want to be able to be recognized both as tadpole.acme.com and tadpole.apex.com. Now, when configuring tadpole under NT 4, you would have had to choose whether tadpole was in acme.com or apex.com—you couldn't choose both as you had to choose domain membership for the whole machine. Under Server 2003, however, you can say that one NIC is a member of acme.com, and that the other is a member of apex.com. In my particular case, I really have no need to do that, which is why Connection-Specific DNS Suffix is empty. In fact, I haven't set the Internet domain name for the adapter or the entire machine as I'm going to get to that a bit later in this chapter.

Next are an English-like description of the NIC's brand and type and the MAC address of the NIC. DHCP Enabled indicates whether I punched in the IP address directly or let DHCP set the IP address for me. As I set the IP address myself, the value is No. If it were Yes, then—as you'll see in the next chapter—IPConfig would furnish more DHCP-specific information. IPConfig then reports the IP address, subnet mask, and default gateway. Finally, it displays the IP address of the DNS server that I configured.

## PING

So all of the settings are correct—but can you reach out to the outside world? TCP/IP has a very handy little tool for finding out whether your TCP/IP software is up and running and whether you have a connection to another point: Ping.

Ping is a program that lets you send a short message to another TCP/IP node, asking, “Are you there?” If it is there, then it says “yes” to the ping, and Ping relays this information back to you. You can see an example of Ping in Figure 6.13; the first line of the screen shows you the syntax, *ping ipaddress*.

**FIGURE 6.13**

A sample Ping output

```

C:\>ping 164.109.1.3
Pinging 164.109.1.3 with 32 bytes of data:
Reply from 164.109.1.3: bytes=32 time=49ms TTL=128
Reply from 164.109.1.3: bytes=32 time=44ms TTL=128
Reply from 164.109.1.3: bytes=32 time=50ms TTL=128
Reply from 164.109.1.3: bytes=32 time=54ms TTL=128

Ping statistics for 164.109.1.3:
    Packets: Sent = 4, Received = 4, Lost = 0 (0% loss),
    Approximate round trip times in milli-seconds:
        Minimum = 44ms, Maximum = 54ms, Average = 49ms

C:\>_

```

In the figure, I pinged the IP address of a server I know of on the Internet. The ping was successful, which is all that matters, and it's a very telling test as the address that I pinged is across the Internet from my system—the fact that I got a response from 164.109.1.3 means that not only is my TCP/IP software working across my segment and across my enterprise, but across the Internet as well.

But when *you're* testing your Internet software, don't use that IP address as there's no sense in flooding the Digital Express guys, the folks who own that machine. Instead, go ahead and ping my router—206.246.253.1 or 68.15.149.65. (I used to use [www.microsoft.com](http://www.microsoft.com) as my Ping example, but now they've got their system rigged so that it won't respond to pings. I guess they couldn't figure out a way to charge for them.)

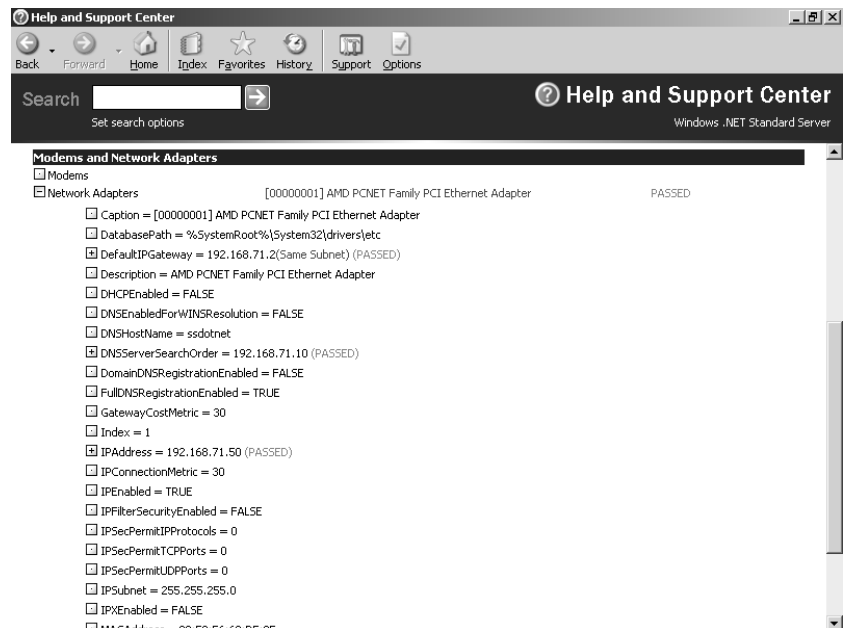

Use the approach outlined in the sidebar “How Do I Make Sure That TCP/IP Is Set Up Properly?” to get the most out of Ping.

### NETSH DIAG GUI

Windows XP introduced a new diagnostic tool for NICs that 2003 includes; to see it, open up a command prompt and type **netsh diag gui**. You'll see a Help and Support Center screen containing a hyperlink labeled Scan Your System; click it and you'll see a short scanning process, followed by an HTML-like screen reporting on your system. You'll see a Modems and Network Adapters section and under that section a line, Network Adapters, with a plus sign next to it and, if all is well, the word PASSED; click the plus sign and you'll see something like Figure 6.14.

**FIGURE 6.14**

Sample netsh gui  
diag output

There wasn't room for the whole report, but it's a pretty nice summary of how your NIC and protocol are configured, as well as a few very simple ping tests.

## Configuration Continued: Setting Domain Names

Thus far, my computer's name is just plain `ssdotnet`, which is a mite shorter than most Internet names; one might expect a name more like `ssdotnet.bigfirm.biz` or the like, a name that looks like *specific machine name.organization name.root*, where *root* is a suffix like *com*, *gov*, or some country identifier.

I intend for my computer `ssdotnet` to be part of an Internet domain named `bigfirm.biz`, so its complete Internet name will be `ssdotnet.bigfirm.biz`. What that really means, in essence, is that if someone pings `ssdotnet.bigfirm.biz`, I want the machine to respond. If I decide to run Web server software on it later, then I want people to be able to see whatever content is on it by pointing their Web browsers to `http://ssdotnet.bigfirm.biz` rather than having to use `http://192.168.71.50`. (I know this probably seems obvious to many of you, but stay with me, there's a point coming.)

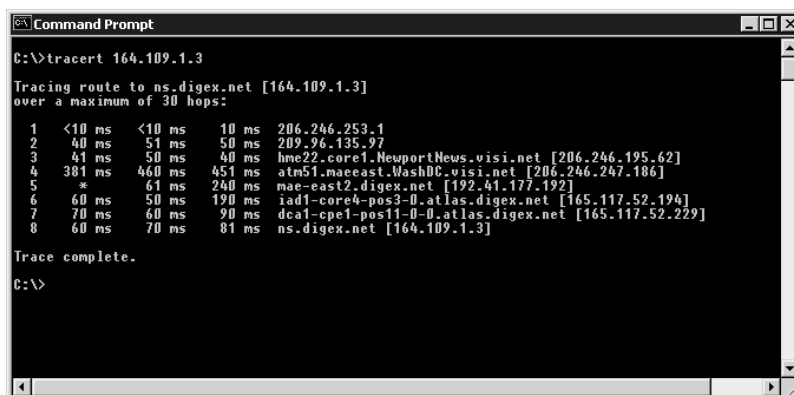

### How Do I Make Sure That TCP/IP Is Set Up Properly?

With these ping tests, you're demonstrating two things: First, that your IP software can get a packet from your computer to the outside world (in other words, that your IP connectivity is functioning), and second, that your connection to a DNS server for name resolution is working.

First, test IP connectivity by pinging specific IP addresses.

In most cases, your connection will work the first time. Start out with an overall "does it work?" test by pinging some distant location on the Internet. As mentioned in the text, you're welcome to ping my router, `206.246.253.1`, or `68.15.149.65`. If that responds correctly, then you've demonstrated that your IP software can get out to the Internet and back.

If it doesn't work, then try pinging something not so far—your default gateway. (Actually, the next thing to do is to look around back and make sure the network cable is still in place. There's nothing more embarrassing than calling in outside network support only to find that your LAN cable fell out of the back of your computer.) If you can successfully ping the default gateway but not my router, then either your firm's external Internet routers have failed or perhaps your default gateway is configured incorrectly. (Or perhaps my friends at my local telephone company and cable companies have had failures in their systems again—a far-too-often occurrence.) Another tool you might try is `tracert`, a souped-up Ping that shows you each of the hops that the IP packet had to use to get from your machine to the destination. It's a command-line command: Just type `tracert` followed by an IP address or DNS name. You can see a sample output in the following figure.

```

C:\>tracert 164.109.1.3

Tracing route to ns.digex.net [164.109.1.3]
over a maximum of 30 hops:
  0  <10 ms  <10 ms  10 ms  206.246.253.1
  1  40 ms  51 ms  50 ms  209.96.135.97
  2  41 ms  50 ms  40 ms  hne22.core1.NewportNews.visi.net [206.246.195.62]
  3  381 ms  460 ms  451 ms  atm51.maceast.Wash0C.visi.net [206.246.247.186]
  4  *  61 ms  240 ms  mae-east2.digex.net [192.41.177.192]
  5  60 ms  50 ms  190 ms  iad1-core4-pos3-0.atlas.digex.net [165.117.52.194]
  6  70 ms  60 ms  90 ms  dca1-cpe1-pos11-0-0.atlas.digex.net [165.117.52.229]
  7  60 ms  70 ms  81 ms  ns.digex.net [164.109.1.3]

Trace complete.

C:\>

```

*Continued on next page*

### HOW DO I MAKE SURE THAT TCP/IP IS SET UP PROPERLY? (*continued*)

If you can't get to the default gateway, then try pinging another computer on your subnet. If you can get to another machine on your subnet but not the gateway, then perhaps you've got the wrong IP address for the gateway or perhaps the gateway is malfunctioning.

If you can't get to another system on your subnet—and I'm assuming that you've already walked over and checked that the other machine is up and running—then it may be that the IP software on your computer isn't running. Verify that by typing **ping 127.0.0.1**.

127.0.0.1 is the "loopback" address. IP software is designed to *always* report success on a ping to 127.0.0.1, if the IP software is functioning. Recheck that you've installed the TCP/IP software and rebooted after installing.

Once you're certain that IP works, try out DNS. Try pinging a distant location, but this time, don't do it by IP address, do it by name—try pinging **www.whitehouse.gov**, **www.internic.net**, or **www.minasi.com**. If the ping works, great; if not, check that you've got the right address punched in for your DNS server and then check the DNS server.

I would have guessed that unless I found some way to tell **ssdotnet** that its full name was actually **ssdotnet.bigfirm.biz**, it wouldn't know to respond when someone pinged it by its full name. But, as it turns out, that's wrong.

If you're sitting at your computer and you type **ping ssdotnet.bigfirm.biz**, then your computer asks your local DNS server what **ssdotnet.bigfirm.biz**'s IP address is. Then your computer just pings that IP address, and **ssdotnet.bigfirm.biz** never even knows *what* name your computer originally called it by. If one of the people running IBM's DNS servers were to decide on a whim to insert an entry into IBM's DNS database that said "iguana.ibm.com has IP address 206.246.253.1," then anyone anywhere pinging **iguana.ibm.com** would end up pinging my router at that address.

The point is, then, that in order to have my computer named **ssdotnet** recognized as **ssdotnet.bigfirm.biz**, I've got to be concerned more with informing **bigfirm.biz**'s DNS server of **ssdotnet**'s IP address than I should be concerned about telling **ssdotnet** that it's in **bigfirm.biz**. So how do I ensure that **bigfirm.biz**'s DNS server finds out about **ssdotnet**? As it turns out, there are three ways to do this. (And even though handling DNS servers is a topic I won't get into until next chapter, it's worth covering this here.)

#### ADD A STATIC DNS ENTRY

The first way to make the DNS server for the Internet domain **bigfirm.biz** know that there's a machine named **ssdotnet.bigfirm.biz** whose IP address is 192.168.71.50 is for an administrator to simply sit down at the DNS server and *tell* it. Depending on what kind of machine the DNS server is running on, the admin will either edit a file or run some kind of management tool. (Again, you'll see how to do that with Server 2003's DNS server in the next chapter.)

#### JOIN THE ACTIVE DIRECTORY DOMAIN OF THE SAME NAME

The second way to tell the DNS server for the Internet domain **bigfirm.biz** to include **ssdotnet.bigfirm.biz** in its list of known hosts is for **ssdotnet** to join the Active Directory domain *named*

bigfirm.biz, assuming that there is one. This is a positive side effect of Active Directory's unifying of AD domain names and Internet (DNS) domain names. If the server named ssdotnet joins an Active Directory domain named bigfirm.biz, then by default the DNS server for the *Internet* domain named bigfirm.biz adds a record in that Internet domain for ssdotnet.bigfirm.biz. (I should point out that this isn't always true when you use a DNS approach called "split-brain DNS" but I'll cover that in the next two chapters.) Joining a domain is fairly easy as long as you have a domain administrator account on bigfirm.biz.

**NOTE** *I know I've not covered Active Directory yet, but don't sweat these references to AD. For now, all you need to know is that an Active Directory domain is a group of computers that trust each other, and you have to join a domain to be part of that trust. You'll see lots more on the topic in Chapter 8 but, again, that's all you need to know for now.*

While logged onto ssdotnet with an account with local administrative powers, click Start/Control Panel/System. You'll see a properties page with several tabs, one of which is labeled Computer Name. Click that tab and you'll see a screen something like Figure 6.15.

**FIGURE 6.15**  
Computer Name tab

Notice the text that says Workgroup—that means that this computer is not currently a member of a domain. (If it were a member of a domain, then you'd see Domain: bigfirm.biz or something like that.) Note also that the full computer name is simply ssdotnet, not ssdotnet with anything after it. I'll join ssdotnet to the bigfirm.biz domain, and you'll see that change. I click Change and see something like Figure 6.16.

**FIGURE 6.16**

The change-domain dialog box

I click the radio button next to Domain and fill in the text field next to Domain with the name of the Active Directory domain, **bigfirm.biz**.

Fill this in, changing the Workgroup radio button to the Domain radio button and filling in the domain name bigfirm.biz. When I click OK, though, the dialog box stops and asks me to demonstrate that I'm an administrator with the ability to create new domain accounts in the bigfirm.biz domain, as you see in Figure 6.17.

**FIGURE 6.17**

Checking domain administration credentials

I fill in an administrator name and password and click OK. The system runs the hard disk for a while and finally I get the message “Welcome to the bigfirm.biz domain.” And—no surprise—I’ve got to reboot to make it take effect. (Interestingly, the screen in Figure 6.15, when it returns, reflects the name change I’ve just done, with a yellow “caution” triangle indicating that the changes don’t take effect until after I reboot.)

After the reboot, two things happen: First, another look at the Network Identification tab shows that the machine's full computer name is now `ssdotnet.bigfirm.biz`. Second, a peek in the DNS database for `bigfirm.biz` shows that there's now an entry for `ssdotnet.bigfirm.biz` with IP address `192.168.71.50`. But how does the DNS server know? Because all Active Directory domains are partially built around a DNS server, and in particular a DNS server that accepts RFC 2136—compliant dynamic updates—that's Geekish for “a DNS server that lets computers register themselves with the DNS server, so administrators don't have to add DNS records by hand for those servers.” When `ssdotnet` booted up, it saw that it had a DNS suffix of `bigfirm.biz`, so it located the primary DNS server for `bigfirm.biz` and added its name to the `bigfirm.biz` names database. (And I promise, I'll describe the whole DNS registration process in detail in the next chapter—those last few sentences were just a teaser.)

#### DIRECTLY ENTER THE DOMAIN NAME INTO NETWORK IDENTIFICATION

But wait—this last scenario may not always make sense. Phillip Morris owns Kraft Foods and Miller Brewing Company. From an internal corporate point of view, it may be (I don't know, as I've never worked for any of the three entities) that everyone working for any of the three thinks of themselves as “Phillip Morris employees,” and Phillip Morris could be headquartered in one large complex in Richmond, Virginia. So from an internal management and IT point of view, they're one organization.

But to the outside world, the three entities seem to behave like separate firms, particularly on the Internet: A visit to `www.kraft.com` or `www.millerbrewing.com` gives no clue that Phillip Morris owns them. It just might be, then, that Phillip Morris doesn't want to be forced to make its DNS names jive with its Active Directory domain names. And they aren't, with Server 2003. You just have to do a little fiddling in the Computer Name tab.

Now that `ssdotnet` is a member of the `bigfirm.biz` Server 2003 domain, let's say for the sake of example that we wanted it to be part of the `minasi.com` Internet (DNS) domain.

I start renaming `ssdotnet` DNS-wise by returning to Computer Name: Start/Control Panel/System, then click the Computer Name tab. In that tab, click the Change button. This time, though, then click the More button to see a dialog box like in Figure 6.18.

**FIGURE 6.18**

DNS Suffix and NetBIOS Computer Name dialog

Notice the check box that says *Change Primary DNS Suffix When Domain Membership Changes*—that's the only thing connecting Internet domain names with Active Directory domain names! To let

this computer be part of the minasi.com Internet DNS domain but still be part of the bigfirm.biz Active Directory domain, I would just uncheck the box, and in Primary DNS Suffix of This Computer, I just fill in minasi.com. Of course, after such a momentous change, a reboot is required!

Before leaving this topic, I should point out that there is one more side effect to associating a machine with a domain: the domain search order. Bring up TCP/IP properties—again, click Start/Control Panel/Network Connections and then the object for your network card, probably a name like Local Area Connection. In the resulting dialog box, click the General tab and then the Properties button. That will raise a property page about your NIC's properties. Click the General tab and then click the object labeled Internet Protocol (TCP/IP) and then the Properties button. That will bring up the Internet Protocol (TCP/IP) properties page, as you saw back in Figure 6.11. Now click the Advanced button in the lower-right part of the page, which will bring up yet another properties page, the Advanced TCP/IP Settings page. It will have four tabs:

**IP Settings** Lets you add more IP addresses or modify some routing properties to a NIC, as you'll see later.

**DNS** Controls how your TCP/IP connection uses DNS, and that's the tab that we'll be looking at next.

**WINS** Controls how your TCP/IP connection identifies and communicates with computers that can't use Active Directory—Windows 9x and NT 4, for example.

**Options** Lets you restrict which ports your TCP/IP connection can use to communicate.

For now, click the DNS tab and you'll see something like Figure 6.19.

**FIGURE 6.19**  
DNS advanced  
properties page

The top field in the screen, DNS Server Addresses in Order of Use, is a bit mislabeled; it really means “these are the DNS servers that IP will use to resolve DNS names.” The section in the middle of the dialog box is the part that I’m mainly interested in here, the part that starts at the radio button labeled Append primary and connection specific DNS suffixes through the radio button labeled Append these DNS suffixes (in order).

To understand domain search order, consider the following question. Suppose you’re part of the research division of American Rocketry, Ltd., working in its Tidewater regional offices in southeast Virginia. American Rocketry might have divided up their DNS domain, americanrocket.com, into three divisions: research, management, and manufacturing, each with its own child domains: research.americanrocket.com, mgmt.americanrocket.com, and manufacturing.americanrocket.com. Furthermore, the folks running the research.americanrocket.com DNS server might have decided to divide up the DNS management job further with two child domains as there are two research facilities—one in the Tidewater area and one at the Bonneville Salt Flats in Utah—so they’ve created child domains tidewater.research.americanrocket.com and bonneville.research.americanrocket.com. If you work in Tidewater as a researcher and your computer’s name is surveyor, then the complete DNS name of your computer is surveyor.tidewater.research.americanrocket.com. If there’s a Web server down the hall that holds all of the content that you use in your intranet named memoryalpha, then to get to it you’ve got to start up your Web browser and point it at <http://memoryalpha.tidewater.research.americanrocket.com>, which could get a bit tedious.

The value of domain search order is this: Your system will be configured with a computer name of surveyor and a domain name of tidewater.research.americanrocket.com. Now that Server 2003 knows your domain name, you can refer to another system in tidewater.research.americanrocket.com by its computer name rather than having to type in the FQDN; you could point the Web browser to <http://memoryalpha> and the browser would find the Web server without any trouble. Just type in a computer name without any periods in it, and your system will know to add your domain name to the end before querying DNS.

By default, Server 2003 does just that—it adds your domain name to the end before querying DNS, and that’s how NT 4 operated as well. But as Server 2003 offers you the ability to put different NICs in different Internet domains, you may have a system with multiple-domain citizenship; that’s what Append Primary and Connection Specific DNS Suffixes refers to.

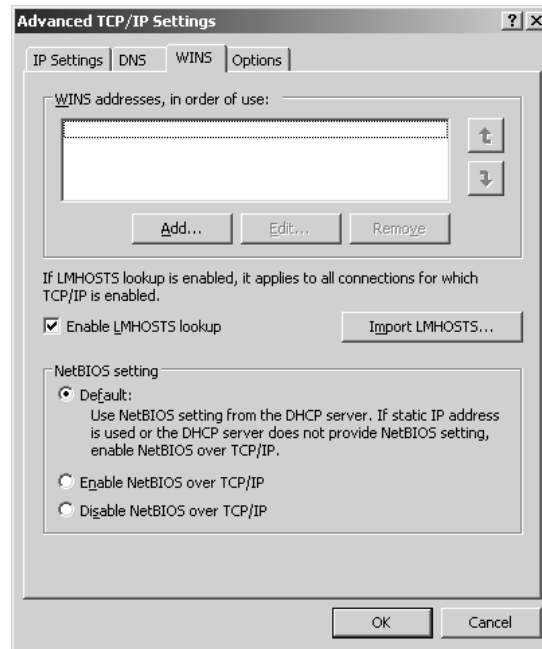

But what if you’re working for a firm like my mythical Phillip Morris/Kraft/Miller example, where a workstation might be in tacobell.com, pizzahut.com, pepsi.com, or kfc.com? Then you might want to have your system try a whole *bunch* of DNS queries before giving up. That’s why you have the option later in the dialog box to enter domain names to search.

Before leaving this dialog box, note Register This Connection’s Addresses in DNS. Remember that the DNS servers associated with an Active Directory enterprise can accept dynamic, RFC 2136 DNS updates so that a workstation or server can insert itself into the DNS name database rather than requiring an administrator to sit down and enter that machine’s IP address and name by hand. Server 2003 machines automatically seek out their local DNS server and try to add themselves to that DNS server’s list of names and IP addresses. If, for some reason, you do *not* want your workstation to do that, then you can just uncheck the box.

## Handling Old Names: Configuring Your Workstation for WINS

While in that advanced properties page for TCP/IP, click the WINS tab and you’ll see something like Figure 6.20.

**FIGURE 6.20**  
WINS client  
configuration tab

Now, if you're *really* lucky, then you'll never have to look at this screen. But I doubt that you're that lucky.

I'll cover WINS in detail in the next chapter, but for now all you need to understand is that you have one or two Server 2003 (or possibly NT) servers acting as name resolvers or WINS servers. This dialog box lets you fill in the names of a primary and secondary WINS server.

In brief, here's what WINS is all about. As you've read, most of the Internet in general as well as Server 2003 uses something called DNS to convert network names to network addresses (or, in network lingo, to "resolve network names"), but now I'm saying that we'll *also* use something else, called WINS, to do what sounds like the same thing. What's going on? In truth, you shouldn't really have to set up WINS at all; NT and Microsoft enterprise networking in general should use DNS for all of its name resolution, but it didn't in Windows for Workgroups, Windows 9x, NT 3.x, and NT 4. It wasn't until Server 2003 shipped that Microsoft networking started relying on Winsock and DNS.

The reason is that Microsoft wanted NT's networking modules to work like the already-existing LAN Manager system, and LAN Manager used a naming system based on its NetBIOS application program interface. A computer's NetBIOS name is the computer name that you gave it when you installed it. When you type **net view \\ajax**, something must resolve \\ajax into an IP address—a NetBIOS-to-IP resolution. WINS does that. In contrast, the rest of the Internet would see a machine called ajax as having a longer name, like ajax.acme.com. If there were a Web server on ajax, then someone outside the company would have to point her Web browser to <http://ajax.acme.com>, and some piece of software would have to resolve ajax.acme.com into an IP address. That piece of software is the socket or Winsock interface, and in either case, it will rely upon not WINS

but DNS to resolve the name. In a few words, then, programs written to employ NetBIOS will use WINS for name resolution, and programs written to employ Winsock use DNS for name resolution.

I can probably guess what you're thinking now, and, yes, DNS and WINS should be integrated, but they can't really ever be completely integrated, because, as you'll see in the next chapter, DNS and WINS serve different masters—DNS serves standard Internet-type applications like Web browsers and newer Microsoft tools like Active Directory, and WINS serves older Microsoft-centric tools like network workgroups or NT 4 domains.

The bigger question at this point is *why am I even talking about this?* After all, it's 2003. That bad old NetBIOS and NT 4 stuff is dead, right? Nope, not in most networks. It's pretty likely that you've still got some Windows 98, Windows Me, and NT 4 systems still attached to your network and who knows, you might even have a few Windows for Workgroups and Windows 95 systems. Back when Active Directory first appeared in Windows 2000, Microsoft kept promising us that WINS would no longer be necessary once 2000 Server—yes, that's 2000 Server, not Server 2003—had been out for a while, but there was some fine print, namely “so long as you throw away all of your old machines or put Windows 2000, XP, or Server 2003 on them.” Most of us can't afford to do that, so we'll be living with WINS servers for the time being—which means that your Server 2003 systems must know where those WINS servers are; hence this dialog box. (Remember that in our simple example we've not configured a WINS server yet, which is why that last figure had a blank WINS Addresses, in Order of Use field.)

I could tell this computer to use a WINS server at 192.168.71.10 by clicking Add, filling in the IP address, and clicking OK. You could only tell pre-2000 Server systems about two WINS servers, but for some reason 2000, XP, and Server 2003 allow you to list as many WINS servers as you like in this dialog box.

Even at its best, WINS can't do the whole name resolution job. Some tough name resolution problems can only be solved with a HOSTS-like file called LMHOSTS. The Enable LMHOSTS Lookup check box lets you use an LMHOSTS file if you've got one installed on your system. I'll explain LMHOSTS in detail in the next chapter.

Below all that is a group of controls labeled NetBIOS Setting offering three options:

- ◆ Default
- ◆ Enable NetBIOS over TCP/IP
- ◆ Disable NetBIOS over TCP/IP

If you're an old Windows 2000 hand, then you'll notice that these options changed a little bit—what is now Default used to be Use DHCP Setting.

The Enable NetBIOS over TCP/IP versus Disable NetBIOS over TCP/IP radio buttons embody a deceptively momentous choice, so it's odd that the choice is tucked away in this obscure properties page. Another way of phrasing the WINS-versus-DNS dichotomy is to say that all of the Microsoft operating systems prior to 2000 Server built all of their networking tools atop a programming interface called NetBIOS, and Windows 2000, XP, and Server 2003 break with that tradition by instead using another programming interface called Winsock. An all-Windows-2000-or-later network would be perfectly happy running only network programs—Web servers, e-mail, file servers, even domain controllers for authentication—that used Winsock. But if those servers want to

communicate with older Windows and NT systems, then they must use older networking programs that are compatible with these old systems, and those older networking programs are built atop NetBIOS.

That means that if your Server 2003 system is acting as a file or print server for any older machines, it needs to keep NetBIOS around. If it's running any applications built for pre-2000 Server versions of NT, it'll probably need NetBIOS. Put simply, you can't shut off NetBIOS until you're free of both old client machines and old network applications. But one day you'll be able to axe NetBIOS, and when you can, you should, as it'll reduce network chatter and free up server memory and CPU power.

### Adding IP Addresses to a Single NIC

If you're still in the Advanced TCP/IP Settings page, click the IP Settings tab, and you'll see something like Figure 6.21.

**FIGURE 6.21**

IP Settings advanced properties tab

This NIC already has the 192.168.71.50 IP address that I gave it earlier. But notice the Add button. This lets you attach different IP addresses to the NIC to assign more than one IP address to a single NIC.

Why would you want to do that? Normally, you wouldn't. But there *is* one case where it would be very useful: when you're hosting multiple Web sites on a single Web server.

For example, suppose I've got two Internet domains, minasi.com and win2kexperts.com. I intend to put up a Web site for minasi.com ([www.minasi.com](http://www.minasi.com)) and another for win2kexperts.com ([www.win2kexperts.com](http://www.win2kexperts.com)). But I want them to be very different Web sites; perhaps the minasi.com site

is a personal site and the win2kexperts site is a business site. Even though [www.minasi.com](http://www.minasi.com) and [www.win2kexperts.com](http://www.win2kexperts.com) are both hosted on a machine at 206.246.253.100, I don't ever want anyone visiting the business site to see pictures of my last vacation, and I don't think my friends care much about my professional résumé.

I separate the two by creating two *virtual sites*. There are two basic ways to give a single Web server “multiple personalities.” You'll read more about how to do that with Internet Information Server in Chapter 17, and in that chapter you'll learn *one* way to create multiple virtual sites. That method doesn't work with old browsers—Netscape 1.x, Internet Explorer 1.x and 2.x, Spyglass—but only with *really* old browsers, so what you'll read in Chapter 17 may well be all you need. But if you ever need the slightly more expensive (and when I say *expensive* here, I mean that you'll have to use an IP address for each virtual site) method that works with *any* browser, then here's briefly how to do it—and it's a great example of why you'd put multiple IP addresses on a single NIC:

1. I assign an extra IP address to the Web server so that it now has two addresses—let's say they're 206.246.253.100 and 206.246.253.101.
2. I then set up DNS so that [www.minasi.com](http://www.minasi.com) points to the first address, 206.246.253.100, and [www.win2kexperts.com](http://www.win2kexperts.com) points to the second address, 206.246.253.101.
3. I've already got the minasi.com Web site running, so I'll need a place to put the win2kexperts.com content. I just create a folder on the Web server called w2kx and put the HTML, images, and so on for win2kexperts.com there.
4. I next tell the Web server to create a “new site.” It then basically needs to know two things: where to find the content (C:\w2kx) and which IP address to associate with the site. I've got to tell it to “start” the site, and I'm in business.

The important thing here is to understand that every one of these sites, each of these “personalities” of your Web server, burns up an IP address, and as you see, you use the IP Settings property tab to add those extra IP addresses to your Web server's NIC.

Whew! Getting IP running on that system was a bit of work. Good thing we can do most of our machines automatically with DHCP—but even that requires configuring, which is why we went through all of this detail. Now that I've got IP on a system, I can return to some of the more techie infrastructure issues—like IP routing.

## Setting Up Routing on Server 2003, NT, and 9x Machines

Up to now, I've assumed that all of your TCP/IP-using machines had a single default gateway that acted as “router to the world” for your machines. That's not always true, as real-life intranets often have multiple routers that lead a machine to different networks. I've also assumed that your Server 2003 network is connected to the Internet, or to your enterprise intranet, via some third-party (Compatible Systems, Bay Networks, Cisco Systems, or whomever) router. That's also not always true, as NT machines can act as IP routers.

Routing problems aren't just *server* problems; they're often workstation problems, as well. So, in this section, I'll take on two topics:

- ◆ How to set up routing tables on your workstations and servers
- ◆ How to use your Server 2003 servers as IP routers

## An Example Multirouter Internet

Suppose you had a workstation on a network with two gateways, as shown in Figure 6.22.

**FIGURE 6.22**

A workstation on a network with two gateways

As is the case for most of these diagrams, a multinet picture can be cryptic, so here's an explanation of what you are looking at.

First, there are three separate Ethernet segments, three separate subnets. They are all class C networks, just to keep things clean. Two of the networks are only represented by clouds; thus, the cloud on the left containing 199.100.200.0 is just shorthand for an Ethernet with up to 254 computers hanging off it, with addresses ranging from 199.100.200.1 through 199.100.200.254. Notice that I said 254, not 253, because *there is no default gateway for these subnets*. As there are only three subnets, this is an intranet, not part of the Internet. One side effect of not being on the Net is that you can use the .1 address for regular old machines. I left the Internet out of this first example because I found that it confused me when I was first trying to get this routing stuff down. I'll add it later, I promise.

There is also another cloud, to the right, representing a network whose addresses range from 200.15.16.1 through 200.15.16.254—network number 200.15.16.0.

In between is a third subnet with address 210.50.200.0. You see a rectangle representing a PC in the middle that has only one Ethernet card in it, and its IP address is 210.50.200.40. The rectangles on the right and left sides of the picture are routers, computers with two Ethernet cards in them and thus two IP addresses apiece. Each has an address on the 210.50.200.0 network, and each has an address either on the 200.15.16.0 network or on the 199.100.200.0 network.

### Adding Entries to Routing Tables: *route add*

Having said that, let's now figure out how to tell the machine at 210.50.200.40 how to route anywhere on this network. These are some of the facts it needs to know:

- ◆ To get a message to the 199.100.200.0 network, send it to the machine at 210.50.200.200.

- ◆ To get a message to the 200.15.16.0 network, send it to the machine at 210.50.200.22.
- ◆ To get a message to the 210.50.200.0 network, just use your own Ethernet card; send it out on the segment, and it'll be heard.

You tell a workstation how to send packets with the `route add` command. Simplified, it looks like this:

```
route add destination mask netmask gatewayaddress
```

Here, *destination* is the address or set of addresses that you want to be able to get to. *Netmask* defines how many addresses are there—is it a C network with 250+ addresses, something subnetted smaller, or perhaps a “supernet” of several C networks? *Gatewayaddress* is just the IP address of the machine that will route your packets to their destination.

The `route add` command for the 199.100.200.0 network would look like this:

```
route add 199.100.200.0 mask 255.255.255.0 210.50.200.200
```

This means, “Send a message anywhere on the 199.100.200.0 network, send it to the machine at 210.50.200.200, and it'll take care of it.”

**TIP** *If you just type the `route add` statement as you see it in the previous text, then your system will forget the routing command when next you boot. You can tell it to remember that route next time with the `-p` (“permanent”) switch, as in `route -p add 199.100.200.0 mask 255.255.255.0 210.50.200.200`. This only works on NT and 2000; you can't make routes permanent under Windows 9x.*

Just a reminder on subnetting, for clarity's sake: Suppose the network on the upper left wasn't a full C network, but rather a subnetted part of it. Suppose it was just the range of addresses from 199.100.200.64 through 199.100.200.127. The network number would be, as always, the first address (199.100.200.64), and the subnet mask would be 255.255.255.192. The `route add` command would then look like this:

```
route add 199.100.200.64 mask 255.255.255.192 210.50.200.200
```

Anyway, back to the example in the picture. Add a command for the right-side network; it looks like this:

```
route add 200.15.16.0 mask 255.255.255.0 210.50.200.22
```

That much will get a Server 2003, NT, XP, 9x, Me, or even DOS-based TCP/IP system up and running.

## Understanding the Prebuilt Routes

Even if you don't ever type a `route add` command at a Windows workstation, you'll find that there are prebuilt routing statements that are automatically generated. Let's look at them. First, we'd need an explicit routing command to tell the 210.50.200.40 machine to get to its own subnet:

```
route add 210.50.200.0 mask 255.255.255.0 210.50.200.40
```

Or, in other words, “To get to your local subnet, route to yourself.”

**NOTE** Remember, you need not run this or any other `route add` command in this section—they’re default routes, therefore they’re always around.

Then, recall that the entire 127.x.y.z range of network addresses is the loopback. Implement that like so:

```
route add 127.0.0.0 mask 255.0.0.0 127.0.0.1
```

This says, “Take any address from 127.0.0.0 through 127.255.255.255 and route it to 127.0.0.1.” The IP software has already had 127.0.0.1 defined for it, so it knows what to do with that. Notice the mask, 255.0.0.0, is a simple class A network mask.

Some Internet software uses intranet multicast groups, so the multicast address must be defined. It is 224.0.0.0. It looks like the loopback route command:

```
route add 224.0.0.0 mask 255.0.0.0 210.50.200.40
```

The system knows to multicast by *shouting*, which means communicating over its local subnet.

**Viewing the Routing Table**

Let’s find out exactly what routing information this computer has. How? Well, on Server 2003, Windows NT, Workgroups, and 9x workstations, there are two commands that will show you what the workstation knows about how to route IP packets. Type either **netstat -rn** or **route print** at a command line—the output is identical, so use either command—and you see something like Figure 6.23.

**FIGURE 6.23**  
Sample route print output

Notice that the output of `route print` is similar to the way you format data in `route add`. Each line shows a network address, which is the desired destination; the netmask, which indicates how many addresses exist at the desired destination; and the gateway, which is the IP address that the workstation should send its packets to in order to reach the destination. But note two more columns: Interface and Metric.

### THE INTERFACE COLUMN

Interface asks itself, “Which of my local IP addresses—the ones physically located inside me, like my loopback and all the IP addresses attached to all of my network cards—should I use to get to that gateway?” On this computer, it’s a moot point because it only has one network card in it.

What might this look like on a multihomed machine, like the router on the left side? It has two IP addresses, 199.100.200.5 and 210.50.200.200. A fragment of its `route` print output might then look like this:

Network	Destination	Netmask	Gateway	Interface	Metric
199.100.200.0	255.255.255.0	199.100.200.5	199.100.200.5	1	
210.50.200.0	255.255.255.0	210.50.200.200	210.50.200.200	1	

There are two networks that the router machine can get to (obviously, or it wouldn’t be much use as a router), and each one has a gateway address, which happens to be the local IP address that the router maintains on each network. But now notice the Interface column: Rather than staying at the same IP address all the way through, this tells the computer, “I’ve already told you which gateway to direct this traffic to; now I’ll tell you which of your local IP addresses to employ in order to get to that gateway in the first place.”

### THE METRIC COLUMN, PART I: WHAT METRIC DOES

The Metric column (what, no English option?) helps IP figure out which route to take when it has more than one option. It was once a simple-to-explain concept, but from Windows XP onward, Microsoft has muddied it a bit. Still, it’s an important concept to understand, so hold onto something solid, the ride’s about to get a bit bumpy.

“Metric” is a value that you can set with the `route add` command, like so:

```
route add 200.15.16.0 mask 255.255.255.0 210.50.200.22 metric 2
```

In that command, adding `metric 2` to the end says, “This route will effectively get you to some destination on the 200.15.16.0 subnet, but you’ve got to go through one router to get there.” The metric number is 2 because you always add 1 to the number of routers to pass through—one router, add one, get a metric of 2.

IP software takes no notice of metrics unless it has to choose between more than one possible route. For instance, suppose your computer is trying to get to some IP address—call it A. Suppose also that your computer is connected to two routers—call them X and Y—and *both* routers can find their way to the destination address A. Your IP software must, then, make a choice: get to A through X or through Y?

I make a similar choice all the time when choosing airlines. I always start from the same place—Norfolk Airport in southern Virginia. But suppose I want to get to, say, Philadelphia, and that I’ve got two choices: United will fly me to Dulles, outside Washington, DC, and I’ll change planes and then fly from Dulles to Philly. Alternatively, USAir will fly me direct from Norfolk to Philadelphia. Which do I choose?

Well, in real life there might be plenty of reasons to choose one over the other, but I think for most of us the answer would be “whichever involves the least number of stops, minimizing the amount of chances that the airline has to lose my bags or screw up my connection.” We’d say that the number of stops is the major *metric* in determining which *route* to take. And IP packets feel the same

way, apparently: whenever given the choice between one or more routes, they take the one with the fewer number of hops. So if router X's route involved three hops (and thus had a metric of 3+1 or 4) and router Y's route involved one hop (and thus had a metric of 1+1 or 2) then system A would choose to route its packet through Y rather than X.

To review, then, *metric used* to refer to the number of routers that an IP packet would have to pass through in order to get to its destination. A metric value of 1 originally meant "your destination is on the same subnet." A metric value of 2 originally meant "you have to go through one router to get to your destination," and so on. So a route's metric value equalled the number of routers your IP packet would have to travel through, plus 1.

### THE METRIC COLUMN, PART 2: HOW WINDOWS USES IT

Or at least, that's the way it *used* to be. As of XP and Server 2003, Microsoft seems to have redefined metric. At startup, Server 2003 tries to communicate through each network interface, and based on the speed of their responses, it sets a default metric for each interface, based on the perceived speed of the link:

Link speed	Metric assigned
200 Mbps>	10
20–200 Mbps	20
4–20 Mbps	30
500 Kbps–4Mbps	40
<500 Kbps	50

In other words, Microsoft has taken what used to mean "the number of hops in a route" and redefined it as "roughly how fast this link is." I imagine their idea was that the whole point of metrics was to find the fastest from amongst a set of possible routes, and that by doing this on-the-fly speed test of a link that they came up with a better approach. I suppose it's not a bad answer, but it's one that runs counter to the way that everyone else uses metrics in IP routing. And let me stress that as far as I can see there's no harm in it, so long as you don't intend to do much in the way of static routing and truthfully you probably won't want to do much static routing on a workstation.

### HOW TO DISABLE AUTOMATIC METRICS

Again, you can probably run a network where all (or almost all) of your systems have automatic metrics, but if you want to follow along in this discussion of IP routing then you'll want to disable them.

Recall that every network card in your system has an IP stack and that there is a properties page for that IP stack, as you saw in Figure 6.11. That includes an Advanced button, which leads to an Advanced TCP/IP Properties page, which contains a tab labeled IP Settings, as you saw in Figure 6.21. Go to that page and you'll note a field at the bottom of the IP Settings page with a check box labeled Automatic Metric. Un-check that box and in the field below it labeled Interface Metric, enter 1 and then click OK, then close any other TCP/IP-related dialog boxes. Do this for each NIC in your system. If I do that, then my `route print` output changes, as you can see in Figure 6.24.

**FIGURE 6.24**

route print after  
disabling automatic  
metrics

### BACK TO THE METRIC FIELD

Now that we've got Server handling metrics in the standard way, let's return to the output in Figure 6.24. As I've already said, the correct value for the metric column should be the number of routers that you've got to hop over in order to get to the subnet in the routing table entry. Since the .40 workstation must go through a router to get to either the 199.100.200.0 or the 200.15.16.0 network, both of those networks should get a metric of 2.

But the screen show shows a metric of 1, not 2, for both the 199.100.200.0 and 200.15.16.0 route—why? Because the computer's not smart enough to figure out how many hops a new route add command involves. But *you* can, by adding the metric parameter and the desired value. A more complete set of route add commands would be

```
route add 200.15.16.0 mask 255.255.255.0 210.50.200.22 metric 2
route add 199.100.200.0 mask 255.255.255.0 210.50.200.200 metric 2
```

Had I done that, then you'd have seen the metric value of 2. You'll learn a bit later that a protocol called RIP will make this process automatic, but for now I want to stick to this manually constructed set of routing tables. (Using hand-constructed routing tables is called *static routing*; the automatic methods like RIP are called *dynamic routing*, and I'll get to them later.)

### ROUTE PRINT OUTPUT EXPLAINED

Now that you can decipher each column in the route print output, I'll finish up explaining the output.

The first line is the loopback information, as you've seen before. It's automatically generated on every 2003/2000/XP/NT/Workgroups/9x machine running the Microsoft TCP/IP stack. The second and third lines are the manually entered routes that tell your machine how to address the 200.15.16.0 and 199.100.200.0 networks. The fourth line is another automatically generated line, and it explains how to address the 210.50.200.0 subnet, which is the local one. The fifth line refers to 210.50.200.40 itself. The mask, 255.255.255.255, means that these aren't routing instructions to get to an entire network, but rather routing instructions to get to a particular computer. It basically says, "If you need to get data to 210.50.200.40, send it to the loopback address." The result: If you ping 210.50.200.40, then no actual communication happens over the network. The sixth line defines how to do a local subnet broadcast. Again, it doesn't point to an entire network, but rather to the particular subnet broadcast address. The seventh line serves Internet multicasting, as you saw

before. And the final address is for something called the *limited broadcast address*, a kind of generic subnet broadcast address.

## Adding the Default Gateway

Suppose you wanted to set up my 210.50.200.40 machine. How would you do it? More specifically, you'd ask me, "Which is the default gateway?"

Well, in the TCP/IP configuration screen that you've seen before, you'd obviously be able to supply the information that the IP address should be 210.50.200.40 and the subnet mask should be 255.255.255.0. But what should you use to fill in the Default Gateway field? I mean, there are *two* gateways, 210.50.100.22 and 210.50.100.200. Which should you use?

The answer? Neither. A *default gateway* is just another entry in the routing table, but it's not specific like the ones you've met so far; it's a catchall entry. This network doesn't get to the Internet, and it can only see two other subnets, each with their own routers (gateways), so I left the Default Gateway field blank. And there's an advantage to that.

## "DESTINATION HOST UNREACHABLE"

If I were to try to ping some address not on the three subnets, such as 25.44.92.4, then I wouldn't get the message that the ping had timed out, or experienced an error, or anything of the sort; rather, I'd get a "destination host unreachable" message. That's important: "Destination host unreachable" doesn't necessarily mean that you can't get to the destination host, but it *does* mean that your workstation doesn't know *how* to get to that host—it lacks any routing information about how to get there at all. Do a `route print` and you'll probably be able to see what's keeping you from getting to your destination.

## BUILDING A DEFAULT GATEWAY BY HAND

When *would* a default gateway make sense in our network? Well, let's add an Internet connection to the network, as shown in Figure 6.25.

**FIGURE 6.25**

Network with an Internet connection

Now we need another `route add` command—but what should it look like? I mean, what’s the generic IP address of the whole Internet?

Believe it or not, there *is* such an address: 0.0.0.0. Think of it as “the network number to end all network numbers.” Remember, any given network’s number is just the first address of the network. And what’s the first address of the Internet? 0.0.0.0. And the network mask? Well, since it doesn’t matter *what* address bits match which other address bits—after all, no matter what your address is, you’re still on the particular “subnet” that is the entire Internet—the subnet mask is also 0.0.0.0. But you’ve got to hop across a router to get to this 0.0.0.0 “subnet,” so let the metric reflect that with this command:

```
route add 0.0.0.0 mask 0.0.0.0 210.50.200.1 metric 2
```

### HANDLING CONFLICTS IN ROUTING INFORMATION

Let’s take a minute and look once more at that metric parameter. You see, we’ve now made IP’s job a bit more complicated, as I promised that we would back when we started talking about metrics. Look at some of the instructions that you’ve given the IP software about how to route:

- ◆ There’s a rule about handling the specific address 210.50.200.40: Just keep the message local at 127.0.0.1, no routing.
- ◆ There’s a rule about how to handle the range from 210.50.200.0 through 210.50.200.255: Shout it out on the subnet, no routing.
- ◆ There’s a rule about how to handle the range from 199.100.200.0 through 199.100.200.255: Send it to 210.50.200.200.
- ◆ There’s a rule about how to handle the range from 200.15.16.0 through 200.15.16.255: Send it to 210.50.200.22.
- ◆ There’s a rule about how to handle *all* Internet addresses: Send the messages to 210.50.200.1.

Here’s what I mean about a conflict: Suppose you want to send an IP packet to 200.15.16.33. You have one rule that says, “Send it to 210.50.200.22” (the local specific router for that subnet) and another that says, “Send it to 210.50.200.1,” (the router to the Internet). Which rule does the software on your computer follow?

Answer: When in doubt, *first* look for the route with the smallest metric. If there is more than one candidate, then take the *most specific* one—in other words, choose the one with the most specific subnet mask.

In this case, there are two entries in the routing table that point to the destination, 200.15.16.33. I haven’t shown you their metrics, but both of them require hopping over one router, so each route has metric 2. As their metrics are tied, you look next to the subnet mask. As the 210.50.200.1 route has a very generic subnet mask (0.0.0.0), your machine would ignore it in comparison to the more specific 210.50.200.22’s subnet mask of 255.255.255.0.

Suppose workstation 210.50.200.40 wanted to get a message to another machine on the subnet; let’s say that its address is 210.50.200.162. Again, there’s a routing conflict, as one route entry just says to send it to 210.50.200.40—in other words, don’t route, shout! There’s another routing entry—the 0.0.0.0 one again—that says it can also get the IP packet to 210.50.200.162, as it claims

it can get any packet *anywhere*. Which to choose? Well, if constructed correctly, an excerpt of the routing table will look something like this:

Destination	Netmask	Gateway	Interface	Metric
0.0.0.0	0.0.0.0	210.50.200.1	210.50.200.40	2
210.50.200.0	255.255.255.0	210.50.200.40	210.50.200.40	1

The first entry is the default gateway. It's got metric 2 because you've got to hop over at least one router to get to the Internet. (In actual fact, it's probably not a bad idea to set this value a bit higher, just to be sure internal IP packets *never* try to get sent over the Internet.) The second entry basically says, "To send data to your local subnet, just say it out loud on your Ethernet card"—again, don't route, shout. As the Internet metric is higher, your machine will know not to try to send a local message by sending it to the default gateway.

One more thing: You wouldn't, of course, want to have to type in those `route add` commands every time you start up your computer. So you'd use a variation on the `route add` command. Just type `route -p add`. Recall that when you add the `-p`, that entry becomes permanent in your system's routing table.

## All Routers Must Know All Subnets

I've talked about how I'd set up my sample network from the point of view of a workstation. It would work, but you can see that it's a real pain to punch in all of those `route add` statements for each workstation. The answer is to make the routers smarter; *then* you can just pick one router to be the default gateway for the .40 workstation, and the workstation needn't worry about anything. So let's take a minute and see how each of the three routers in this system would be set up.

The first router is the one on the left, which routes between 199.100.200.0 and 210.50.200.0. It must know three things:

- ◆ It can get to 199.100.200.0 through its 199.100.200.5 interface.
- ◆ It can get to 210.50.200.0 through its 210.50.200.200 interface.
- ◆ It can get to the Internet through 210.50.200.1, which it gets to through its 210.50.200.200 interface.

In fact, you would not have to type in routing commands telling it how to get to 199.100.200.0 or 210.50.200.0; assuming it's an NT machine, the NT routing software figures that out automatically. But you can tell it to get to the Internet by setting a default gateway:

```
route add 0.0.0.0 mask 0.0.0.0 210.50.200.1 metric 2
```

The routing software is then smart enough to realize that it should get to 210.50.200.1 via its 210.50.200.200 interface.

The second router, the one on the right, routes between 200.15.16.0 and 210.50.200.0. It can get to both of those networks directly, and, as with the first router, we don't have to tell it about them. But to get to the Internet, it must route packets to 210.50.200.1, and so, like the first router, it should have a default gateway of 210.50.200.1.

Now let's tackle the third router, the machine at 210.50.200.1, which is the Internet gateway. It must know that it should use the Internet as its default gateway. For example, on my Compatible Systems routers, there is a magical address WAN that just means the modem connection to the Internet. I essentially tell it, "Route add 0.0.0.0 mask 0.0.0.0 WAN," and packets travel to and from the Internet over the modem. The router must then be told of each of the three subnets, like so:

```
route add 210.50.200.0 mask 255.255.255.0 210.50.200.1 metric 1
route add 199.100.200.0 mask 255.255.255.0 210.50.200.200 metric 2
route add 200.15.16.0 mask 255.255.255.0 210.50.200.22 metric 2
```

## Using RIP to Simplify Workstation Management

Thus far, I've shown you how to tell your workstations how to exploit routers on the network. In most cases, you won't need to build such large, complex routing tables by hand, and in almost no case will you *want* to build those tables.

Ideally, you shouldn't have to type in static tables; instead, your workstations could just suck up routing information automatically from the nearby routers, using some kind of browser-type protocol. You *can* do such a thing with the Routing Information Protocol (RIP).

RIP is an incredibly simple protocol. Routers running RIP broadcast their routing tables about twice a minute. Any workstation running RIP software hears the routing tables and incorporates them into its *own* routing tables. Result: You put a new router on the system, and you needn't punch in any static routes.

RIP version 2 ships as part of Server 2003. The Microsoft implementation supports both IP and IPX. Routes detected by RIP show up in `route print` statements just as if they were static routes.

## An Alternative Dynamic Routing Protocol: OSPF

Although RIP has been around for some time, it's an awfully chatty protocol. Twice a minute, each RIP router broadcasts its entire routing table for all to hear. A more intelligent and bandwidth-parsimonious but more complex to set up dynamic routing protocol is available in the form of the Open Shortest Path First (OSPF) protocol. You have to feed the routers a bit more information about the layout of your sites, but once you do, OSPF quickly generates the shortest routes for your packets.

## Using an NT Machine as a LAN/LAN Router

In the process of expanding your company's intranet, you need routers. For a network of any size, the best bet is probably to buy dedicated routers, boxes from companies such as Cisco Systems, Bay Networks, or Compatible Systems.

Dedicated routers are fast and come with some impressive management tools: neat GUI programs that let you control and monitor your network from your workstation. But routers have one disadvantage: They're expensive. I haven't seen an Ethernet-to-Ethernet IP router available for less than \$3,000. Again, don't misunderstand me: These routers are probably worth what they cost in terms of the ease that they bring to network management and the speed with which they route data. But you might have more than one subnet on a given site, and you might *not* have the three grand, so you're looking for an alternative.

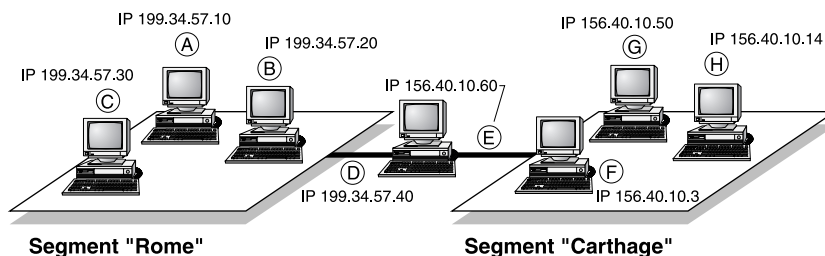

How about a software alternative? Any NT server, from 3.51 through Server 2003, can act as a simple IP router—all you need is a multihomed PC (one with two or more network cards installed in it) and Windows NT 4.

Just open the Control Panel, open the Network applet, then the Protocols tab, and the TCP/IP protocol. Click the Routing tab, and you see an option called Enable IP Routing. That's how you turn on NT's routing capability.

Making a Server 2003 system a router is a bit more complex. Let's see how to set up this router. Let's return to that cross-Mediterranean rivalry and set up a LAN-to-LAN router for Carthage and Rome. Imagine you have an intranet that looks like Figure 6.26.

**FIGURE 6.26**

A sample intranet

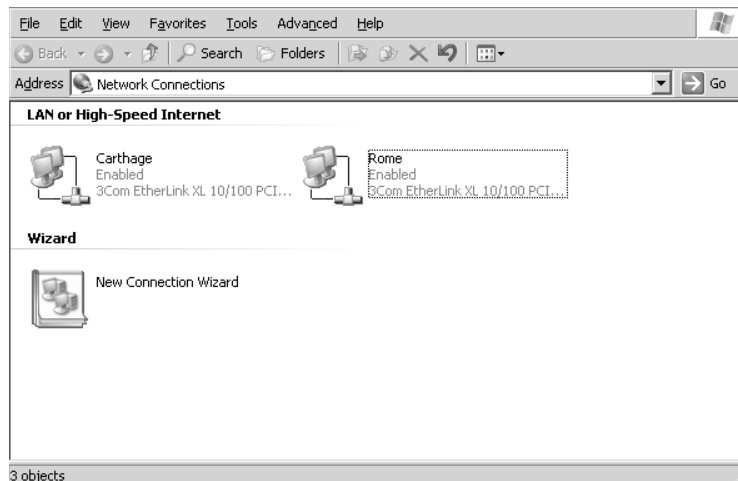

We're going to use the machine that's on both Rome and Carthage as the router. Actually, there's no choice here, as it's the *only* machine in both TCP/IP subnets, and any router between two subnets must be a member of both subnets. First I'll look at how to set up the machine with adapters D and E as a router, and then I'll take a slightly more complex example:

1. The machine between Rome and Carthage—let's call it MEDITERRANEAN—needs two Ethernet cards. Install two network cards (let's use Ethernet for this example) in a Server 2003 system machine. Microsoft *intended* for you to only be able to use 2003 Server for IP routing, but you can use XP as well with a Registry hack, so long as you're only doing static routing—I haven't been able to figure out how to make Professional do RIP or OSPF routing.
2. Configure the Ethernet card on the Rome subnet with IP address 199.34.57.40 and the Ethernet card on the Carthage subnet with IP address 156.40.10.60. Here's how: Once you've got a second NIC installed in the MEDITERRANEAN system, open up Network and Dial-Up Connections and it'll look like Figure 6.27.

**FIGURE 6.27**

Network and Dial-Up Connections with two NICs

3. Right-click either of the two connection objects and choose Properties, and you'll then see the screen that lets you modify the TCP/IP properties for that NIC, including its static IP address. (Notice you can also rename the NICs; I've renamed them from Local Area Connection to more descriptive names.) Once I've set the IP addresses properly, an `ipconfig /all` looks like Figure 6.28.

**FIGURE 6.28**

`ipconfig /all`  
before enabling  
routing

```
C:\>ipconfig /all

Windows IP Configuration

Host Name . . . . . : Mediterranean
Primary Dns Suffix . . . . . :

Subnet Mask . . . . . : 255.255.255.0
Default Gateway . . . . . : 

C:\>
```

Note that this IPConfig output is larger than the previous ones, mainly because it's got to report on two NICs. There's no DNS server specified and no domain name specified because (1) it simplified the IPConfig output and (2) routers usually needn't have DNS names for their interfaces. Note also that IP Routing Enabled is No. That's important—just because a Server 2003 system has NICs attached to different subnets doesn't automatically mean that the system will act as a router.

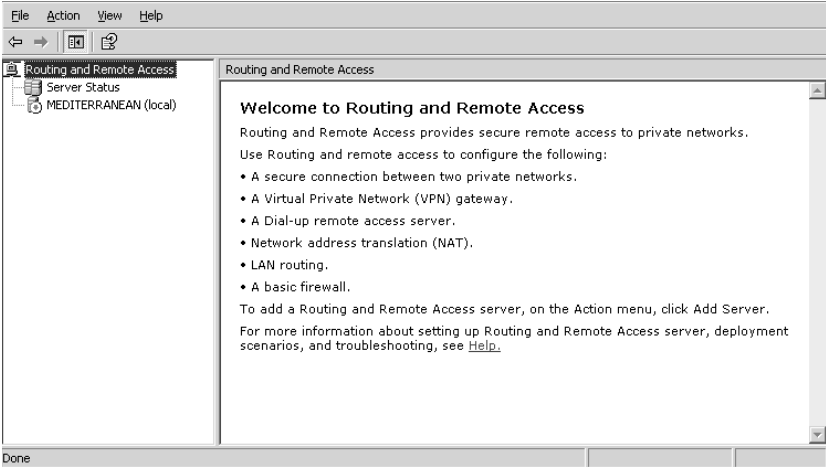

4. Next, turn on routing. You can turn on simple static routing for either a Server 2003 or Professional machine by looking in the key `HKEY_LOCAL_MACHINE\System\CurrentControlSet\Services\Tcpip\Parameters` for the value named `IPEnableRouter`, which will be set to 0. Change the value to 1, reboot the system, and it'll do static routing between the subnets that it's directly connected to.

I suggested the Registry hack because it's the only way that I've found to make an XP or 2000 Professional machine an IP router—which is odd, because under NT 4 Workstation there was a check box in the Control Panel to enable IP routing. Maybe it was an oversight, or perhaps Microsoft wants to sell you a copy of Server if you want to do even the simplest IP routing?

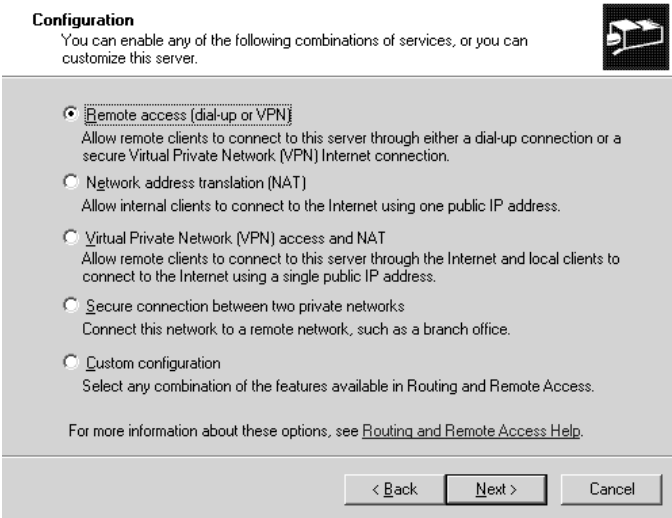

In any case, if the routing machine is running 2003 Server, then no Registry fooling around is needed. Instead, click Start/Administrative Tools/Routing and Remote Access, which will show you an MMC console like Figure 6.29.

Note the red arrow next to MEDITERRANEAN. That indicates that routing hasn't been turned on yet. To turn routing on, right-click MEDITERRANEAN in the left pane and choose Configure and Enable Routing and Remote Access. That, not surprisingly, starts off a wizard, the Routing and Remote Access Server Setup Wizard. Click Next and you'll then see a screen like Figure 6.30.

**FIGURE 6.29**  
Opening RRAS  
administrator screen

**FIGURE 6.30**  
Initial RRAS setup  
wizard screen

Setting up a router can be a bit challenging, so Microsoft built four “precooked” router setups and offers them in combination with a fifth option that allows you to build the router as you like. Take that fifth option, Custom Configuration, and click Next to go to the Custom Configuration screen, as you see in Figure 6.31.

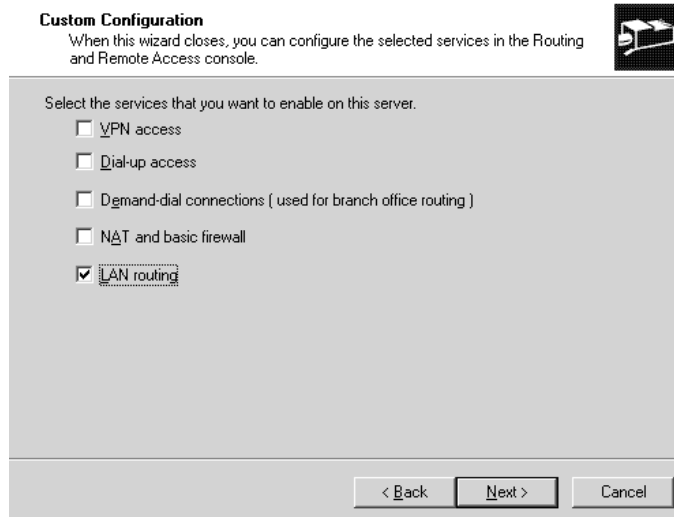

Check LAN Routing and Next and Finish to complete the wizard. Server 2003 will beep and ask you if you want to start the Routing and Remote Access Service; click Yes. You’ll then see a screen like Figure 6.32.

You have now successfully built your first router! As MEDITERREANEAN’s routing is turned on and because it’s directly connected to both the 199 and 156 networks, it will automatically route packets between the networks. Try it out if you like—put one computer on the same segment as

MEDITERRANEAN's 156.40.10.60 NIC, give the machine an address in that subnet, like 156.40.10.17, and set its default gateway (okay, we're being a bit lazy, but this is just a test) to 156.40.10.60. On the segment connected to MEDITERRANEAN's other NIC, attach a machine with an IP address of 199.34.57.21 and set its default gateway to 199.34.57.40. You will find that the two "outer" machines, 199.34.57.21 and 156.40.10.17, can ping each other.

**FIGURE 6.31**

Choose what the router will do

**FIGURE 6.32**

RRAS management console with routing enabled

One more point before moving on. You've already learned how to use `route add` from the command line to add a static route. RRAS lets you do that from the GUI as well. In the left panel, you see an object labeled IP Routing. Open it and you'll see three other objects, one labeled General, one labeled Static Routes and one labeled NAT/Basic Firewall. Right-click Static Routes and choose New Static Route, and you'll see a dialog box like Figure 6.33.

**FIGURE 6.33**

Dialog box for adding a new static route

Okay, so it’s not a very useful dialog box—I could probably type the `route add` command more quickly than I could open this dialog box and punch in its values—but at least it’s not another three-screen wizard that only asks one question, right?

**More Complex Static Routing**

By now, you’ve set up an IP router to move traffic from one subnet to another. It will *not*, however, route traffic among three or more subnets. Why not? Well, the default router software isn’t very smart. Look at Figure 6.34, and you’ll see what I mean.

**FIGURE 6.34**

An intranet with three subnets

Here, you see an intranet with just three subnets: 200.200.1.0, 200.200.2.0, and 200.200.3.0. For ease of discussion, let’s call network 200.200.1.0 “network 1,” 200.200.2.0 “network 2,” and 200.200.3.0 “network 3.” The network 1 to network 2 router, machine A, has addresses 200.200.1.1 and 200.200.2.40, and the network 2 to network 3 router, machine B, has addresses 200.200.3.75 and 200.200.2.50.

Once you turn on IP routing in machine A, it's smart enough to be able to route packets from network 1 to network 2 and packets from network 2 to network 1. But if it receives a packet from network 1 intended for network 3, it has no idea what to do about it.

Machine B has the same problem, basically. It knows how to go from network 2 to network 3 and from network 3 to network 2, but it has no idea how to find network 1.

How do you solve this problem? Either with static routes or with RIP. The best answer is probably to put the RIP router on both machine A and machine B, and they will end up discovering each other's routes through the RIP broadcasts. But how would you tell machine A how to find network 3 and how would you tell machine B to find network 1? With static `route add` commands.

On machine A, tell it about network 3 like so:

```
route add 200.200.3.0 mask 255.255.255.0 200.200.2.50
```

(Or, if you're feeling GUI, use RRAS.) You're saying to this machine, "In order to find network 200.200.3.0, use the IP address 200.200.2.50; it's attached to a machine that can get the packets to that network." For the sake of completeness, you might add the "metric 2" parameter to the end.

On machine B, tell it about network 1 in a similar way:

```
route add 200.200.1.0 mask 255.255.255.0 200.200.2.40
```

Remember that in both cases the "mask" information says, "I'm giving you information about a subnet, but the mask says how useful the information is." And if you want the router to *remember* these routes through reboots, don't forget the `-p` option to make the route permanent.

## Using Server 2003 as an Internet Gateway/Router

Thus far, we've talked about networks that talk to one another and that are somehow connected to the Internet. Now let's see *how* to get your network connected to the Internet, and where Server 2003 can fit in. There are a few ways to do this:

- ◆ You could dial in to the Internet with a standard modem from a Server 2003 and then use a built-in service called Internet Connection Sharing to share Internet access to all of the systems in your network.
- ◆ You could connect to the Internet via a persistent, high-speed connection like cable modem or DSL and share that connection with Internet Connection Sharing.
- ◆ You could do either of the above and instead of Internet Connection Sharing you might use Network Address Translation, another routing option on Server 2003.

You'll see how to do these in the next few sections. But before we get too heavily into this, let me offer a bit of advice: you may not truly *want* to use your server as a LAN/WAN router. If possible, this is a job for a dedicated device. (You know—one without a rotating hard disk that could develop problems with its bearings or a snazzy graphics card that could fail.)

I first figured out how to make a computer with an Ethernet card and a modem into a LAN/WAN Internet router back in 1992, when everything with the name "router" cost thousands of dollars and inexpensive persistent Internet connections like DSL and cable modem were just a fantasy of a technofuture. But that's all changed tremendously by now. My PC-based routers—which first ran OS/2, then ran NT 3.5 and 3.51—were prone to all of the unreliability that *anything* PC-based suffers from, from

varying degrees of software reliability to, again, problems with hard disks and video cards. But they were still cheaper than shelling out the price of a small car to buy a Cisco router at the time.

But that's slowly changed. By the mid-'90s, we were able to replace our NT router box with the Compatible Systems mr900i, a terrific box that I picked up for \$850. It was easy to manage, came with a nice Windows-based router management program, did RIP, was much cheaper than buying a Pentium and a copy of Server 2003, and was as fast as the wind. It only connected via modem, but that worked fine for our needs at the time. On later networks, I've used the Lucent Pipeline router, another quite good product in the \$550 to \$2000 range, which includes an optional security package to turn the router into a firewall-like device. In another network, I've used the Cisco 1602, at a cost of about \$1500, if I recall rightly.

But nowadays, there is no need at all to even think about spending more than \$200 to share a single IP address, whether acquired with dial-up or via cable modem or DSL. Firms like Dlink, Linksys, and Lucent make some terrific devices that act as LAN/WAN router, offer network address translation, firewall protection, and even sport an easy-to-use Web-based control interface. Some even do wireless. Now, understand that these will only work if you're sharing *one* IP address—devices for sharing more IP addresses are more expensive—but even the expensive multi-address devices (like the Cisco 1602 that I mentioned) are still faster, cheaper, and more reliable than a Windows-based router.

Why, then, do I include the following section, where I show you how to do all of these routing tasks with Windows Server 2003? Because sometimes you just have a system lying around and it doesn't cost you anything, because you've already paid for it; in that case, you might want to use it as a router. Or because you have some very specialized routing task that you want to handle, and 2003 systems are naturally more flexible than a dedicated special-purpose device. Or you might want to sit down and simply "do it yourself," as I initially did—it was a great way to learn IP routing.

## WAN Connection Options

Take a look at Figure 6.35 to see how we'll get your internal network connected to the Internet using Server 2003.

**FIGURE 6.35**  
LAN/WAN router  
overview diagram

To the left in Figure 6.35, you see your company's local area network connected to the Server 2003 machine that will act as the gateway server. Your computer has two network connections, as do all routers: an Ethernet card that connects it to your internal network, and then some kind of WAN connection to your Internet provider.

The most common kinds of WAN connections are

- ◆ A dial-up modem, offering a connection speed of up to 56Kbps
- ◆ An ISDN modem, offering a connection speed of up to 144Kbps
- ◆ A cable modem, with speeds in the megabit per second range
- ◆ A DSL modem, with cable-like speeds
- ◆ Your "WAN" connection to the Internet might actually be a LAN connection, as you might be a small group inside some larger company—for example, you might be setting up a training room inside your firm and want to separate your training room's network from the corporate network.

**NOTE** *In every case, I'm going to assume that you get just one routable IP address from your ISP and that you'll use some kind of NAT/PAT-like system to share it by giving the PCs in your intranet nonroutable addresses. If you're getting more than one address from your ISP then you'll probably get a dedicated router of some kind from them to do the job; it normally doesn't make sense to use Windows servers in that event.*

People tend to freeze up at the WAN connection part, expecting some insurmountable complexity. But it's not too bad.

Modem and ISDN connections are dial-up connections, not continuous connections. If you intend to host any Internet servers on your local network, such as if you want to run your own DNS, Web, FTP, or e-mail servers, then your network needs a *persistent* connection; it must be connected to the Internet 24 hours a day, 365.24219878 days a year (to be nearly exact, that is).

**NOTE** *That's an important point: if you're planning on running a server that offers information to the Internet, then your Internet connection must be persistent, and you need to ensure that you have the same IP address from your ISP constantly. Servers are no good unless people can find you, and unless you have the same IP address all the time and are connected to the Internet all the time, they won't be able to find you.*

Dial-up is a pain for building consistent connections because it's hard to keep up and connected. Years ago, when I had my company connected to the Internet on a shoestring budget, I connected our network to our ISP with a 14.4Kbps modem. I used a "flat-rate" phone account, one that cost \$25 a month with no charges for local calls. The call to the ISP was local, so I figured I'd just dial up and not hang up. Essentially, I figured, \$25 a month bought me a moderately noisy 14.4K dedicated line to the Internet—good deal, right?

It was a constant pain, and let me try to convince you not to try it for your routed Internet connection. First of all, the phone company computers go around and periodically disconnect any dial-up connection that's been up and running too long. Second, most ISPs think *fault-tolerant* refers to their belief that customers will tolerate the ISP's faulty infrastructure, so many ISPs end up rebooting their systems periodically, which kicks anyone off the modems and drops the dial-up connection.

Back in 1992, when I had the 14.4 connection running, I had to establish the dial-up connection myself, and when the connection would drop periodically, I'd have to reestablish it with a few commands at the router. You'll see that RRAS has a feature called *on-demand dialing*, which is supposed to sense whenever anyone on the local network needs to get to the Internet, and when the Server 2003 router senses that need, it dials up the Internet. It *sounds* as if this might be the way to ensure that a dial-up connection dials up and stays up: Why not just run a simple batch file that does a ping to somewhere out on the Internet and use the Scheduler service to automatically run the batch file every 20 minutes or so? Seems like a great idea, but in my experience the demand dialer has trouble figuring out whether the modem is currently connected. I've had RRAS tell me that a demand-dial connection was up and running when I could clearly see that the "carrier detect" light on the modem was off.

ISDN offers some of the same problems with the extra fact that you usually get charged by the minute for ISDN connections, which can run up the meter fairly quickly.

The answer for many may be a dedicated connection called a *frame relay* connection. You're charged a flat monthly rate for it, depending on things like how far away you are from the ISP and how fast the connection is. In my experience, a fairly low-speed, 56Kbps frame relay runs around \$150–\$200 per month. That's just the telco charges for the frame, however; the ISP will levy additional charges to rent you the IP addresses, route your packets, and whatever other services they offer. But you probably will not connect your frame relay directly into your Server box directly; you'll probably only be using frame relay if you've leased a group of IP addresses from your ISP and, as I've suggested, in that case the ISP will probably strongly recommend that you let them install a dedicated router device on your site.

Both cable modem and DSL are very easy to set up in that they connect to your gateway PC using a simple Ethernet connection—nothing new to learn there.

## Collect the Pieces and Get Started

If you're connecting with cable modem or DSL then have this information beforehand:

- ◆ If you've arranged for a static IP address, have the IP address, subnet mask, and address of the default gateway, and
- ◆ The address of any DNS and e-mail servers on the ISP's network.

If you're dialing in, then get those pieces of information, but also get the number to dial into the ISP. If you're dialing in with ISDN, then be sure to talk to the ISP beforehand and get the SPIDs. . . no two ISPs seem to do ISDN the same way. Once you've collected that information, get started by doing the following:

- ◆ Get network cards in all of the local machines and in the server.
- ◆ Install the TCP/IP protocol on them. Set their TCP/IP stacks to get IP addresses from DHCP; you'll see more about that later.
- ◆ Attach the WAN connection device—modem, ISDN, DSL modem, cable modem, or whatever—on the gateway.

From this point, you've got a few different options to connect your intranet to an ISP; we'll take them one at a time.

## Lower-Cost LAN-to-WAN Routing with Internet Connection Sharing

As I've already said, the main aspects of this LAN/WAN connectivity are that:

- ◆ The only machine on the network with a “regulation,” IANA- or ISP-issued IP address is the gateway.
- ◆ The other machines have nonroutable addresses.
- ◆ All of the “heavy lifting,” routing-wise, is being done by the gateway computer. In fact, the ISP has no idea whatsoever that all of those other computers are accessing the Internet via the gateway.

Recall from our earlier “routing the nonroutable” discussion that this functionality is generically called network address translation (NAT) routing and was until recently fairly expensive to implement, requiring special routers. But ever since Windows 98 Second Edition, Microsoft Windows OSes have included the ability to act as a NAT router. (Even XP or 2000 Pro can do it.) Called Internet Connection Sharing, this will work on any kind of Internet connection, whether it's a modem, ISDN, cable modem, DSL, or whatever.

**NOTE** *Just to be on the safe side, check your “use agreement” with your ISP. Some ISPs specifically forbid any kind of sharing.*

Basically, there are just four steps to make this work:

1. Attach all of your internal computers together in a network.
2. Connect one of the computers (the one running ICS) to the Internet either via a modem or another Ethernet card. And yes, that's *another* Ethernet card—you can't put the Internet connection on the same segment as the connection to the internal, nonroutable machines. So if you wanted to share a cable modem or DSL connection with your Server system, then you'd have two Ethernet cards in your Server: one connected to your DSL/cable modem, and the other connected to your internal network.
3. You'll now have two connections on the ICS computer—one to the local Ethernet connecting the internal nonroutable machines, and one to the Internet. On the Internet connection, turn on ICS.
4. Tell all of the internal, nonroutable computers to automatically get their IP addresses (which they'll end up getting from the ICS machine), then reboot them.

Once you do all that, the internal systems will have nonroutable IP addresses in the range 192.168.0.2–192.168.0.254—but they'll be able to access the Internet because of ICS's abilities.

**WARNING** *Before starting, ensure that Routing and Remote Access Services are not running on this computer. ICS will refuse to run on a system with RRAS enabled.*

### Step One: Connect the Internal Network—and Meet APIPA

This is easy. Just put an Ethernet card in every computer in your home, small business, or whatever set of machines you need ICS for. (I'm kind of hoping you've already done this, or it's reasonable to wonder why you're reading this book!) When configuring the TCP/IP settings as you saw back in Figure 6.11, don't bother punching in any values; instead, just click the radio button labeled Obtain an IP Address Automatically.

Now boot the systems and do an `ipconfig /all`. You'll find that they all have IP addresses in the range between 169.254.0.1 through 169.254.255.254. Where did *those* addresses come from? They're a feature of Microsoft networking since Windows 2000 called Automatic Private IP Addressing (APIPA).

The idea in most IP-based networks, as you'll see in the next chapter, is to set up a kind of server called a Dynamic Host Configuration Protocol (DHCP) server somewhere on the network. That DHCP server then automatically supplies IP addresses to all systems on the network, freeing you from having to walk around to every system and punch in a different IP address. But what happens if you have a system that (1) expects to find a DHCP server and therefore doesn't *have* a static IP address, but that (2) finds itself on a network without a DHCP server? Well, under NT 4, that system would basically just disable its TCP/IP software, and running IPCONFIG would just show your NIC with an IP address of 0.0.0.0. Under Windows 2000 and later OSes, however, it randomly assigns itself an address in the range of 169.254.0.1 through 169.254.255.254, checking to make sure that no one else has this address. Granted, it's not a terribly useful way to get IP addresses on important systems like Web servers, but for a small network that's not intending to talk to any other network, it's not a bad answer. But it's only a temporary answer, as we'll see, because ICS actually includes a basic, no-configuration-necessary DHCP server inside it, and so when we get ICS running, then its DHCP server will hand out more useful addresses to the machines on your internal network—your “intranet.”

### Step Two: Get Connected to Your ISP

The next step is just to get connected to your ISP. How you do that depends on whether you're dialing up or connecting via some high-speed connection like cable/DSL modem or directly via a corporate network. We'll look at how to get connected via dial-up first.

#### GET CONNECTED TO YOUR ISP (DIAL-UP)

**NOTE** *If you connect via DSL or cable modem, then skip this section and go to the next, “Get Connected to Your ISP (Cable Modem/DSL).”*

As has been the case with Microsoft OSes since Windows 95, you tell your system to dial up to an ISP by creating a Dial-Up Connection object or, to use Microsoft's phrase, you will create a *connectoid*. (Where they come up with their “wordoids” is beyond me, although I *do* find the tech world's willingness to coin new phrases at a hatdrop—see, I can do it too—interesting.)

Click Start/Control Panel/Network Connections/New Connection Wizard and Server will start a new wizard; click Next to get past the inevitable initial screen and you'll see something like Figure 6.36.

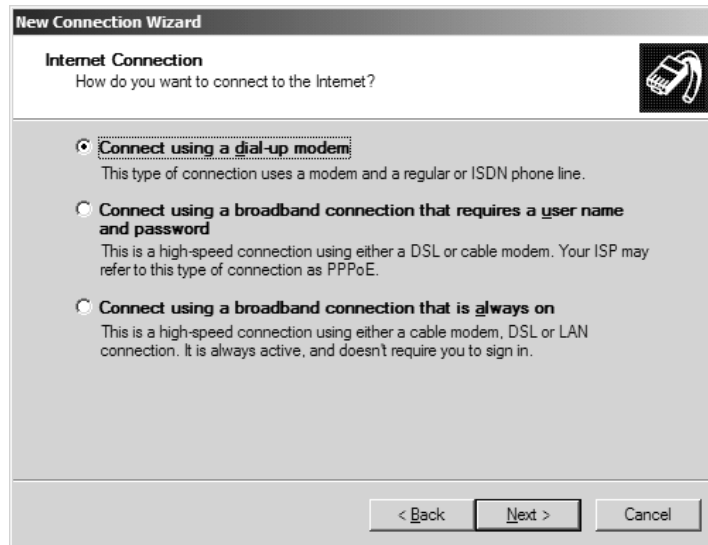

Click Connect to the Internet and Next, and you'll see a screen like Figure 6.37.

**FIGURE 6.36**

Creating a new connection

**FIGURE 6.37**

How to connect?

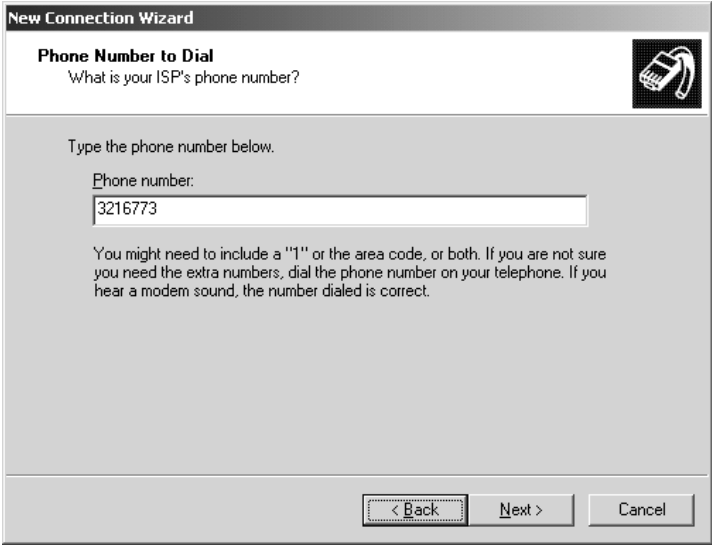

Tell the wizard that this is just a modem dial-up to the Internet by clicking the radio button labeled **Connect Using a Dial-up Modem** and click **Next**. You'll then see a screen like Figure 6.38.

This asks for your ISP name, but don't think that Server will then go out to the Internet (as if it could at this point!) and download info on this ISP; this is really just a label for this connectoid. Fill in a descriptive name and click **Next** to see something like Figure 6.39.

**FIGURE 6.38**  
Name that  
connectoid

**FIGURE 6.39**  
Number to dial

Fill in the number to dial for your ISP and click Next to see Figure 6.40.

Server 2003 wants to know which profiles should use this. As we're just building a router, and routers don't much care *who's* routing through them, set this to *Anyone's Use* and click Next. You'll see Figure 6.41.

**FIGURE 6.40**

Who gets to use this?

**New Connection Wizard**

**Connection Availability**  
You can make the new connection available to any user or only to yourself.

A connection that is created for your use only is saved in your user account and is not available unless you are logged on.

Create this connection for:

☒ Anyone's use

☐ My use only

< Back   Next >   Cancel

**FIGURE 6.41**

Login information

**New Connection Wizard**

**Internet Account Information**  
You will need an account name and password to sign in to your Internet account.

Type an ISP account name and password, then write down this information and store it in a safe place. (If you have forgotten an existing account name or password, contact your ISP.)

User name: Joeblow

Password: .....

Confirm password: .....

☒ Use this account name and password when anyone connects to the Internet from this computer

☒ Make this the default Internet connection

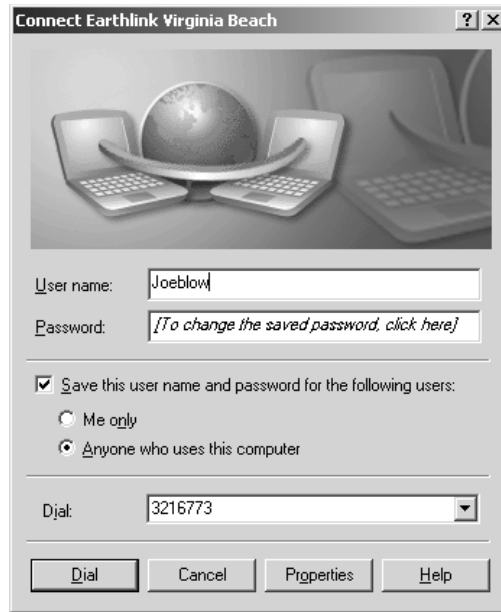

☐ Turn on Internet Connection Firewall for this connection

< Back   Next >   Cancel

Finally, you need to tell the system what user name and password to employ to get onto the ISP. Fill that in, click Next and Finish and you've got your connectoid, which will open automatically, looking something like Figure 6.42.

**FIGURE 6.42**

Initial connectoid

Click the Dial button to check your connectoid. Make sure that you can ping places on the Internet both by IP address and by name. Remember, *first* ping with IP addresses to ensure that routing is working. *Then* ping by DNS names, like `www.minasi.com`. If pingging by IP address works but pingging by DNS names does not, then the routing is working fine—the problem’s with DNS. Then also check that you can ping inside your internal network, your intranet. Again, we’re just worried about routing here, so just ping the internal systems by their IP addresses.

Hooked up and pingging okay? Great—then skip down to “Step Three: Turn ICS On.”

### GET CONNECTED TO YOUR ISP (CABLE MODEM/DSL)

If you connect to the Internet via DSL or cable modem, then you won’t be creating one of those connectoids. Instead, as I said earlier in the chapter, you usually connect to a DSL/cable modem with a regular old Ethernet card. Typically, then, all you have to do is install an Ethernet card in your system—remember that it will be a separate Ethernet card from the one that connects to your other computers—and then run a standard Ethernet cable from your DSL/cable modem to the Ethernet card.

I said “usually” because you might choose instead to connect your DSL/cable modem to your PC with a USB connection. I recommend against this for reasons that I mentioned earlier. And once in a great while, you might have to load an extra bit of software on your computer to be able to communicate with your cable modem provider. I’ve never seen this myself but I’m told that some DSL modem companies make you install some extra piece of software that looks a bit like a modem dialer program so that you can log onto their cable modem network. (I’m *hoping* you don’t have to use that kind of connection because honestly I can’t advise you about how to share it, as there’s no guarantee that such a nonstandard LAN/WAN connection would work with ICS.)

In most cases, though, it's simple: put the Ethernet card in your PC, connect it to the DSL/cable modem, and turn the computer on. A DHCP system at the DSL/cable provider will give your PC a routable IP address. Note that this will probably be an IP address that changes from time to time, so you may have to approach your provider about a static—that is, unchanging—address if you want to host Internet-visible services like Web or mail.

Now try it before going any further. Make sure that the Server 2003 machine attached to the DSL/cable modem connection can surf the Net without any trouble. And check that its other NIC also has a 169.254.x.x address, as there's no DHCP server on your intranet segment. An `ipconfig /all` should show one NIC with a routable address and another with a 169.254.x.x address. You should also be able to ping the computers inside your intranet.

At this point, you might be tempted to put a hub on that cable modem or DSL connection and then just hang your other internal PCs off that hub. *Don't*. At least, not if you want ICS to work.

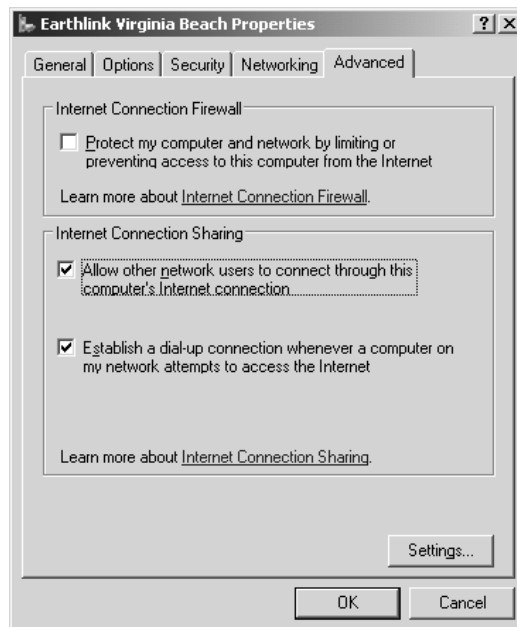

### Step Three: Turn ICS On

If you haven't already done it, go to Network Connections (Start/Control Panel, then right-click Network Connections and choose Open), and you'll see a dialog box like the one that you saw back in Figure 6.9, Network and Dial-Up Connections. You'll see at least one Ethernet connection, probably labeled Local Area Connection, which represents the NIC attached to the internal network. You'll also see an object representing your connection to the Internet—if you dial up with a modem then it'll be a Dial-Up connectoid, or if you're using DSL or cable modem it'll be another Local Area Connection object.

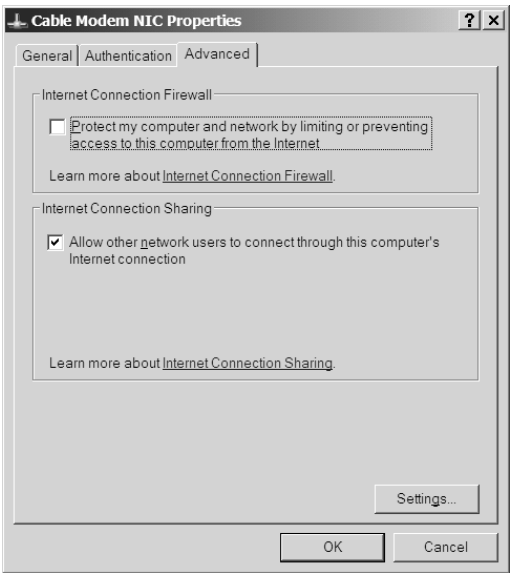

Right-click that object and choose Properties, then in the resulting property page click Advanced. The Advanced page for a connectoid contains different information than the Advanced page of a connectoid for a network card, so you'll either see something like Figure 6.43 or 6.44.

**FIGURE 6.43**

Advanced properties for a dial-up connection

**FIGURE 6.44**  
Advanced properties  
for a network card

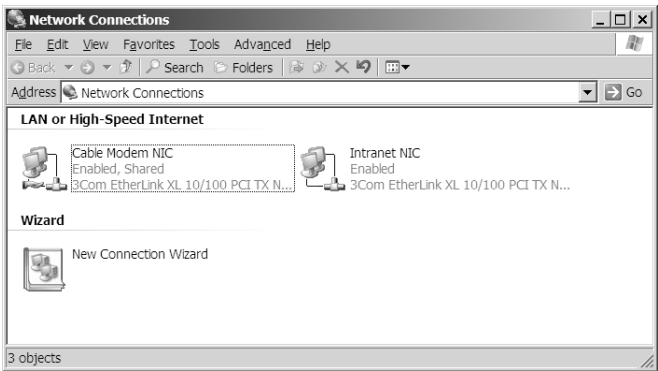

In those figures, check the box labeled Allow Other Network Users to Connect through This Computer's Internet Connection, and click OK. When you click OK to clear the properties page, you may get a confirmation message saying something like this:

When Internet Connection Sharing is enabled, your LAN adapter will be set to use IP address 192.168.0.1. Your computer may lose connectivity with other computers on your network. If these other computers have static IP addresses, you should set them to obtain their IP addresses automatically. Are you sure you want to enable Internet Connection Sharing?

I say “may” because sometimes it pops up and sometimes it doesn't; I've not figured out what makes it appear or not.

Click OK and you'll return to Network Connections, where you'll see that your connectoid or NIC now have the status “shared” in addition to “enabled,” “connected,” or the like. For example, the shared cable modem connection produces a Network Connection window that looks like Figure 6.45.

**FIGURE 6.45**  
Network  
Connections with  
ICS enabled

## Step Four: Configure the Intranet Machines

You're now ready to share the wealth, Internet connection-wise. You have already configured your systems in your internal network, your intranet, to get their IP addresses automatically. "Automatically" means that they look for a DHCP server and if there is one then they get their IP addresses from that DHCP server. If there's no DHCP server—which has been the case until recently on your intranet—then they just give themselves APIPA addresses in the 169.254.x.x range.

Now that ICS is running, your network now has a DHCP server, as ICS includes a simple DHCP server. You need to go tell your systems on your intranet to try to find a DHCP server again and, while there are several ways to do that, the simplest is to just reboot. But before you do, check the machines—it appears that XP systems are smart enough to detect that there's now a DHCP server in residence, and so you'll probably find that they've *already* got an address. The client systems will all have addresses in the 192.168.0.x range.

## What About the Firewall?

You probably noticed back in Figures 6.43 and 6.44 the check box referencing something called the Internet Connection Firewall (ICF). It's a very simple firewall, but better than nothing. It basically rejects any data originating out in the public Internet... *unless* that data from the public Internet is a response to a request from your computer.

Suppose, for example, that my computer tried to ping your computer. A ping is just a packet of data that asks your computer to respond, as you've seen. Your computer would not respond to the ping, as the firewall would see the incoming ping packet ("ICMP packet" is the more accurate phrase) and ask, "Does this answer some question that we asked someone on the Internet?" Of course, it wouldn't, as I initiated the conversation, not you.

In contrast, suppose you pinged *me* from behind your firewall. (Assume I don't have a firewall, and have a routable address on the public Internet.) Your ICMP request comes to me and my computer responds with an acknowledgment packet. That acknowledgment goes to your computer and is examined by ICF, which says, "Hmmm...why is this guy sending me data? IS HE TRYING TO HACK ME???" As ICF has been keeping track of all of the outgoing traffic, however, it says, "Ah, now I see...this is just an answer to our ping," and so it lets it past. Such a firewall type is called a "stateful" firewall, as it keeps track of the "state" of conversations on the Internet.

If you decide to use ICF, then you should be aware of a few things. First, don't ever turn ICF on *inside* your network, particularly on servers. Remember, ICF rejects any incoming data that isn't a response to some request; but servers don't *make* requests, they *answer* requests. (Well, basically.) So if you had your Web server behind ICF then everyone who tried to connect to your Web server would be rebuffed. You'd have a *secure* server, all right, just not a very useful one. Additionally, servers in a domain do a lot of back-and-forth communication for authentication, and ICF would block a lot of that communication, which would render any ICFed system unable to participate in the domain. ICFing a workstation would make it impossible to offer its user remote control, use backup agents, and the like. So if you are going to use ICF, only use it on a machine that stands between your intranet and the Internet—what firewall types call your "edge" machine.

I just suggested that ICF would make a Web server useless, but that's not 100 percent true. If you had a Web server directly connected to the public Internet and you wanted some basic firewall protection for it—a quite good idea—then ICF's not a bad idea. But how do you keep it from turning your Web visitors away? Back on that Advanced tab, click the Settings button and you'll see check

boxes that tell ICF to pass traffic for particular kinds of servers—Web, FTP, e-mail, etc. You can even open particular ports if you know their numbers.

### **Beyond ICS: Setting Up Network Address Translation (NAT) on Server 2003**

ICS is great, but what if you want more? On the one hand, ICS lets you easily connect a bunch of internal machines to the Internet via one routable address—it's quite literally a matter of a click or two and you're done. But you can't change the range of addresses that ICS's mini-DHCP server gives out. Nor can you facilitate *incoming* traffic—ICS is basically a simple port address translation router. Any system inside your network can initiate an outbound conversation, but outside systems on the public Internet can't initiate an incoming conversation. Furthermore, ICS really only makes sense if you only have one routable IP address. That won't always be true—and so you'll sometimes want to configure network address translation rather than ICS.

For simplicity's sake, let me assume that your Internet connection is via a NIC of some kind—DSL, cable modem, or perhaps you've built an isolated network within your Internet-connected business—rather than a dial-up connection. For example, consider a training lab: Most medium- to large-sized companies have a room or two filled with a bunch of networked computers used for teaching classes. Those computers typically get nonroutable addresses but sometimes need outside Internet access, and so corporate IT departments usually need to set aside a routable address or two for the training lab and then need to somehow share those routable addresses with the training lab's non-routable addresses. Most places use a Cisco router to accomplish that sharing, but there's no reason why a Server 2003 server that's already in the training lab can't do that job and save the training department the cost of the Cisco router.

And, before we go any further, let me clarify that the machine sitting between the private non-routable network and the public Internet is a Server 2003 machine. It *can't* be an XP Professional machine, as Pro only offers ICS—no NAT. For the sake of this explanation, let's call that in-between box *Between*. As you've already read, looking in Network Connections will show two Local Area Network connection objects.

As you've also already read, enabling ICS in this scenario is simple. Just open Network Connections, find the NIC that's connected to the Internet and choose Properties. In the properties page that results, click the Advanced tab, check the box labeled Allow Other Network Users to Connect through This Computer's Internet Connection, click OK, and then click Yes to the resulting dialog box. No news here—you just read how to do that. After a brief delay, ICS will start working. The NIC attached to the private network now has the static IP address 192.168.0.1. Your Internet-attached computer now runs a simple kind of DHCP server that hands out IP addresses in the private network range of 192.168.0.0 through 192.168.0.255. Set the computers on the internal network to look to DHCP for their IP addresses and reboot them, and they will get addresses on the 192.168.0.0 network and will look to the 192.168.0.1 system as their default gateway. Try a ping from any system on the internal network and you'll see that network now has Internet connectivity.

### **ICS LIMITATIONS**

But ICS is limited in several ways. First of all, you cannot configure anything about the DHCP server built into ICS. Second, while any system on the internal network can access systems on the Internet, it's not possible for systems on the Internet to access the systems on the private network—if I were to ping your system at (for example) 192.168.0.100 from a computer on the Internet, I would not get

a response from your system. That could be good from a security point of view, and so many people might not see this as a disadvantage at all.

But suppose you had a Web server on an internal machine hosting a terrific site that you wanted to offer to the public Internet. And suppose a *different* machine, also on the internal network, ran a mail server that, of course, won't be much good unless it can both send mail and receive mail. You could, of course, also just install the mail server and Web server software on Between, but you might not want one box acting as router, mail, and Web server—to make that work you'll have to abandon ICS and instead use NAT and its support of “inbound” connections. But NAT's a bit more complex to set up, so let's start out by duplicating ICS's functions, then we'll add inbound connections.

### RRAS/NAT SETUP TO DUPLICATE ICS

Start off by disabling Internet Connection Sharing on Between; let me start this explanation by first using NAT to simply reproduce what ICS does. *Then* we can add on it.

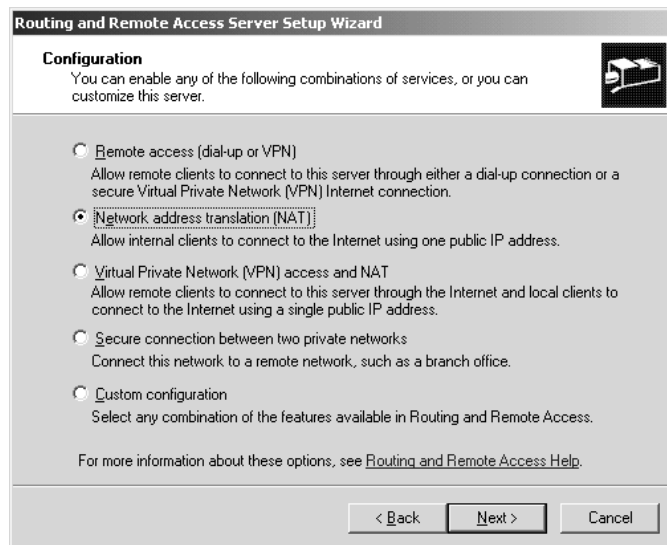

For ease of explanation, name the NIC attached to the public Internet Cable modem NIC. Name the NIC attached to your intranet Intranet NIC.

Assign the address 192.168.0.1 to the Intranet NIC. (You needn't use *that* IP address in general—I'm just duplicating ICS's functionality as closely as I can.) Next, 2003 requires that we enable our old friend Routing and Remote Access. I've walked you through RRAS a few times now, so I'll be brief:

1. Click Start/Administrative Tools/Routing and Remote Access.
2. You will see an icon representing your Server 2003 server system in the left panel of the MMC screen. Right-click it and choose Configure Routing and Remote Access, which starts the RRAS Setup Wizard.
3. Click Next to get to the first screen, labeled Configuration, as you see in Figure 6.46.

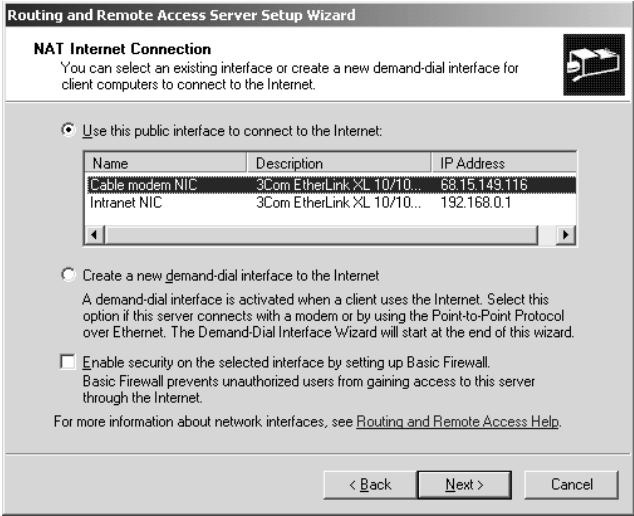

**FIGURE 6.46**

RRAS Configuration page

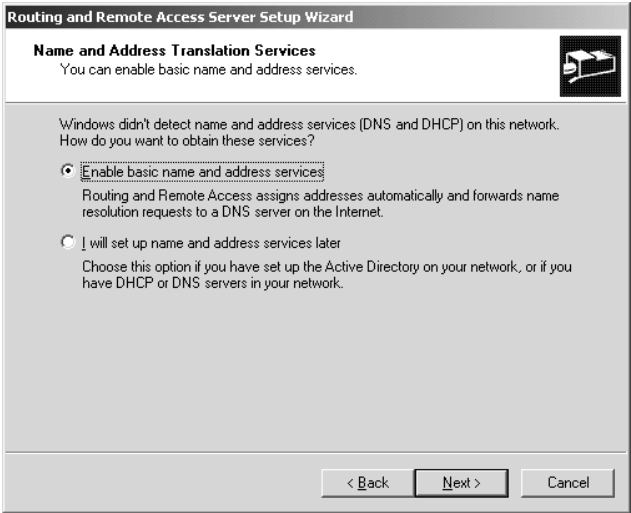

4. Choose Network Address Translation (NAT) and click Next to get to the NAT configuration screen in Figure 6.47.

**FIGURE 6.47**  
NAT connection

5. There's a lot going on in this panel. First, up top, the wizard wants you to tell it which NIC is attached to the Internet. It has guessed that the Cable modem NIC is, as it's got a routable address. If it guesses wrong in your case, then just click the NIC that *is* attached to the public Internet. Second, notice the Create a New Demand-Dial Interface to the Internet option. You'd use this if you wanted to use a modem to attach to the Internet. I'm not going to walk you through that step-by-step because if you click that radio button then the process looks pretty much identical to what you saw in the earlier ICS discussion. Finally, at the bottom, there's a check box to turn on a simple ICF-like firewall. Again, turn it on if you like—but only on systems that truly face the public Internet directly. If you were just creating an internal training network inside your company and the “public” NIC were in fact just a NIC on your corporate intranet, then you probably wouldn't want a firewall enabled. Once you've got this as you'd like it, click Next to see something like Figure 6.48.

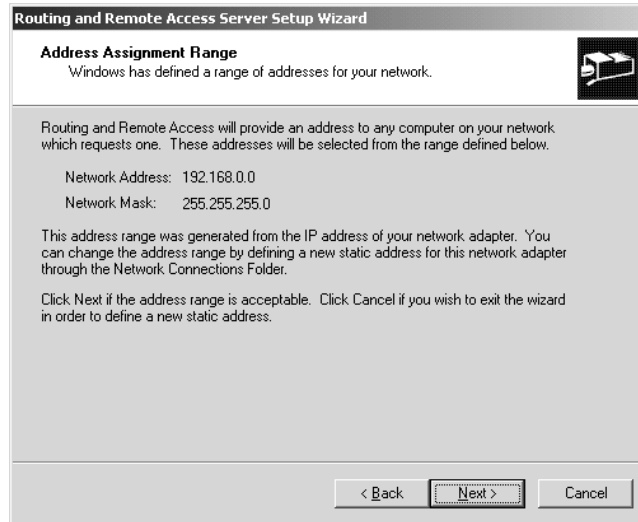

**FIGURE 6.48**  
How to handle DNS  
and DHCP

6. NAT under 2003 works a bit differently than it did under 2000—for the better, in my opinion. The basic firewall is a nice touch, but the ease of configuring NAT is just as welcome. Click Enable Basic Name and Address Services, and click Next to tell NAT what addresses to use, as you see in Figure 6.49.

**FIGURE 6.49**

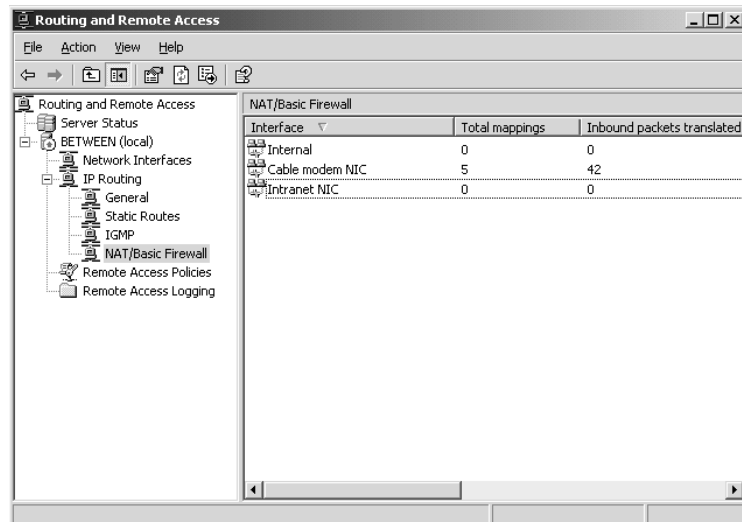

NAT sets up an address range

7. Another nice touch—NAT just looks at the address that you set for the Intranet NIC and says, “Well, I guess he wants me to use the subnet that address fits in.”
8. With that, click Next and Finish and your NAT router is working. RRAS will look something like Figure 6.50.

**FIGURE 6.50**

RRAS after NAT setup

### BEYOND ICS I: PORT MAPPING

Now we've duplicated ICS's functionality in NAT. Let's take it further.

Discussions of sharing a single routable address, or a small number of routable addresses, with a larger number of machines on a *nonroutable* network usually have DSL or cable modem connections in mind. But that's not the only potential "target market," so to speak, for NAT. As you've read elsewhere in this chapter, sharing a routable address via ICS only allows the internal (nonroutable) computers to initiate conversations to the outside Internet, not the reverse. For example, an internal computer could surf an external Web site; but if you were to set up one of the internal 192.168.0.0 computers as a Web server, then it would be impossible for a computer on the routable public Internet to surf that Web server. Is there a way around this? Well, if your internal-network-to-Internet connection is just a machine running ICS, then you're stuck—but with NAT, you can easily arrange matters so that external computers can connect to resources on your internal network.

How you'd let the Internet access an internal Web server (or mail server, FTP server, or whatever else; I'll stick to Web servers here for simplicity, but making any type of server available works the same) depends crucially on one question: How many routable IP addresses do you have available? Let's first consider the case wherein you only have one routable IP address available. In case it's not obvious, you have no choice about what to do with that address: You've got to assign it to the computer acting as the router (which, for simplicity, I'll just call the router).

One way to offer a public Web server in this one-address case would be, of course, to set up IIS on the router. But you might not want to do that, either because NT (and therefore 2003) has never been all that good at doing a lot of different things on one machine, or perhaps because you need a system with more horsepower to run a complex site.

Just to make this explanation concrete, let's arbitrarily assign a few IP addresses. Let's say that the router has a routable IP address of 68.15.149.116, and that its internal nonroutable address is 192.168.0.1. Let's suppose the computer on the internal network that's running the Web server is on the internal nonroutable address 192.168.0.51. That Web server needs a routable address to be visible to the public Internet, but you've already used your only routable address on the router—what to do?

NAT allows you to redirect a particular port from the router to a particular port on a particular computer on the internal network. Web connections usually come into a Web server on port 80, so you just tell the router to refer any incoming communications on the router's port 80 to port 80 on 192.168.0.51. And as I promised, I'll show you how to set up that Web server on 192.168.0.51...but I need to take an intermediate step first.

To tell NAT that you're going to map a particular port to a particular internal address, open RRAS and open the NAT/Basic Firewall object in the left pane. In the right pane you'll see three objects: your intranet NIC, the NIC connected to the Internet (Cable modem NIC, in our example), and something called Internal. Right-click the NIC connected to the Internet and choose Properties, and then click the tab labeled Services and Ports. You'll see a screen like Figure 6.51.

This page lists the most common servers that you'd probably want to build for your network—mail servers, remote control, VPNs, just about anything you'd want.

Notice I said "*just about*." For some reason, a regular old Web server isn't there. We've got to build it as a custom port map, which is why I'm leaving it for a bit later. Right now, let's say that the machine at .51 is a POP mail server. Check the box labeled Post-Office Protocol Version 3 (POP3). That raises a dialog box called Edit Service, as you see in Figure 6.52.

**FIGURE 6.51**

Mapping ports to particular systems in NAT

**FIGURE 6.52**

Assigning an internal address for the port

All you need do is to punch in the server's IP address in the "private address" field, and click OK. In a nice touch, this causes the basic firewall to open that port, if you've got the basic firewall enabled.

Now let's punch a "custom" hole in the NAT router for our Web server. Back at that Cable modem NIC properties page (which will have a different name, recall, if you didn't name the NIC attached to the public Internet Cable modem NIC) and the Services and Ports tab that you saw in Figure 6.51, click Edit to see a dialog box like Figure 6.53.

**FIGURE 6.53**

Defining a  
Web server

It's very similar to the dialog that you saw in Figure 6.52, but you have to add a name (Web Server), specify an incoming and outgoing port (80 in both cases, as you see in the figure) and finish up by telling NAT which internal address to map the port 80 traffic to.

To review what I'm trying to accomplish here: A request comes in to the Web server at 68.15.149.116 or, in other words, a request comes in to 68.15.149.116:80, as 80 is the HTTP port. What I want NAT to do is move the request over to the machine addressed as 192.168.0.51, and address it to port 80 on that machine. When might I have set the incoming and outgoing ports to different values? In my experience, you *wouldn't* do it all that often, but if for some reason you wanted to set up the Web server at 192.168.0.51 on port 10000, then you'd fill in **10000** on Outgoing Port so that traffic from the Internet—which expects to do Web business on port 80—would get to the Web server.

#### **BEYOND ICS II: ADJUSTING ADDRESS RANGES AND FIREWALL OPTIONS**

But recall that one of my complaints with ICS was that it forced me to use the 192.168.0.x range. Can NAT do better? Sure. In RRAS, right-click the object labeled NAT/Basic Firewall and

choose Properties, then click the tab labeled Address Assignment and you'll see something like Figure 6.54.

**FIGURE 6.54**

Changing the internal address range

From this page you could change your range of internal addresses to anything you want. But if you do, then be sure that the static address that you give the intranet-attached NIC is on the same subnet as your address range! Also, if you have systems inside your intranet with static IP addresses, you can just click the Exclude button and specify them. Then the mini-DHCP server in NAT doesn't accidentally give those addresses to some other system on your intranet.

Finally, what if you initially turned off the firewall but then decide that you'd like it enabled? Open the NAT/Basic Firewall object in the left pane of the MMC and in the right pane you'll see an object representing the NIC attached to the Internet—Cable modem NIC, in my example. Right-click that and choose Properties, then click the NAT/Basic Firewall tab. It will look like Figure 6.55.

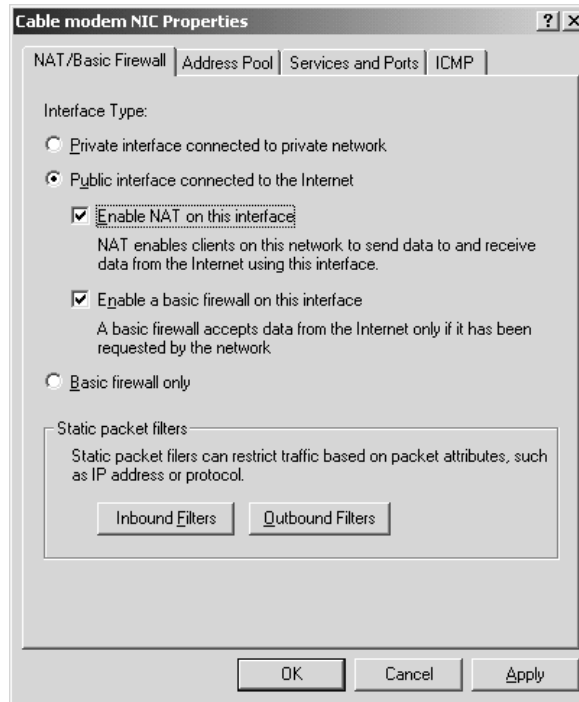

Just click Enable a Basic Firewall on This Interface, and you've got at least *some* protection from the bad guys.

### TROUBLESHOOTING ICS AND NAT

Sometimes you'll try to set up ICS or NAT and it doesn't work. Don't give up—fixing routers can be easy. Just be methodical. Consider that there are three components to any intranet-to-Internet routing system—the Internet, the gateway (the box running ICS, NAT, or whatever—the thing acting as a router), and the intranet (the machines inside your network that want to get to the Internet).

**FIGURE 6.55**

Turning the firewall  
on/off

First, check that the gateway PC can communicate with the Internet. Check this with a ping to an IP address, *not* a DNS address—check IP connectivity without confusing things vis-à-vis name resolution; for example, ping 206.246.253.1. Then do a ping to some location by its DNS address; for example, ping `www.minasi.com`. If these don't work, then either your connection to the outside world (cable, DSL, or whatever) has failed, or you've got something strange going on in your routing table that makes it try to route to the Internet via the internal network. If IP pings work but DNS pings don't, then check DNS.

Next, check that the gateway can communicate with the intranet. Ping systems inside your network, again by IP address and then DNS. Same approach here—check routing if it's an IP problem, DNS/WINS if it's a name problem.

Then check that the intranet systems can ping the gateway. As before, ping the IP address (the intranet side, 192.168.0.1, or whatever you set it to), then the name.

Finally, check that the intranet systems can ping the outside world through the gateway, by IP and by name. Using this simple methodology breaks down the problem into something tractable.

## Understanding IPsec

Basic garden-variety IP lacks security, and that's fine in most cases—if you're just visiting my Web page, then you really don't care much if anyone were to snoop on you, unless of course your boss had issued an edict against visiting my site. And it's possible but very unlikely that someone on the Internet, sitting on a computer between you and me, would take the time to somehow intercept the data that my Web site were sending your browser, modifying it before sending it to you so as to produce a falsified page.

But many communications *do* need security. If you were to visit my Web site to buy something online, then you'd want *that* communication secured. SSL solves that problem, but it's pretty much restricted to a Web-only protocol. If a company had two offices across the country from one another but used the Internet to connect a server in one site to a server in the other site, then the company would probably want to ensure that any communications between those two servers both couldn't be snooped upon and couldn't be modified along the way by evildoers. SSL wouldn't really be the answer for that.

Instead, another set of protocols called IP Security (IPSec) seek to provide a generic answer for securing IP-based networks. IPSec operates at the same layer as IP, rather than SSL, which, again, is an application-layer protocol. IPSec is also a necessary part of using the Virtual Private Network (VPN) protocol L2TP—you can't run L2TP without IPSec.

#### **IPSEC'S FOUR SECURITY OPTIONS**

IPSec lets you choose how secure a communication between two computers will be. Basically, it offers four levels of security:

- ◆ Block transmissions
- ◆ Encrypt transmissions
- ◆ Sign transmissions
- ◆ Permit transmissions to travel unchanged, without signing or encrypting them

Let's examine those in a bit more detail.

#### **Block Transmission**

This does just what it sounds like: It blocks transmissions. When you tell IPSec to "block" traffic from machine X to machine Y, then the IPSec code on machine Y just simply discards any traffic coming in from machine X.

Although this might seem at first blush to be kind of useless, if you think about it then you'll see that it isn't at all. In some senses, blocking traffic is the most extreme option for security, right? For example, my firm might have a competitor whose systems run on subnet 200.200.100.0, and I don't want them to be able to send me mail, visit my Web site, or communicate with my network in any way. (These could clearly be mortal-enemy types of competitors.) I could set up IPSec on my systems to block that subnet, just discarding any packets that arrive.

#### **Encrypt Transmission**

Here, I *want* to allow traffic to pass from machine X to machine Y, but I'm worried that someone will eavesdrop on the network connection between X and Y. So I tell IPSec to use a protocol called the Encapsulating Security Payload—and I'll bet you didn't need to be precognitive to guess that its acronym is ESP—to encrypt the traffic before putting it on the network. Snoopers will only see an unreadable, random-looking stream of bytes.

Notice how convenient it is that IPSec works way down at the network protocol layer—it can encrypt *anything*. Do you like the convenience of Telnet but hate that it sends its information in cleartext? Just tell IPSec that whenever machine X and machine Y are using Telnet to communicate that IPSec should use ESP to encrypt the communication. No modification required at all to the Telnet server or client.

When would encryption be useful? Perhaps you have a few machines inside your intranet that handle very sensitive information—payroll info or perhaps customer credit cards. The data might be kept on a machine named SQL1, and it might be entered and edited only from workstations WS1, WS2, and WS3. You might fear that an insider might set up a sniffer on the network to trap this traffic as it goes by, collecting privileged information. You can keep people from accessing SQL1's database in the first place with permissions, as you already know. But you can keep people from listening on the wire by creating IPSec policies on SQL1 that force it to encrypt any communications to and from WS1, WS2, or WS3, and you can create similar policies on those workstations.

Or, in another instance, suppose you had a server in Chicago and offices all around the country, containing workstations that need to access data on that server. Suppose also that the only way that the offices connect to Chicago is over the public Internet, and you're (rightly) concerned that running company data over the public Internet might not be the best idea, security-wise. You could create an IPSec policy on the Chicago server so that it will only accept encrypted traffic—it never accepts cleartext communications. You would then create IPSec policies on the workstations so that they only communicate with the Chicago server via ESP.

**NOTE** *And in case you're thinking, "What if that company had firewalls at every location—would IPSec work through a firewall?" The answer is yes. You must open UDP port 500 and permit protocols number 50 and 51.*

### **Sign Transmission**

In certain kinds of network attacks, the bad guys fool your computer into thinking that transmissions from them are transmissions from someone that you trust. Or other attacks involve grabbing transmission packets somewhere between you and the trusted person, modifying the packets and sending them along to you—a so-called "man-in-the-middle" attack. IPSec lets you guard against this with a protocol called Authentication Header (AH). AH is a method for digitally *signing* communications. If your computer and mine are performing signed communications, then we're *not* encrypting our data—anyone listening on the wire could overhear our communications. Instead, digital signing adds a bit of data to the end of our network packets that we can use to verify that the data wasn't changed in transit.

### **Permit Transmission**

*Permit* is IPSec's phrase for "no security at all." It just tells IPSec to let the traffic pass without any changes to it and no checks on its integrity. This is basically what happens in a TCP/IP-based network that doesn't include any IPSec. Why, then, have a "permit" action at all? So that you can create rules that restrict some things but not others, such as a rule (which you'll see us build later) that says, "Block all incoming traffic *except* for traffic on ports 80 and 443—permit that traffic."

### **IPSEC FILTERS**

Now that you know what IPSec can do, let's examine an important flexibility about IPSec—its filters. In my examples so far, I've said that you can direct IPSec to encrypt traffic between two particular systems. In another example, I said that you could tell IPSec not only to encrypt transmissions between two particular systems, but that you could further refine IPSec's mission by saying that it should encrypt transmissions between those two systems *only when running Telnet*. In the section on blocking traffic altogether, I suggested that you might want to tell your Web server to block any traffic at all from subnet 200.200.100.0.

More specifically, you can use filters to restrict IPSec to securing communications:

- ◆ By the source computer's IP address, IP subnet, or DNS name
- ◆ By the destination computer's IP address, IP subnet, or DNS name
- ◆ By the port and port type (TCP, UDP, ICMP, and so on)

All of this makes for a very nice amount of flexibility in IPSec-ing.

#### IPSEC RULES = IPSEC ACTIONS + IPSEC FILTERS

Blocking, encrypting, signing, or permitting traffic is said to be an IPSec *action*. You've just met IPSec filters. But to use IPSec, you combine a filter and an action to produce a *rule*. For example, suppose you want to tell the IPSec system on a given computer, "Encrypt all Telnet traffic from the computer at 10.10.11.3." *That's* a rule. It has a filter part and an action part:

- ◆ The *filter* part says, "Only activate this rule if there is traffic that is (1) from IP address 10.10.11.3, and (2) uses TCP port 23." (In case you didn't know, Telnet uses port 23.)
- ◆ The *action* part says, "Encrypt the traffic."

We'll build some IPSec rules, filters, and actions in a bit, once I've gotten a few more concepts out of the way.

#### SIGNING AND ENCRYPTING NEED ONE MORE PIECE: AUTHENTICATION

To make either digital signatures or encryption work, you need a set of agreed-upon *keys*—passwords, basically. So whenever you create an IPSec rule, then you'll have to tell IPSec how to authenticate.

Microsoft's IPSec supports three methods of authenticating: Kerberos, certificates, or an agreed-upon key. The Kerberos option only works between computers that are either in an Active Directory domain, or in AD domains that trust one another. Simply having two computers that have Kerberos clients won't be sufficient and, insofar as I can see, even two Windows systems that are members of the same Unix-based Kerberos version 5 realm (the Kerberos version of what we call a domain in the Microsoft world) can't use IPSec to communicate while authenticating with Kerberos. Perhaps Microsoft should have called this option "Active Directory" rather than "Kerberos."

The *certificates* option allows you to use Public Key Infrastructure (PKI) certificates to identify a machine. The *preshared key* option lets you use a regular cleartext string as the key. Not very secure, but as Microsoft is always very careful to say, "Hey, it was in the RFC, so we had to include it." I love the preshared key option, myself, as it's great for experimentation. No need to set up a certificate or an AD domain—just tell both machines to use a preshared key and they type in some text, like "this is a secret" on both machines. I wouldn't use it in a production environment, but for teaching and testing purposes, it's great.

**WARNING** *Microsoft's IPSec implementation of authentication has a sort of annoying habit: It demands an authentication method whether IPSec needs it or not. You see, simply permitting traffic through without changing it, or blocking it altogether, does not require any agreed-upon keys, so in theory any rule that only includes permitting and blocking should not require choosing an authentication method—it'd be like the Department of Motor Vehicles asking you whether you put regular or high-test gas in your electric car when you registered it. But, again, Microsoft's IPSec asks you for an authentication method anyway, even though it'll never use it. So if you're building an IPSec rule that only permits and/or blocks, then go ahead and choose any authentication method; it doesn't matter.*

### HOW IPSEC WORKS IN WINDOWS

That was the theory. Let's see how to actually do IPSec in Win2K and later OSes. There isn't really an "IPSec manager" program built into Windows; instead, Microsoft set things up so that you do IPSec entirely through policies, whether local policies or domain-based policies.

**NOTE** *I know we haven't covered domain-based group policies yet, but don't worry—I'll show you how to do this with a local policy. Then, as you'll learn later when we cover domain-based group policies in Chapter 9, the only real difference between local policies and domain policies is that you can centrally create a domain policy on an Active Directory domain controller and it then gets distributed to machines around the network. That's convenient because it means that you needn't travel around to each machine on your network to configure IPSec—or any of the hundreds of other things that domain policies can do.*

To make IPSec do our bidding, we'll first open the Local Security Policy snap-in: Click Start/Programs/Administrative Tools/Local Security Policy, or Start/Run and type **secpol.msc** and press Enter. It's a standard MMC snap-in, and in the left "command" pane, you'll see icons for Account Policies, Local Policies, Public Key Policies, and one called IP Security Policies on Local Machine—click on that. You'll see a screen like Figure 6.56.

**FIGURE 6.56**

Initial IPSec policies

In the right pane, you see three policies—Client (Respond Only), Secure Server (Require Security), and Server (Request Security). Those are three prebuilt policies that Microsoft ships with the OS. In the extreme right column, you see No next to each one; that means none of them are activated or *assigned* in Windows lingo. You can activate any policy by right-clicking it and choosing Assign. But you can only have one policy assigned at a time, that's important—if you want to add some functionality to a current IPSec policy, then you can't just create a new policy and assign it, as that will *unassign* whatever policy is currently in force.

So, for example, suppose I were configuring IPSec on a server and I wanted to instruct that server to always encrypt communications when talking to server SV1 and to always digitally sign communications when talking to server SV2. I could create a policy that forces my system to encrypt when talking to SV1 and a second policy that forces my system to sign when talking to SV2. But if I did, then I'd see that I can only have one policy in force at a time. The *correct* way to see to handling SV1 and SV2 correctly would be to create *one* policy that contained *two* rules—one for SV1 and one for SV2. And note that you do not have to have *any* IPSec policies assigned at a given time—in fact, in Figure 6.66, no policies were assigned.

Let's review what we've seen so far about IPSec:

- ◆ You control and enable IPSec on Microsoft operating systems through policies. You can only have one IPSec policy active on any given machine.
- ◆ Policies contain rules, which tell IPSec what to do, and authentication methods, which tell IPSec how the receiver (or receivers) and the transmitter (or transmitters) will exchange a password. They will then use that password in order to sign or encrypt the traffic. Even though permit and block rules don't use authentication, Windows requires that you specify an authentication method.
- ◆ IPSec lets you authenticate via the Active Directory, PKI certificates, or a preshared key.
- ◆ Rules contain a filter or filters that tell the rule when to kick in, and rules contain actions that tell the rule what to do.
- ◆ There are four possible actions: block, encrypt, sign, or permit.

If that sounds like perhaps more work than you bargained for just to get a bit of secure traffic, then wait, don't run away—Microsoft has prebuilt three nice, generic policies that might just fill the bill for you. So you might not have to write any policies at all—just find the one that works for your needs and turn it on.

### **Default IPSec Policies**

The three policies that come with IPSec are called Client (Respond Only), Server (Request Security), and Secure Server (Require Security).

The Client (Respond Only) policy tells a computer not to use IPSec unless requested. So, for example, suppose you set this policy on your workstation and try to access a Web site on a system that doesn't support IPSec. In that case, the server (the Web server) won't try to initiate IPSec with your computer, so your computer won't insist on IPSec-ing the transaction, so all is well. But if your computer tries to connect to a server that *does* do IPSec, then the server will say to your workstation, "let's do IPSec," and your workstation will be able to oblige.

The Server (Request Security) policy should cause your computer to attempt to initiate IPSec whenever possible. But if the client computer either can't or won't use IPSec, then your computer should talk to it anyway.

As you'd expect, the Secure Server (Require Security) policy is designed to disallow any communications that don't use IPSec.

### **Creating a Custom IPSec Policy**

Let's walk through a simple example of setting up an IPSec policy that will ensure an encrypted connection between two machines. Suppose you work at home and have a persistent connection to

the Internet—DSL, cable modem, or the like—with a static IP address of 199.10.10.3. Your job involves updating a database on a machine across the Internet from you, a machine at 206.20.20.10. You want that connection to be encrypted and, just for simplicity’s sake, we’ll use a preshared key. In this simple example, I’ll assume that the only system that 199.10.10.3 wants to IPsec with is the 206.20.20.10 machine, and vice versa.

We’ll need two policies—one for the 199.10.10.3 machine and one for the 206.20.20.10 machine. Each has two rules in addition to the default rule. The first rule for 199.10.10.3 will consist of this:

**Filter** Trigger the rule whenever there is traffic to 206.20.20.10, over any port.

**Action** Encrypt the data.

**Authentication** Preshared key, key “secret.”

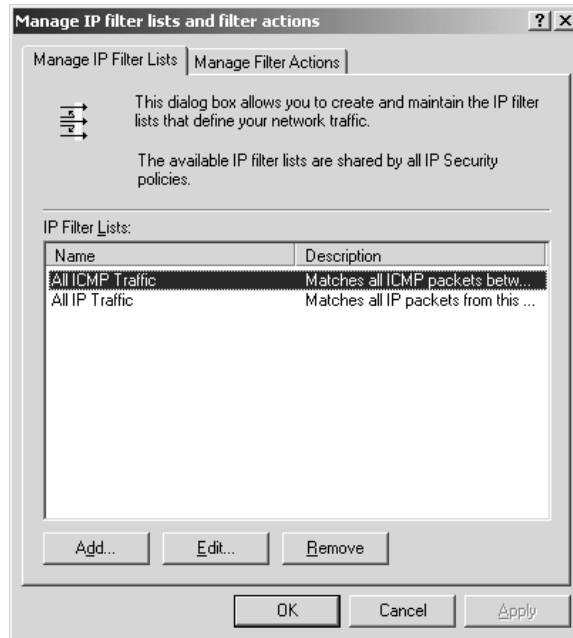

The second rule is the reverse—trigger the rule whenever there is traffic *from* 206.20.20.10; the rest of the rule is the same as the first.

The easiest way to create a rule is to first define filters and actions, and *then* create the rule out of the new filter and action.

To define a filter, in Local Security Policy, right-click the object labeled IP Security Policies on Local Machine and choose Manage IP Filter Lists and Filter Actions. You’ll see a dialog box like the one in Figure 6.57.

**FIGURE 6.57**

Dialog box to manage filters and actions

Notice that there are already two filters—All ICMP Traffic and All IP Traffic. They are there because Microsoft needed them to define the three prebuilt policies. I’ll create the “traffic to 206.20.20.10” rule by clicking Add to open the dialog box in Figure 6.58.

**FIGURE 6.58**

Creating a new filter, part 1

This dialog box doesn't actually let you create a new filter; it's sort of a staging area for new filters. (Don't ask me why they built it this way.) Give the filter a name, such as Comms with 206.20.20.10. Then, to define the filter, uncheck Use Add Wizard and click Add to raise the dialog box you see in Figure 6.59.

**FIGURE 6.59**

Filter Properties dialog box

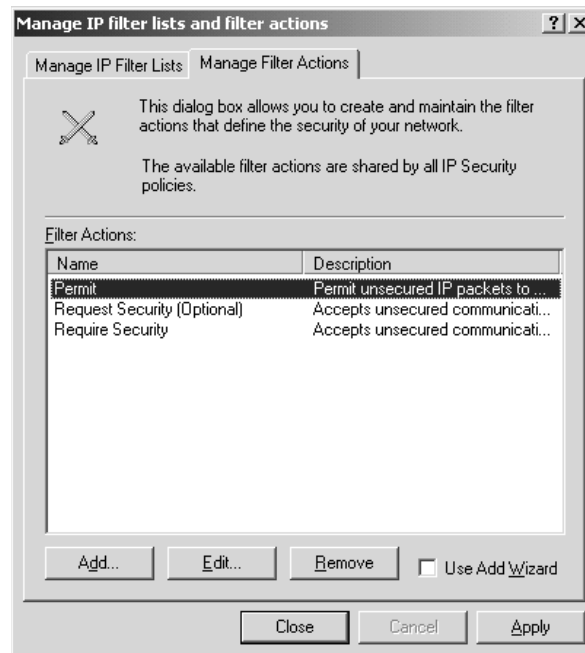

For Source Address, leave it as is. For Destination Address, click the drop-down arrow and you'll see nine options: My IP Address, Any IP Address, A Specific DNS Name, A Specific IP Address, four options (DNS, DHCP, WINS and Default Gateway) that dynamically refer to those four types of servers, and A Specific IP Subnet. Choose A Specific IP Address, and punch in **206.20.20.10**. If you like, click the Description tab and describe the filter. If you were going to specify only traffic on a particular port, then you'd click the Protocol tab—it lets you specify the protocol type (UDP, TCP, ICMP, and others) and a port number.

One more thing before you click OK—the Mirrored check box. Leave it checked. *Mirror* means to use the rule in both directions—don't just activate it from “my address” to 206.20.20.10; also activate it from 206.20.20.10 to “my address.” This saves us the trouble of creating that second rule—quite convenient. Now you're ready to click OK until you're back to the Manage IP Filter Lists and Filter Actions dialog box.

**Defining an Action** Next, to define an action, click the tab labeled Manage Filter Actions. You'll see something like Figure 6.60.

**FIGURE 6.60**  
Default filter actions

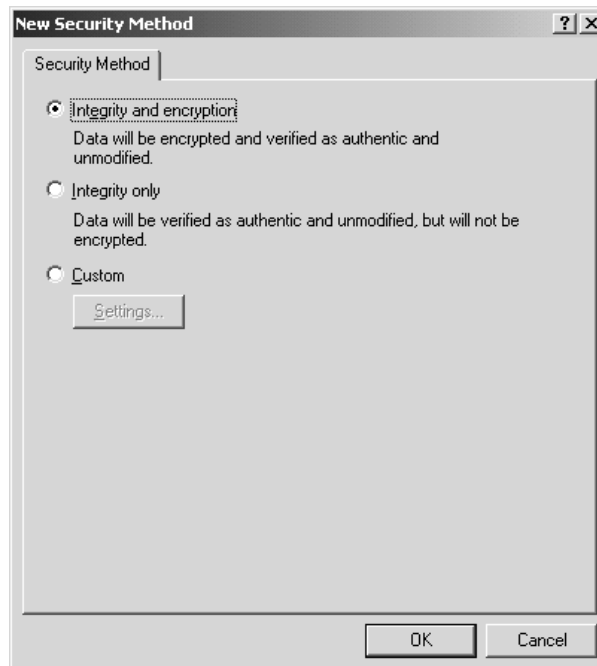

As before, skip the wizard—it's of no help. Uncheck Use Add Wizard, and click Add to show a dialog box like Figure 6.61.

Thus far, I've said that IPSec offers four possible actions, but you see only three here—Permit, Block, and Negotiate Security. That's because Negotiate Security includes signing and encryption. You can see the check box that tells your system to accept nonsecured information, but leave it unchecked: We want to be sure that this communication is secured, or we don't want to do it at all. To specify the encryption, ensure that the radio button Negotiate Security is chosen, and then click Add to see a dialog box like the one in Figure 6.62.

**FIGURE 6.61**  
Defining the action

**FIGURE 6.62**  
Choosing signing or encryption

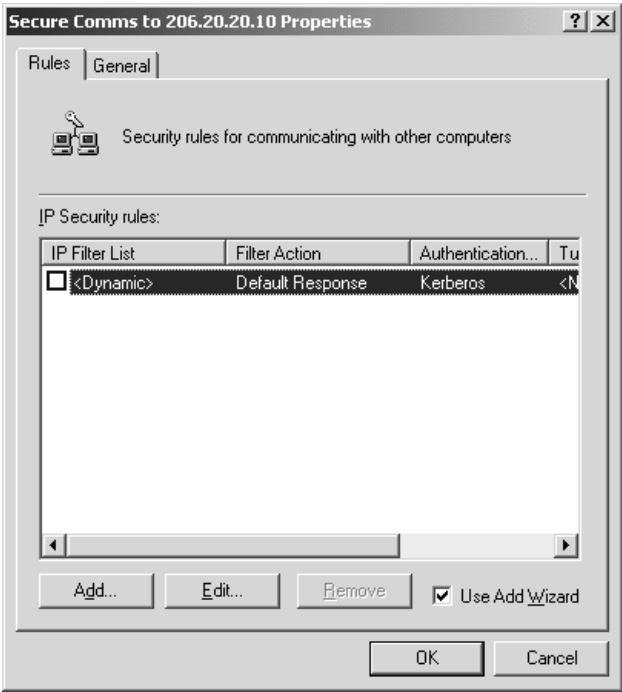

Click Integrity and Encryption and OK to choose encryption. As you can see, you could choose signing-only by clicking Integrity Only. Click OK to clear the dialog box and return to New Filter Action Properties. Click the General tab and give the filter a name, such as Require Encryption. Click OK to return to the Manage IP Filter Lists and Filter Actions dialog box, and then click Close to close that dialog box.

**Building an IPSec Rule** Now let's assemble the filter and action into a rule. In Local Security Policy, again right-click the object labeled IP Security Policies on Local Machine and choose Create IP Security Policy. That will start a wizard; click Next and it will prompt you for a name and description of the rule. Name it Secure comms to 206.20.20.10 and click Next.

Next, the IPSec Policy Wizard will ask if you want to include the "default response rule." Uncheck the check box—skip the default response rule—and click Next, then Finish. You'll see a dialog box like Figure 6.63.

**FIGURE 6.63**  
Showing rules in  
the policy

Make sure that the Use Add Wizard check box is unchecked, and click Add to show a dialog box like you see in Figure 6.64.

You've done most of the hard work; now just stitch a filter to an action, choose an authentication method, name the rule, and you'll be done. Choose the filter by clicking its radio button—Comms with 206.20.20.10 in my example—and click the Filter Action tab to reveal the possible actions. Click the radio button next to your desired action—I called mine Require Encryption—and click the tab labeled Authentication Methods. You'll see a dialog box like the one in Figure 6.65.

**FIGURE 6.64**  
Defining a rule

**FIGURE 6.65**  
Authentication  
methods

Click Add to choose the authentication method, and you'll see the dialog box in Figure 6.66.

**FIGURE 6.66**

Choosing an authentication method

Here you can see the three options for authentication—Kerberos, certificate, or a preshared key. If both machines were in the same Active Directory domain, then the easiest thing to do would be the default—Kerberos, which I've suggested should be labeled "Active Directory" instead. But for simplicity's sake, I'll use a preshared key. So I click the Use This String option and type in a phrase. I used the extremely-hard-to-guess phrase, "this is a secret." Then I click OK three times, and I'm back in Local Security Settings. In the right pane, I see the possible IPSec policies, and the one that I just created will be there. I right-click that policy and choose Assign.

Now I'm done on the 199.10.10.3 side. Next, I'd go to the 206.20.20.10 machine and create an identical policy, *except* that I'd replace the references to 206.20.20.10 with 199.10.10.3. But how could you check that you've actually got encryption working between the two systems? With a program called Ipsecmon—just click Start/Run and type `ipsecmon` and click OK. Ipsecmon isn't very pretty, but it *will* identify systems that you are communicating with via IPSec and what level of security you are using.

### USING IPSEC TO PROTECT SYSTEMS THROUGH PACKET FILTERING

Here's another neat thing that you can do with IPSec—filter packets. It's not a common use of IPSec, but it works pretty well.

One way to at least partially secure a system is to shut down unused ports, to tell your system, "Don't accept any traffic except on the following ports." For example, suppose you've got a Server 2003 system that is solely a Web server; that's all that it does. You *could* decide to tell that system, "only

accept incoming traffic on TCP ports 80 and 443,” as TCP port 80 is the port that, by default, Web browsers will use to access a Web site. Point your browser to `www.acme.com` and your browser will ask the machine at `www.acme.com`, “Please accept this request at your port 80.” Your Web server uses port 443 for *secured* communications—SSL. In this section, I want to show you how to use IPSec to disable every port on your system except 80 and 443. But before I do, two notes on this process.

First, you probably know that you can do this far more simply via the built-in filtering ability of TCP/IP. If not, take a look at the Advanced properties of your IP stack—right-click My Network Places, choose Properties, and you’ll see an icon for your network adapter. Right-click *that*, and choose Properties, and you’ll see a properties sheet that includes objects for, among other things, an object called Internet Protocol (TCP/IP). Left-click that object, then click the Properties button, and you’ll get a properties page on your TCP/IP stack. In that page, click Advanced and then Options. The Options page will probably offer two items—IP Security and TCP/IP Filtering. Click TCP/IP Filtering and then the Properties button.

You’ll see a dialog box that allows you to tell your system, “Only accept the following ports.” So, with a few clicks, you could tell your system to only accept traffic on TCP ports 80 and 443—believe me, far fewer clicks than will be required with IPSec. So why do it this way? For three reasons: First because it’s a nice, easy example of working with IPSec. And second, and more importantly, you wouldn’t want to have to walk around to every system and do all of that clicking; you issue IPSec commands to your system via group policies, either local policies or domain-based policies. It’s very convenient to be able to describe a port filter once in the form of an IPSec policy, then use group policies to apply that filter to dozens of machines with just a few clicks in the Active Directory. And, finally, although the built-in TCP/IP filtering is nice, it only lets you shut down every port *except* a small list of ports. What if you wanted to do the reverse—allow every port *except* a few? You can’t do that from TCP/IP filtering. You *can* easily do it from IPSec. When might this be useful? Consider that you’d also like to secure machines that *don’t* run a Web server. As you know, Microsoft seems obsessed with installing IIS on just about every machine, so you may have a lot of Web servers running that you never knew about. But so many viruses attack Web servers, so you *really* want to protect these “accidental” Web servers. One way might be to create a policy that is the reverse of what I’m doing here—create an IPSec policy that passes everything *except* ports 80 and 443. Then apply that policy to every machine *except* the Web servers.

My second caveat is to note that simply filtering ports 80 and 443 on a Web server is a very simple approach to security, and probably *too* simple. The built-in SMTP server that runs on every IIS box by default wouldn’t work, as SMTP needs port 25. And, worse, any remote access tool, such as Telnet or Terminal Services, wouldn’t work either, as they employ ports other than 80 and 443. You would then have to do all of your Web server administration by sitting down at the Web server and logging in locally. If you were *really* going to secure your system, you’d want to do a bit more research to discover which ports your particular installation uses.

### **The Rules**

As before, we’ll first create the filter and the action, and then assemble it into a rule. (I’ll spare you the dialog box screen shots; the process is the same as in the earlier example. I’ll just focus on what you’ll need to know to make this work.) This time, we’ll need more than one rule—four, actually. If they don’t make sense upon an initial reading, don’t worry—I’m about to explain them. In IPSec-ese,

then, you'd state the objective "block all traffic except the traffic coming in on TCP ports 80 and 443" with four rules:

- ◆ If network traffic of any kind or any port *enters* this computer from any other computer, block it.
- ◆ If network traffic of any kind or any port *originates* at this computer and is addressed to go to any computer on the Internet, let it pass.
- ◆ If TCP traffic on port 80 enters this computer from any other computer, let it pass.
- ◆ If TCP traffic on port 443 enters this computer from any other computer, let it pass.

Upon first reading those four bullet points, you're likely to say, "Wait...the first rule says to block *all* traffic of any kind, and the third one says to allow TCP port 80 traffic. Doesn't that conflict?" It looks that way, but it's the only way that we can give IPSec an even mildly complicated filtering rule. When IPSec comes across a conflict in rules, it takes the more specific of the conflicting rules. Let's stress that.

*The rule about conflicting IPSec rules is this: The specific rule beats the more generic rule.*

So, for example, suppose traffic comes in on TCP port 80. Rule One says, "It's incoming data; ignore it." Rule Three says, "It's incoming data *on port 80*; keep it." Rule Three is more specific, so it wins.

Let's see how to build the policy's four rules.

### **Building Rule One**

Rule One says, "Block all incoming traffic." Let's break that down into its filter and its action. As you've seen, you create a filter by specifying this:

- ◆ Source address: the address that the potentially filtered data comes from
- ◆ Destination address: the address that the potentially filtered data is going to
- ◆ Port and protocol: the protocol and port that the data travels to or from
- ◆ Mirroring: Whether or not to automatically mirror the filter

A filter that wants to describe "all incoming traffic" would have these values:

- ◆ Source address: any IP address
- ◆ Destination address: my IP address
- ◆ Port and protocol: any
- ◆ Mirroring: no

Notice that you do *not* want mirroring. That's because I want to block all incoming traffic and permit all outgoing traffic. If I wanted to do that same thing to both incoming and outgoing traffic, then I'd mirror the rule. As all four rules are *asymmetric*, we won't mirror any of them.

Rule One's action is to block traffic, so create a block action. Stitch the "all incoming traffic" filter with the "block" action, and you've got Rule One.

But what about authentication? Recall that blocking and permitting don't modify the data, they just pass it through or discard it, so they don't need any password. But IPSec wants to see authentication, so pick any type that you like—it won't matter. (Although if you pick Kerberos on a system that is not a member of an Active Directory domain, then the GUI will offer a dire-sounding dialog box that basically says, "Are you sure?" Just tell it that yes, you're sure.)

**Building Rule Two**

The second rule permits all outgoing traffic. The filter is very much like the last one, although source and destination are reversed:

- ◆ Source: my IP address
- ◆ Destination: any IP address
- ◆ Ports and protocols: any
- ◆ Mirroring: no

For an action, choose the already-built Permit one. Assemble the rule and, again, choose any authentication method that you like.

**Building Rules Three and Four**

Next, we'll build the rules that pass traffic on ports 80 and 443. The filter is a trifle more complicated; here's the criteria for the port 80 one:

- ◆ Source address: any IP address
- ◆ Destination address: my IP address
- ◆ Ports and protocol: port 80 on TCP
- ◆ Mirrored: no

When building the filter, first set the source and destination addresses, and then uncheck the Mirror check box. Then click the Protocol tab to see something like Figure 6.67.

**FIGURE 6.67**

Configuring a protocol filter

In the Protocol tab, first choose TCP under Select a Protocol Type, and then click the radio button To This Port and fill in **80**.

For the action, choose the Permit action. Again, do anything that you like for Authentication, as it does not matter. Do the same thing for Rule Four, except specify port **443** instead of port 80.

Once you've got your policy assembled, assign it and then try it out. You won't be able to ping your Web server, nor will you be able to access its SMTP server, nor an FTP server if you have one running on that system. But you *will* be able to access its Web pages, both secured and unsecured.

### A FEW FINAL THOUGHTS ABOUT IPSEC

I haven't covered all of IPsec here, as IPsec could probably fill a book—I've just tried to hit the high points. But I don't want to leave without mentioning a few things.

First, IPsec will *not* work in conjunction with Network Address Translation unless both sides of your communication run a relatively new (late 2001 and later) modification of IPsec called IPsec NAT Traversal. If your workstation sat behind a NAT router, at, say, 192.168.23.3, and you wanted to create a secure IPsec connection with a server on the public Internet, then you would not be able to use IPsec unless the NAT router were a Server 2003 or later system. Basically you need pretty recent and IPsec NAT traversal-aware routers on both sides to make it work.

Second, I've been talking about IPsec as a one-to-one way for systems to communicate. But IPsec also has a feature called *tunneling* whereby most of your systems needn't be IPsec aware at all. Instead, they'd funnel all of their communications through a single IPsec-aware computer that is prepared to "relay" their communications to another IPsec-aware computer on a remote site. Thus, if you had 100 machines at one location and 100 machines at another location, and you wanted machines at each location to be able to talk to all of the machines on the other location, but you wanted security while the data traveled from one location to another, then you could just designate one machine at each location as a sort of "firewall" box. Those boxes would tunnel IP traffic from one site to another.

Third, IPsec is a standard, not just a Microsoft functionality. So in theory you should be able to use Microsoft's IPsec to communicate with other vendor's tools. But test that before you start to rely upon it—I've heard that many non-Microsoft implementations can run into trouble trying to talk with IPsec-enabled Windows boxes.

Fourth, IPsec first appeared with 2000 Server. Earlier versions of the operating system—and lamer ones, like Windows Me—cannot do IPsec communications.

## Network Load Balancing Clusters (NLBC)

Sometimes you'll put a server on your network and it gets *popular*. Whether it's a Web server, FTP, or firewall server, you sometimes get to the point where you either need to get a bigger and faster server, or fewer customers. Most of us will opt for the former rather than the latter option, but it's a shame to take a server that's doing the whole job and then just replace it with another—sure, it's nice to have the greater power of the faster server, but wouldn't it be neat if that new server could *add* to the old server's power, instead of replacing it?

### NLB Overview

You can achieve this with Network Load Balancing Clusters (NLBC). It's a feature that first appeared in Windows 2000 Server in the more-expensive Advanced Server offering, but now Microsoft

offers it on all editions of Server 2003. NLBC lets you take two or more computers and make them look like one computer to the outside world. Incoming requests are divided up between the two or more members of the NLBC “cluster,” letting you slowly add more and more computers to create a pretty powerful Web site. That means that you could gang together a bunch—32 maximum—of cheap computers to create a seemingly powerful Web presence ... although of course having to buy a whole bunch of Server 2003 *licenses* might eat up your hardware savings!

It’s important that you understand that this is *not* “clustering” in the high-powered sense that Enterprise/Advanced offers. Basically, two or more computers each have their own static IP address, as usual. But they also take on an extra IP address—and every one of the NLB cluster members take on the same value for their extra IP address. Anyone in the outside world can connect to that IP address, as they would to any other IP address. But what’s different here is that, again, two or more systems *share* that IP address. That normally wouldn’t work, as giving two systems the same IP address usually means that at least one of them can’t communicate; but NLB fixes that. As systems ask to be connected to the shared IP address, NLB invisibly assigns each visitor to a particular cluster member. So, for example, if I had two servers running IIS with the same content, I could make them an NLB cluster and give them a new cluster IP address. When the first person asks to attach to that cluster address, then one of the servers will get the request. When the second person asks to attach to the cluster address, she gets connected to the second server. The third person gets connected to the first server, and so on.

This clearly only works if you’ve got two or more servers that offer the precisely same data. It also presents some problems if these servers accept data from a customer and then store it somewhere. For example, if we were clustering two Web servers that took orders for, say, books, then each of those servers has to be able to store those orders. If they store them on local databases then at the end of the day you’ll have two separate databases, each containing about one half of the day’s orders, so you’ll have to merge those databases somehow. Or you could have both Web servers store their transactions on a separate shared database server, or something like that. What I’m trying to point out here is that some things will require more planning in order to make them work as an NLB clustered application than others. (And as this isn’t a Web application building book, I’m going to duck those issues...) But remember that some kinds of server applications, like file servers, are really not a good match with NLB. But Web servers, Terminal Servers, and Microsoft’s Internet Acceleration and Security (ISA) firewall can benefit from NLB.

## Getting Ready

Here’s the very simplified list of what you’ll need in order to build a two-system NLB cluster:

- ◆ Every system needs a static IP address: each of the two servers needs a static IP address, so get that ready.
- ◆ You’ll need *another* static IP address for the shared cluster address.
- ◆ You’ll need a DNS name for the cluster, like cluster.bigfirm.biz, and the DNS entry should correspond to the shared static IP address from the cluster. (I know, I’ve not done DNS or, for that matter, Web servers yet, forgive me—this topic doesn’t exactly fit in anywhere. If you like, just skim this now and return to it after learning about DNS and Web. I’ll wait!)
- ◆ You’ll need whatever kind of server software that you want to cluster on both systems. In my example, that means installing Internet Information Service on each server.

I'm going to show you how to do an NLB cluster with in its simplest form—two Web servers. I worked out this example on two systems with the following characteristics:

- ◆ One of the servers is named CADOTNET and has a static IP address of 206.246.253.151. Remember, every member of an NLB cluster must have a static IP address.
- ◆ The other server is named 5000SC and has a static address of 206.246.253.150.
- ◆ The NLB cluster's shared IP address will be 206.246.253.152.

### Step One: Install Static IP Addresses and Server Software

Let me warn you that NLB is a neat tool when it works, but that it has very exacting requirements and can produce some very disconcerting-looking errors while you set it up. So I'm a strong believer that you need to get each of the two servers running on their own in tip-top shape before you start tilting with NLB.

In my example system, I configured 5000SC with a static address of 206.246.253.150, a subnet mask of 255.255.255.0, and a default gateway of 206.246.253.1. Those numbers make sense for me because they're in my C network range, but use whatever range works for you. Remember, though: at minimum you must supply an IP address, subnet mask, default gateway, and IP address for a DNS server. Do that for both systems. (You can copy my IP address range to try it out, but make sure that you set all of your test systems it use the IP address range or, again, adapt the example for your IP address range.)

**WARNING** *All cluster members must have static IP addresses in the same subnet!*

Then make sure that the Web server software is running on each server. In pre-2003 versions of Server, you pretty much always got a Web server installed on every server, but that's not the case any more, thank goodness. But do get IIS on both CADOTNET and 5000SC. Put simple home pages on them—I just create a file in Inetpub\wwwroot named `default.htm` that just contains the text, "Hello, you're visiting [the computer's name]." It works fine for testing purposes. Remember that in an actual implementation you would put identical Web content on each server.

Go to some other computer, start up Internet Explorer and try to view those Web server pages. For simplicity's sake I just punch the actual IP addresses into IE's Address bar so that I needn't even create DNS entries for the cluster members CADOTNET and 5000SC. Make sure the home pages come up as expected; if not, fix them—NLB just makes problems like this worse!

### Step Two: Create a DNS Entry for the Cluster

The cluster's not built yet, but let's get DNS ready for it. (Again, sorry I'm referring to things later in the book.) Assign the cluster a name and, as you've already read, a static IP address. In my example I've decided to call my cluster `cluster.bigfirm.biz` and give it an IP address of 206.246.253.152. I just go to the DNS server for `bigfirm.biz` and create a static host entry—an "A record"—matching `cluster.bigfirm.biz` with the IP address 206.246.253.152.

As you'll read in the next chapter, you can test that your new host entry is installed right with the `nslookup` tool—just type `nslookup cluster.bigfirm.biz` and the command should return the IP address that you assigned to `cluster.bigfirm.biz`.

### Step Three: Set Up NLB for CADOTNET

It actually doesn't matter which of the two systems you set up first; I arbitrarily set up CADOTNET first. Open the properties for CADOTNET's NIC as you've seen before: Start/Control Panel/Network

Connections/Local Area Connection or whatever name CADOTNET's NIC has. In the resulting Local Area Network Status page, click the Properties button. It'll look something like Figure 6.68.

**FIGURE 6.68**  
NIC properties page

You may have noticed before that the service named Network Load Balancing was unchecked; time to put it to work. Check the box next to it and then click the Properties button. You'll see something like Figure 6.69—well, only *like* it; I've already filled it in in that screen shot.

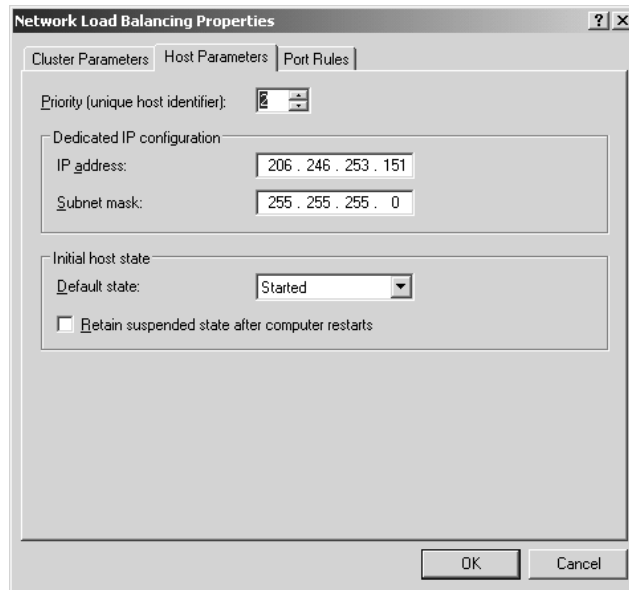

**FIGURE 6.69**  
Identifying the cluster

This is where we breathe life into the cluster. Remember that we needed an extra static IP address that all of the cluster members would share? This is where you enter it, along with its subnet mask and cluster name. For Cluster Operation Mode, I've not found much use for Multicast and it can give some routers fits, so I tend to stay with Unicast. Make the cluster remote-controllable if you like; I avoid it and use other remote control tools. You will have to configure a screen like this for every cluster member—*fill in the same information on the Cluster Parameters tab for every member!* Then click the Host Parameters tab to see Figure 6.70.

**FIGURE 6.70**

Member-specific information

I just said that you configure the Cluster Parameters identically for each member; *this* tab is where you configure the particular member. In Dedicated IP Configuration, just repeat the static IP address and subnet mask of this particular system—note that I have not filled in the cluster's IP address, just the static IP address that *this* computer has. You'll also need to set a value for Priority, as each computer in the cluster must have a different value. Even though it's called Priority, in the particular application that we'll have—Web servers, again—it doesn't really do much in the way of prioritizing. I've set CADOTNET to a priority of 2.

At this point, just click OK to close Network Load Balancing Properties and return to Local Area Connection Properties.

#### Step Four: Add the Cluster IP Address to CADOTNET's IP Software

CADOTNET's almost done...but not quite yet. Next, click the Internet Protocol (TCP/IP) object and the Properties button, then the Advanced button and the IP Settings tab to get the Advanced TCP/IP Settings page and the IP Settings tab in that page. We're going to add a second IP address here—the shared IP address that identifies the cluster.

Under IP Addresses, click the button labeled Add and fill in the IP address of the shared cluster IP address. In my example, that's 206.246.253.152. You are not *replacing* the server's current

IP address; you're just adding another IP address to the server's NIC. Click Add when you've filled in the cluster's shared IP address and subnet, and the Advanced TCP/IP Settings page will look like Figure 6.71.

**FIGURE 6.71**

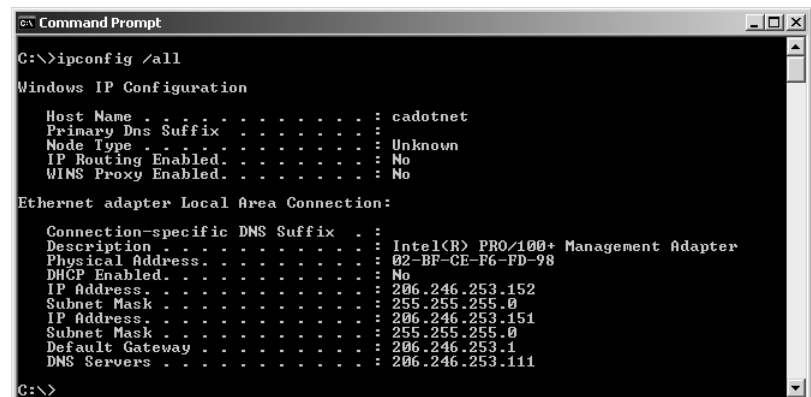

CADOTNET with  
cluster IP added

Click OK to clear the Advanced TCP/IP page, OK to clear the Internet Protocol (TCP/IP) properties page, and Close to close the NIC's property page. Try an `ipconfig /all` to make sure that it worked, and it'll look something like Figure 6.72.

**FIGURE 6.72**

`ipconfig /all`  
after adding second  
IP address

If you just see addresses like 0.0.0.0, then don't panic—NLB can sometimes take up to five or so minutes to get things settled. If Server raises any panicky messages about things not being configured right, click the messages away and give it five minutes, *then* try the `ipconfig /all` again. If the IP addresses are still wrong, then go back and check the things that you punched into the dialogs.

At this point, CADOTNET is done.

### Step Five: Configure 5000SC

Next, go back and do the same thing for 5000SC. Check the box for Network Load Balancing and fill in the Cluster Parameters tab exactly as you did for CADOTNET. On the Host Parameters page, use 5000SC's IP address of 206.246.253.150 rather than 206.246.253.151, and set the Priority to 1. Again, go to Advanced TCP/IP Properties and add a second IP address, 206.246.253.152.

When you close all of the NIC's property pages and dialog boxes, just relax—the cluster will *definitely* take several minutes to get set up, and the second system that you set up (5000SC in this case) will emit all kinds of scary “TCP/IP is not configured properly...” messages. Relax. Go get a snack. Don't watch—it's better for your blood pressure. Microsoft *really* needs to remove the trauma from this process. But after a few minutes, all will be well.

Go to a machine on your subnet (or any other machine that can route to your cluster's IP addresses, actually), start up Internet Explorer and try typing in the static IP addresses of each server, as well as the cluster's IP address. You should see the home pages from each server, and then one of the two server's home pages when you use the shared cluster IP address. Now go to other machines, run IE and again point to the shared cluster IP address—you'll see that different machines get different home pages. Your cluster is working! (Again, in the real world you'd have the same content on both Web servers, so no one could easily figure out which cluster member he was on...which is just what you want.)

One more note before I leave this: do not try to ping one cluster member from another cluster member. A side-effect of NLB is that while all of the cluster members can all connect as easily to client machines as each other, the cluster members cannot communicate with each other!

Well, by now, you're on an intranet in the traditional way. Microsoft adds two possible options to this setup: the Dynamic Host Configuration Protocol (DHCP) and the Windows Internet Name Service (WINS). You'll meet these two, as well as the essential third (Domain Name System, DNS) and a few other services, in the next chapter.

## Chapter 7

# TCP/IP Infrastructure: DHCP, WINS, and DNS

WHETHER YOU'RE HOOKING UP a two-computer intranet in your house to share an Internet connection or weaving a world-spanning Internet, you've got to solve two basic problems. First, every system on the network needs a unique IP address and requires configuration—it needs to know the address of its default router, what its domain name is, where the nearest DNS server is, and the like. And second, it needs help finding its way around the network: How do I send mail to Jane over at Acme Industries? How do I connect to the server that will let me buy books or shoes online? Or, more mundanely, how do I find a server that will log me in?

Microsoft OS-based networks that are TCP/IP-based need three technologies to accomplish IP configuration and name management: the Dynamic Host Configuration Protocol (DHCP), the Domain Name System (DNS), and the Windows Internet Name Service (WINS). Of the three, WINS is something of a relic, a technology that in *theory* you can forgo altogether, but in practice you can only do it if your network includes nothing but computers running Windows 2000 or later, and if your network-aware applications are built for post-NT 4 rather than NT 4 or earlier operating systems. Furthermore, this chapter is *essential* because if you don't do a great job designing your DNS architecture, then Active Directory will run terribly; in many ways, DNS is the foundation of Active Directory.

### DHCP: Automatic TCP/IP Configuration

In Chapter 6, you learned how to set up IP on a Server 2003 system. Ah, but now ask yourself, “Do I really want to walk around to 3000 workstations and do this by hand?” Auuugghhhh! Oops, sorry, what I really meant was, “Of course not.” Who wants to have to remember which IP address you gave to *that* machine so you don't put the address on *this* machine? Or how'd you like to get a phone call every time some visiting dignitary needs an IP address for his laptop? No thanks. DHCP will greatly simplify the task, so let's see how to set it up.

By the way, this discussion assumes you've already read Chapter 6; don't think if you decided from the start to go with DHCP that you could jump in here without reading the preceding chapter.

## Simplifying TCP/IP Administration: BOOTP

“I have a little list / it never can be missed.” Well, OK, that’s not exactly what Pooh-Bah sings in *The Mikado*, but it fits here. You see, back when I first put TCP/IP on my company’s computers, in 1993, I had to keep this list of PCs and IP addresses in a notebook. It was basically a kind of master directory of which IP addresses had been used so far.

Obviously, I had to consult it whenever I put TCP/IP on each new computer. Obvious, sure, but what’s unfortunate is that I never seemed to have the notebook with me when I needed it. So I started keeping this list of computers and IP addresses on one of my servers, in a kind of common HOSTS file. It served two purposes: First, it told me what IP addresses were already used, and second, it gave me a HOSTS file to copy to the local computer’s hard disk.

But, I recall thinking, this is silly. Keeping track of IP addresses and the machines using them is a rote, mechanical job—you know, the kind of job computers are good at.

Unknown to me, the Internet world apparently had a similar feeling and so invented a TCP/IP protocol called “the bootstrap protocol,” usually abbreviated “BOOTP,” which was first described in RFC 951. With BOOTP, a network administrator would first collect a list of MAC addresses for each LAN card. I’ve already mentioned the 48-bit identifiers on each network card, which are good examples of MAC addresses.

Next, the administrator would assign an IP address to each MAC address. A server on the company’s intranet would then hold this table of MAC address/IP address pairs. Then, when a BOOTP-enabled workstation would start up for the day, it would broadcast a request for an IP address. The BOOTP server would recognize the MAC address from the broadcaster and would supply the IP address to the workstation. So BOOTP was (and is) a neat way to configure TCP/IP on a computer without having to travel to it.

But BOOTP doesn’t stop there. Once a BOOTP server delivers an IP address to a computer, it also delivers a small startup operating system, a “bootstrap loader.” (That’s where the phrase “boot disk” comes from; in the old days, we’d have to hand-enter a small program into a computer to make the computer smart enough to be able to read its own disk drive or to start communicating on the network. That small program let a computer “lift itself by its own bootstraps,” in the old phrase, and became known as a bootstrap loader and eventually just became “the boot loader,” “boot disk” and similar phrases.) The idea with BOOTP was that you could have a computer that ran entirely off the network, with no local hard or floppy disks at all. As such a computer couldn’t boot from its (nonexistent) floppy or hard disks, then it needed to get its startup programs from *somewhere*. A BOOTP server solved that by first handing the computer an IP address and then downloading a startup boot program.

This was a great improvement over the static IP addressing system that I’ve described so far. Administrators didn’t have to physically travel to each workstation to give it its own IP address; they needed only to modify a file on the BOOTP server when a new machine arrived or if it was necessary to change IP addresses for a particular set of machines.

Another great benefit of BOOTP is that it provides protection from the “helpful user.” Suppose you have user Tom, who sits next to user Dick. Dick’s machine isn’t accessing the network correctly, so helpful user Tom says, “Well, *I’m* getting on the Net fine, so let’s just copy all of this confusing network stuff from my machine to yours.” The result is that both machines end up with identical configurations—including identical IP addresses, so now neither Tom *nor* Dick can access the network without errors! In contrast, if Tom’s machine is only set up to go get its IP address from

its local BOOTP server, then setting up Dick's machine identically will cause no harm, as it will just tell Dick's machine to get *its* address from the BOOTP server. Dick will get a different address (provided that the network administrator has typed in an IP address for Dick's MAC address), and all will be well.

## DHCP: BOOTP Plus

BOOTP's ability to hand out IP addresses from a central location is terrific, but it's not dynamic, and in the PC world we typically don't care about getting bootstrap code from a central server; as you probably know, we tend to boot our computers from a local read-only memory chip called the BIOS and then from code on a local hard disk. Additionally, BOOTP requires the network administrator to find out beforehand all the MAC addresses of the Ethernet cards on the network. This isn't *impossible* information to obtain, but it's a bit of a pain (usually typing `ipconfig /all` from a command line yields the data). Furthermore, there's no provision for handing out temporary IP addresses, such as an IP address for a laptop used by a visiting executive. (I suppose you could keep a store of PCMCIA Ethernet cards whose MAC addresses had been preinstalled into the BOOTP database, but even so, it's getting to be some real work.) So someone came up with a somewhat simplified tool that is BOOTP-like but that doesn't focus on delivering boot code: DHCP.

DHCP improves upon BOOTP in that you just give it a range of IP addresses that it's allowed to hand out, and it gives them out first come, first served to whatever computers request them. If, on the other hand, you want DHCP to maintain full BOOTP-like behavior, then you can; it's possible with DHCP to preassign IP addresses to particular MAC addresses (it's called *DHCP reservation*), as with BOOTP.

With DHCP, you only have to hardwire the IP addresses of a few machines, such as your BOOTP/DHCP server and your default gateway.

Both DHCP and BOOTP use UDP ports 67 and 68, so you won't be able to install both a BOOTP server and a DHCP server on the same computer. Now, Microsoft does not supply a BOOTP server; this note would mostly be relevant only if you tried to install a third-party BOOTP server. But Windows NT 4 Server and its newer siblings also allow you to make a computer a *BOOTP forwarding agent*. If you enable that software on a DHCP server, the server stops giving out IP addresses.

Let's see how to get a DHCP server up on your network so the IP addresses will start getting handed out, and then we'll take a look at how DHCP works.

## AVOID STATIC IP: USE DHCP EVERYWHERE!

In a minute, I'll get into the nitty-gritty of setting up DHCP servers and handing out IP addresses. But before I do, let's address a big, overall network configuration question: Which machines should have static IP addresses, and which machines should get their addresses from DHCP servers?

In general, the answer is that the only machines that should have static IP addresses should be your WINS servers, DNS servers, and DHCP servers. In actual fact, you'll probably put the WINS, DNS, and DHCP server functions on the same machines.

"But wait!" I hear you cry, "Are you suggesting that I let my domain controllers, mail servers, Web servers, and the like all have floating, random IP addresses assigned by DHCP willy-nilly?" No, not at all. Recall that you can assign a particular IP address to a particular MAC address using a DHCP reservation. My suggestion, then, is that you sit down and figure out which machines need fixed

IP addresses, get the MAC addresses of the NICs in those machines, and then create reservations in DHCP for those machines. (You'll see how a bit later.)

## Installing and Configuring DHCP Servers

DHCP servers are the machines that provide IP addresses to machines that request access to the LAN. DHCP only works if the TCP/IP software on the workstations is *built* to work with DHCP. If the TCP/IP software includes a *DHCP client*. Nowadays, just about every network-aware OS includes DHCP clients—Macs, Linux, and every Microsoft desktop and server OS since 1994 have included them.

### INSTALLING THE DHCP SERVICE

To get ready for DHCP configuration:

- ◆ Have an IP address ready for your DHCP server—this is one computer on your network that *must* have a hardwired (“static”) IP address.
- ◆ Know which IP addresses are free to assign. You use these available IP addresses to create a pool of IP addresses.

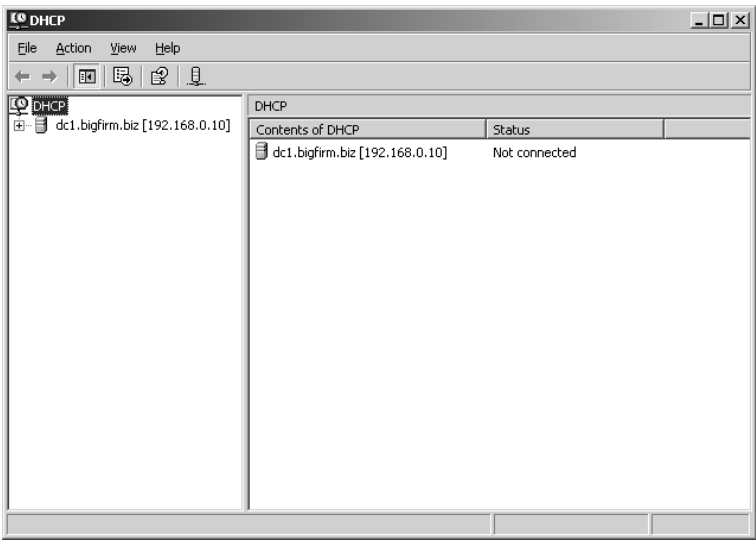

You install the software to make your server a DHCP server in the same way that you install most other network services, from the Add/Remove Windows Components applet of the Control Panel. Step-by-step, it looks like this:

1. Open the Control Panel's Add or Remove Programs applet (Start/Control Panel/Add or Remove Programs).
2. Click Add/Remove Windows Components and wait a bit while the Windows Components Wizard starts up.
3. Click Networking Services and then the Details button.
4. Click the check box next to Dynamic Host Configuration Protocol (DHCP).
5. Click OK to return to Windows Components.
6. Click Next to install the service. The system will say that it is “Configuring Components” for a while, probably a few minutes. Make sure you have the Server CD around; it'll want you to insert it. A couple of rounds of FreeCell, and the Completing the Windows Components Wizard screen appears.
7. Click Finish to end the wizard.
8. Click Close to close Add/Remove Windows Components.

And best of all, you needn't reboot afterward. You control DHCP with the DHCP snap-in, which you'll find in Administrative Tools: Start/Administrative Tools/DHCP. Start it up, and the opening screen looks like most MMC snap-ins, with the left and right panes. This particular one lists your server, with a plus sign next to it. Click the plus sign and you'll see a screen like Figure 7.1.

Notice that this snap-in lists the server in the left pane. That's because you can control as many DHCP servers as you like from this program. All you need do to add a DHCP server to the list of servers that you control is to just select Action/Add Server.

**FIGURE 7.1**  
DHCP manager  
opening screen

**AUTHORIZING DHCP SERVERS (FOR ACTIVE DIRECTORY USERS)**

Now, before we go any further, I have to add a note here about DHCP and Active Directory because if you're running AD, then you won't be able to make your DHCP server work without a little adjustment—hence the note *now* rather than in the next chapter. If you're not running AD, then feel free to skip this section, but just remember that you saw this—or it'll come bite you *later*, when you've gotten your AD up and running.

Click the plus sign next to the small icon that looks like a tower computer in Figure 7.1. There's a small circular blob next to it. It's sort of small, so you may not be able to see it in the screen shot, but to the left of "dc1.bigfirm.biz [192.168.0.10]" is a small arrow that points downward—in color, it's red. That arrow represents a nice touch on Microsoft's part.

You see, under NT 4, 3.51, and 3.5, anyone with an NT Server installation CD could set up NT Server on a computer and make herself an administrator of that server. With administrative powers, she could then set up a DHCP server. Now, the job of a DHCP server, recall, is to hand out IP addresses to computers who want to be part of the network. The problem arises when the administrator of this new server decides just for fun to offer a bunch of meaningless IP addresses, a range of addresses that your firm doesn't actually own. The result? Well, the next time a machine in the company needs an IP address, it asks any server within earshot for an IP address. The server with the meaningless addresses responds, as do the valid servers—but the server with the bogus addresses is likely to respond more quickly than the valid servers (it doesn't have anything else to do) and so many client PCs will end up with IP addresses from the server with the bogus addresses. Those addresses won't route and so those people won't be able to get anything done on the network.

Why would someone set up a server with bogus addresses? Usually it's not for a malicious reason. Rather, it's more common that someone's just trying to learn DHCP and sets up a server to play around with, not realizing "test" DHCP servers are indistinguishable from "real" DHCP servers to the client machines. Such a DHCP server is called a *rogue* DHCP server.

Windows 2000 and later versions of Server solve the problem of rogue DHCP servers by disabling new DHCP servers until a member of AD's most powerful forest-wide group, the Enterprise Admins (you'll meet them in the next chapter), "authorizes" them in the Active Directory. With those versions of Server, anyone can set up a DHCP server, but the server won't start handing out addresses until authorized. This isn't foolproof, as only machines that are members of Active Directory-based domains seek to be authorized. Someone who wanted to maliciously set up a rogue DHCP server could simply install a copy of Server 2003 and not join it to the domain, *then* set up a DHCP server—but, again, that's not the most common problem.

You authorize a server with the DHCP snap-in by starting up the DHCP snap-in while logged in as an Enterprise Admin. From the DHCP snap-in, click the server and then select Action/Manage Authorized Servers, and you'll see a dialog box like the one in Figure 7.2.

**FIGURE 7.2**

List of authorized DHCP servers

You can see that there are no servers authorized yet, so let's authorize this one. Click Authorize and you'll see the dialog box in Figure 7.3.

**FIGURE 7.3**

Authorizing a new DHCP server

I've filled in the IP address of this server. Click OK, and you'll be asked to confirm that you do indeed want to add this server. Click the Yes button, and you'll return to the list of authorized servers. Click Close to close that dialog box and you'll see the DHCP snap-in looking as in Figure 7.1, save that the red down-pointing arrow is now a green up-pointing arrow.

You should be able to click the server and then press F5 to refresh the display to see the green arrow. In my experience, however, you usually have to close the DHCP manager and then reopen it to see the green arrow appear. (Once I not only had to close and reopen it, I also had to press F5. Clearly the DHCP manager isn't one of those chatty kinds of entities that constantly yammer on about their current condition—no, this app is downright reticent about its mood.)

Now you can offer IP addresses with this server.

If you *don't* have an Active Directory running, then you needn't authorize the server, as clearly there wouldn't be anything to authorize it *with*. But here's an interesting side effect of how 2000 or 2003 servers authorize DHCP servers. (Again, I know that some of you don't even *have* an Active Directory yet, but pay attention to this, or it'll bite you when you first set up your AD.)

If you are running a DHCP server on a network without an Active Directory, and all of a sudden bring up an AD, then the DHCP server will sense that, *even if it's not part of the AD domain*. It will then shut itself down. This *always* trips me up when I'm doing a class and I'm demonstrating Active Directory—first I get the DHCP and DNS servers up and running, then I create the AD, but then forget to authorize the already-running DHCP server that conveniently sniffs out the Active Directory and consequently disables itself. Anyway, just thought I'd mention it—now let's get back to the whys and wherefores of DHCP setup.

### CREATING A RANGE OF ADDRESSES: DHCP “SCOPES”

That DHCP snap-in isn't really much to look at, is it? Well, it won't be, as there are no scopes set up yet. Scopes? What's a scope?

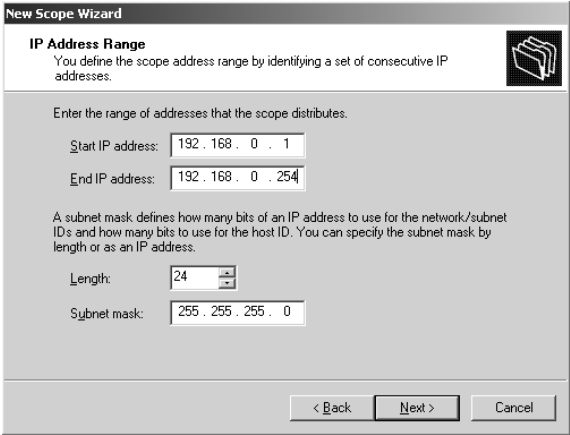

#### CREATING THE SCOPE

For DHCP to give out IP addresses, it must know the range of IP addresses that it can give out. Microsoft calls a range of IP addresses, and the descriptive information associated with them, a *scope*. To create a scope, right-click the server's icon and choose New Scope, which starts the New Scope Wizard. Click Next from its opening screen and you'll see a screen like the one in Figure 7.4.

**FIGURE 7.4**  
Naming the scope

In this screen, you simply identify the scope, giving it a name and a comment. In my experience, I've never really figured out why there's a name *and* a comment, as the name has no real use; it could well *be* a comment, in effect. Fill in appropriate values for your network, and click Next to see a screen like Figure 7.5.

**FIGURE 7.5**  
Defining the IP  
address range

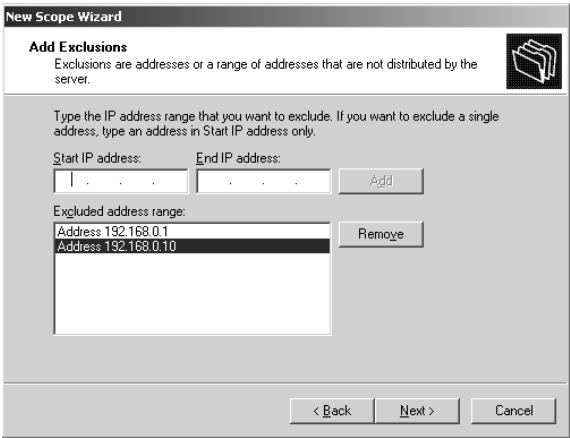

**SPECIFYING IP ADDRESS RANGE**

A scope is simply a range of IP addresses—a pool from which they can be drawn. In the example in Figure 7.5, I've created a scope that ranges from 192.168.0.1 through 192.168.0.254—in other words, I'm going to use DHCP to help me create and manage a class C intranet of nonroutable addresses.

I don't want to get too sidetracked on the issue of scopes just now (I'll cover multiscope considerations later), but let me mention why you'd have more than one scope on a DHCP server. You can assign a scope to each subnet serviced by your DHCP servers—and, yes, it is possible for one DHCP server to handle multiple subnets. In contrast, however, a DHCP server won't let you create more than one scope *in the same subnet*. I will, however, show you how to get more than one server to act as a DHCP server (for the sake of fault tolerance) in a minute.

I put DHCP in charge of giving out *all* of my Internet addresses, but clearly that makes no sense, as I must have at least *one* static IP address around—the one on my DHCP server. So I need to tell the DHCP server not to give *that* one away, but how to do it? Click Next twice—the wizard seems to need two clicks on the Next button here—to see the next screen, where I'll tell the server what addresses to avoid, as in Figure 7.6.

**FIGURE 7.6**  
Excluding address  
ranges

As you see, I've excluded several addresses: The .1 address is the default gateway, a NAT router, and the .10 address is this server itself. Notice that you can specify one address by itself; you don't *have* to specify starting and ending addresses in a one-address range.

### **SPECIFYING MORE RANGES: SUPERSCOPIES**

As you read in Chapter 6, in general there's a one-to-one relationship between physical network segments and subnets. IP was designed to let systems that could directly "shout" at each other do that, communicating directly rather than burdening routers.

Sometimes, however, you'll see two separate subnets on a single segment. That's often because a single network can't accommodate all of the segment's machines. For example, if you started your enterprise with 180 hosts and acquired a slash 24 network, you'd have enough addresses for 254 devices, presuming that you didn't subnet. But what about when your firm grows to need 300 machines? You might go out to your ISP and get another slash 24, another 254 addresses.

Now you've got two networks. You *could* break your network up into two segments and apply one set of network addresses to each segment. But you might not want to: Suppose your one segment can support all of your machines and you can't see the point in messing around with more routers—what then?

You create a *superscope*. The idea with a superscope is that it contains more than one range of IP addresses—more than one scope—but applies them to a single segment. You can do it simply—just define two separate scopes on a DHCP server, then right-click the server, choose New Superscope, and you'll have the superscope. You can then add scopes to the superscope as you like; don't forget that you might have to change the subnet mask to reflect the larger range of addresses.

But what about the mechanics of a superscope? When you put a new machine on this subnet and it broadcasts to find a DHCP server and get an IP address, will it get an IP address from the first scope or the second? The answer is that it doesn't matter. If you're just shoehorning two IP subnets onto the same physical segment simply because you're out of IP addresses on an existing subnet, then it doesn't matter whether a workstation gets an IP address from the first range of IP addresses or the second range of IP addresses, as all of the enterprise's routers know how to find either range.

Once in a while, however, you have two ranges of IP addresses on the same physical network for a reason—perhaps one range is composed of IANA- or ISP-assigned IP addresses and the other is composed of nonroutable addresses. You probably have good reasons, then, to put some computers on the routable addresses and some on the nonroutable addresses. But how to get DHCP to help there? After all, both the routable and nonroutable ranges are in the same shouting radius, so to speak. When a workstation asks DHCP for an address, how would DHCP know whether to give that workstation a routable or nonroutable address?

The answer is that DHCP can't—there's no magic here. There would have to be some kind of setting on the client that the client could use to give DHCP a clue about what network it wanted to be a member of, the routable or nonroutable. What you must do in a situation like that is decide which machines go in the routable network and which go in the nonroutable network and then enter their MAC addresses by hand into DHCP with *reservations* (which I'll cover later), much as network administrators must when using BOOTP instead of DHCP.

### **SETTING LEASE DURATION**

Returning to the wizard, click Next and you see a screen like Figure 7.7.

**FIGURE 7.7**

Set lease duration.

As you'll read in a few pages, when I explain the internals of DHCP, the DHCP server doesn't give the client PC an IP address to use forever. The client PC only gets the IP address for a specific period of time called a *lease*, and by the time the lease period's up, the client must either lease it or another address from a DHCP server, or the client must stop using IP altogether, immediately. But how long should that lease be? Although that was something of an issue when DHCP first appeared in NT 3.5, it doesn't matter all that much what you set it for now, so long as you set it for longer than a few days; the default of eight days is probably good.

Actually, what I just wrote is true unless, that is, you're creating a subnet that will serve computers connecting with wireless 802.1x network cards. Those connections tend to be more short-term, so in that case you might want to set the lease time shorter. What do you do if your subnet supports both wired and wireless connections? Then you have to make the call—short, long, or somewhere in between?

We'll talk more about lease durations when we discuss DHCP internals later. Click Next to move to Figure 7.8.

### SETTING CLIENT OPTIONS

Remember all of those options in the Advanced tab for TCP/IP Properties when you configured static IP addresses in the preceding chapter? Well, you needn't travel around to the workstations and set them, as DHCP lets you configure those things right from the server. DHCP can provide default values for a whole host of TCP/IP parameters, including these basic items:

- ◆ Default gateway
- ◆ Domain name
- ◆ DNS server
- ◆ WINS server

**FIGURE 7.8**  
Configure DHCP  
Options screen.

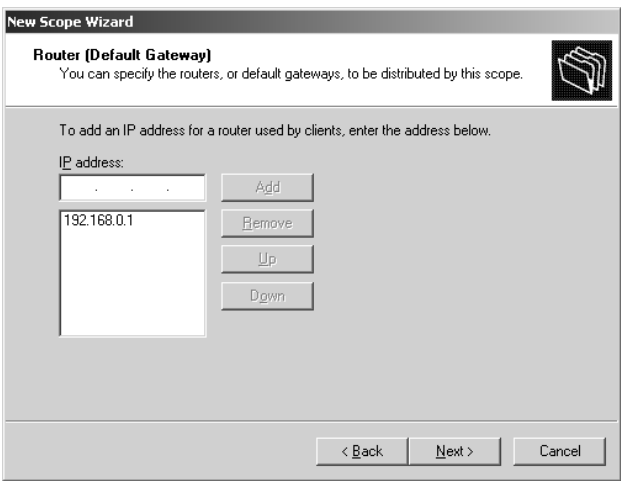

Notice I said *default*. You can override any of these options at the workstation. For example, if you said that by default everyone's DNS server was 10.0.100.1 but wanted one particular PC to instead use the DNS server at 10.200.200.10, then you could just walk over to the PC and use the Advanced button in the TCP/IP properties page (see Chapter 6 if you don't recall how to find that) to enter a DNS name. Even though the DHCP server would offer a DNS server address of 10.0.100.1 to the PC, the PC's DHCP client software would see that the PC had been configured to use 10.200.200.10 instead and would use that address rather than 10.0.100.1. Any other DHCP-supplied options, however, wouldn't be ignored. The general rule is, then:

*Any TCP/IP characteristic specifically configured on the client, such as a DNS server or WINS server, overrides any value that DHCP provides.*

Click Next to tell DHCP that you want to configure these options, and to see the first client option, shown in Figure 7.9.

**FIGURE 7.9**  
Set default gateway.

You may recall that in the last chapter I said that when configuring TCP/IP on a Windows system, the “big four” characteristics, so to speak, are IP address, subnet mask, IP address of the default gateway, and address or addresses of local DNS server(s). By its nature, any DHCP lease gives the first two; this is the third.

Although you *can* enter any number of gateways, there’s no point in entering more than one, as I’ve never found a situation wherein Microsoft’s IP could use a second, third, or fourth possible gateway upon discovering that the first gateway is down. In fact, Microsoft specifically recommends that you only specify *one* default gateway on a system, even if it’s got multiple NICs with independent Internet connections!

Following that advice, I’ve only specified one gateway, as you see in Figure 7.9. Click Next to see the next option screen, as in Figure 7.10.

**FIGURE 7.10**

Set domain name.

**New Scope Wizard**

**Domain Name and DNS Servers**  
The Domain Name System (DNS) maps and translates domain names used by clients on your network.

You can specify the parent domain you want the client computers on your network to use for DNS name resolution.

Parent domain:

To configure scope clients to use DNS servers on your network, enter the IP addresses for those servers.

Server name:	IP address:	
<input type="text"/>	<input type="text"/>	Add
<input type="text"/>	<input type="text"/>	Remove
<input type="text"/>	<input type="text"/>	Up
<input type="text"/>	<input type="text"/>	Down

Resolve

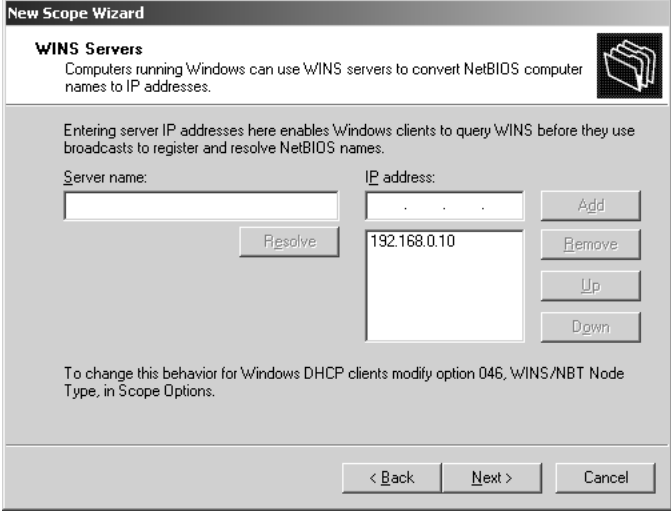

< Back   Next >   Cancel

In this wizard screen, you tell the DHCP server that whenever it leases a client PC an IP address from this scope, it should also set that client PC’s DNS domain name to some value—win2ktest.com, in this case—and to tell the client PC that it can find DNS servers at some address. I’ve chosen *not* to specify DNS servers, however, because *all* of the scopes in my enterprise share two DNS servers, and I don’t want to have to reenter these DNS servers for every scope. As you’ll see in a few pages, I can instead just tell this server, “Give this particular DNS server to *all* scopes.” I have, however, specified a DNS suffix of bigfirm.biz for all systems. That way, every system’s DNS name ends with bigfirm.biz and that means, as you’ll see later in the DNS section, that the system registers itself with the DNS server for bigfirm.biz. Click Next to see the next screen, as in Figure 7.11.

Most of us will still have the necessary evil of WINS servers; here’s where you tell the client where to find your enterprise’s WINS servers.

**FIGURE 7.11**

Set WINS server(s).

**New Scope Wizard**

**WINS Servers**  
Computers running Windows can use WINS servers to convert NetBIOS computer names to IP addresses.

Entering server IP addresses here enables Windows clients to query WINS before they use broadcasts to register and resolve NetBIOS names.

Server name:  IP address:

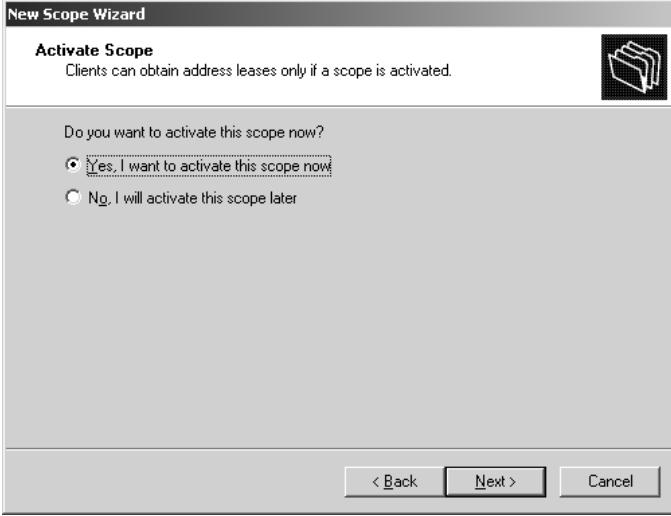

To change this behavior for Windows DHCP clients modify option 046, WINS/NBT Node Type, in Scope Options.

**ACTIVATING THE SCOPE**

Click Next and you can get the scope started, as you see in Figure 7.12.

**FIGURE 7.12**

Activate the scope.

**New Scope Wizard**

**Activate Scope**  
Clients can obtain address leases only if a scope is activated.

Do you want to activate this scope now?

☒ Yes, I want to activate this scope now

☐ No, I will activate this scope later

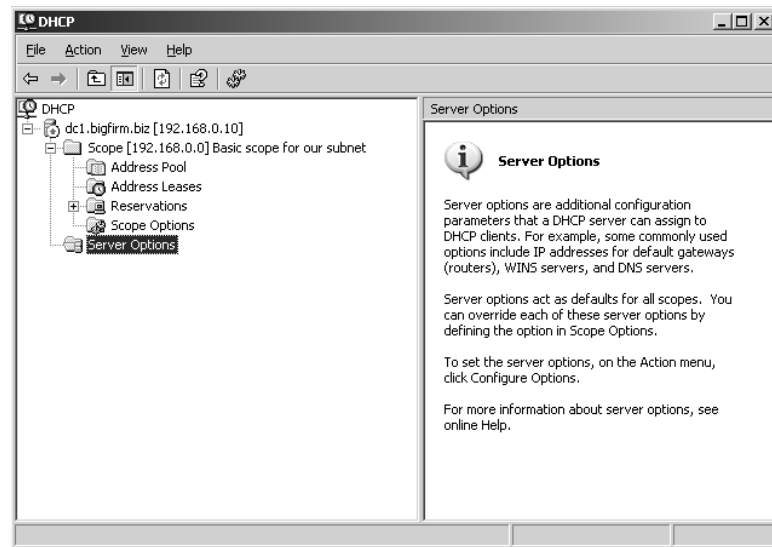

That's all for the basic scope options, so the wizard's done. On the way out, it asks if you're ready for this server to start handing out leases on IP addresses. Click Yes and Next, and the wizard will finish, starting the scope in the process. The DHCP snap-in then looks like Figure 7.13.

Taking a minute and looking at the hierarchy in Figure 7.13 underscores a few things about how DHCP works. The snap-in enables you to control any number of DHCP servers from a central

location, although you see only one in this example screen, the machine at 192.168.0.10. Each server can have several subnets that it serves, with one range of IP addresses for each subnet. The ranges are called scopes, and again this example machine only shows one scope, but could host many—I've seen one large corporate DHCP server that hosts 1200 scopes! Within the scope there are several pieces of information: the range of addresses (**Address Pool**), the list of addresses that this server has given out (**Address Leases**), addresses that we've preassigned to particular systems (**Reservations**, which I'll cover a bit later), and particular TCP/IP settings that the DHCP server should give to any clients (**Scope Options**). If you were to click **Scope Options**, then you'd notice that the options include something we didn't set—WINS/NBT Node Type. That's DHCP-ese for the fact that the client PC will be set up to use a WINS server—in other words—that the client will be set up as something called a *hybrid node*, which I'll cover later in this chapter in the WINS section.

**FIGURE 7.13**

DHCP snap-in with activated scope

### SETTING OPTIONS FOR ALL SCOPES

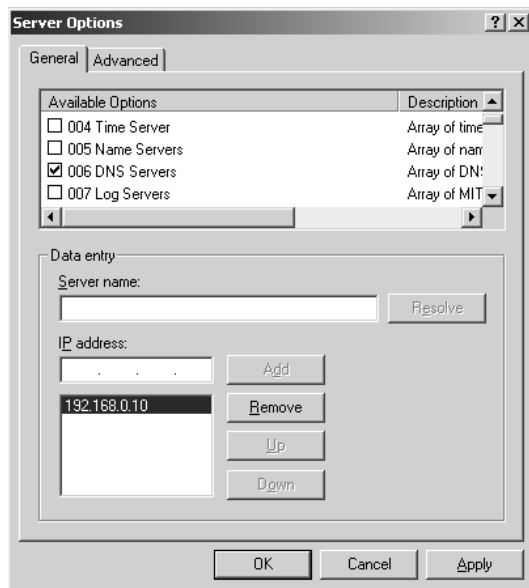

Notice the folder lower in the interface labeled **Server Options**. The server options are useful when you're putting more than one scope on a server. It could be that if you have three different subnets and a couple hundred machines, you've only got two DNS servers, and those machines serve your entire enterprise. When configuring those scopes, it would be a pain to have to retype in those DNS servers—the same two DNS servers—for all three scopes. **Server Options** solves that problem by allowing you to set options for *all* of a given server's scopes in one operation. Just right-click the **Server Options** folder and choose **Configure Options** to see a dialog box like the one in Figure 7.14.

Here I've clicked **DNS Servers**, and you can see that it allows me to enter DNS server addresses, as the wizard did. A bit of scrolling down shows that there are a *lot* of potential DHCP options. But, despite the fact that there seem to be bushels of sadly unused parameters mutely begging to be used, *don't*. Even though they exist, the Microsoft DHCP *client*—the part of Windows, DOS,

Windows 9x, NT, Windows 2000, XP, and 2003 that knows how to get IP addresses from a DHCP server—does not know how to use any options save the ones I just mentioned. Microsoft included the other things just to remain compatible with BOOTP.

**FIGURE 7.14**  
Server Options  
dialog box

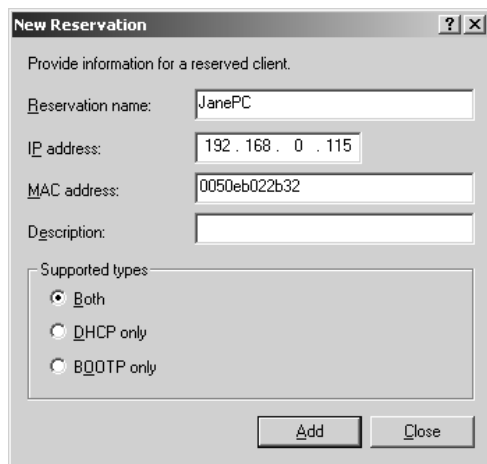

### FORCING A PARTICULAR IP ADDRESS ON A CLIENT: DHCP RESERVATIONS

Sometimes, BOOTP doesn't seem like a bad idea. There are times that you'd like to be able to say, *this* computer gets *that* IP address. Fortunately, it's easy to accomplish that with DHCP reservations.

Look at the DHCP snap-in and you'll see a folder labeled **Reservations**. Right-click that folder and choose **New Reservation**. You'll see a dialog box like the one in Figure 7.15.

**FIGURE 7.15**  
Reserving an IP  
address

Here, you see that I'm assigning the .115 address to a machine with a particular MAC address.

So far, it sounds like DHCP pretty much hasn't changed since NT 4, and in large measure that's true. But it has added superscopes and support for dynamic DNS even on systems that don't understand dynamic DNS. And there's one more interesting difference. Once you've created a reservation, open the **Reservations** folder and you'll see an object representing that reservation. Right-click it and you'll see **Configure Options**; click that and you'll see that you can set things like DNS server, domain name, WINS server, and the like for one specific reservation! Now, that's a pretty neat new feature.

### ADVANCED OPTIONS: USING AND UNDERSTANDING USER AND VENDOR CLASSES

As you've seen, you can assign different DHCP options either to all scopes (the **Server Options** folder) or to a particular scope. You've even seen that you can assign DHCP options to a particular machine's reservation! But there's another way to assign options, through *user classes* and *vendor classes*. Here's how you use them.

You can make a machine a member of a user class by just telling the computer that it's a member of that class. You could have classes such as laptop or test-computers.

Machines are also potentially members of vendor classes, but you can't control that—it's hard-wired into their operating systems. For example, all Windows 2000 machines are automatically members of a vendor class called Microsoft and one called Microsoft Windows 2000; Windows 98 and Me computers are automatically members of vendor classes Microsoft and Microsoft Windows 98. Vendor classes determine what options are available for you to give to your DHCP client.

You can use DHCP to apply a particular option to a particular system. The vendor class determines which options are available to the system—"default" includes the basic by-the-RFC stuff you've always seen, for example, Microsoft vendor options would offer nonstandard new options that would only be relevant to a system running a Microsoft operating system—and the user class determines whether to apply that option. Thus, you could use user and vendor options to say, "If this system is a member of the IBM-laptops class (a user class), then set the Router option (which is in the DHCP Standard Options vendor)."

You can see the user and vendor class controls like so:

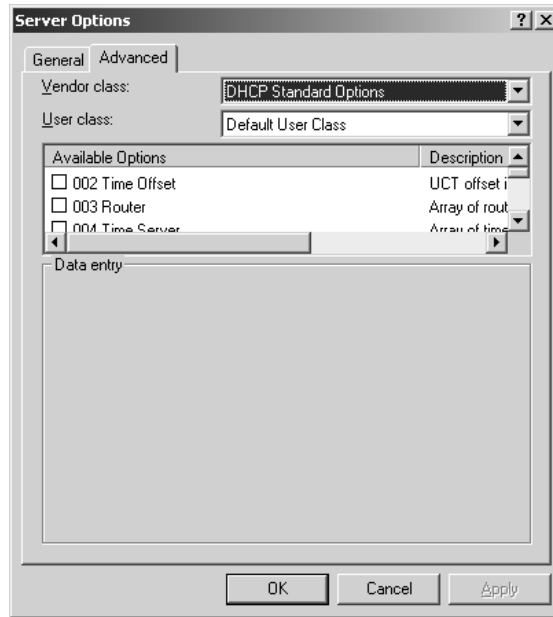

1. Open the DHCP snap-in (Start/Administrative Tools/DHCP).
2. Open either a scope's options or the server options by right-clicking the **Scope Options** or **Server Options** folders and choosing **Configure Options**.
3. Click the **Advanced** tab. You'll see something like Figure 7.16.

### Prebuilt Vendor Classes

Click the Vendor Class drop-down list and you'll see four options: DHCP Standard Options, Microsoft Options, Microsoft Windows 2000 Options, and Microsoft Windows 98 Options. (Interesting that there are Win2K options, but no XP or 2003 options, hmmm?) While DHCP Standard Options is enabled, notice that you get all of the usual options—router, domain name, time server, name server, and so on. But click Microsoft Options, and you'll see a few non-RFC options that Microsoft added.

**FIGURE 7.16**

Advanced tab  
showing vendor  
and user class  
drop-down lists

The Microsoft Disable NetBIOS Option tells the computer to shut down the NetBIOS-over-TCP (NetBT) interface. If you don't know what NetBT is, then don't worry—I'll cover it right after I finish DHCP. But briefly, it's a piece of software that pretty much all NT-aware software built before Windows 2000 depends upon. If you've got an NT 4 workstation logging onto an Active Directory-based domain, then you need NetBT. Most modern networks still have enough pre-2000 stuff around that they still need NetBT, but in time—2004 or 2005, I'd guess—most of us will be able to shut NetBT off. The result, once you can do it, is a noticeably faster network. To enable this—that is, to shut off NetBT—check the box next to Microsoft Disable NetBIOS Option, which will enable the Data Entry/Long field; enter **0x2**.

Check the Microsoft Release DHCP Lease on Shutdown Option and fill the Data Entry/Long field with **0x1** to enable. This tells a Windows 2000 system and later to release its DHCP lease upon shutdown, as the name indicates. Why is this useful? Consider this scenario: An employee works at her laptop in the office during the day, with her laptop connected to the company network via an Ethernet connection. The user shuts down the machine and takes it home. At home, she wants to check her mail, so connects her laptop to a phone line to dial in. She turns on the computer, which sees that it has an Ethernet card that has a DHCP lease. It tries to re-contact the DHCP server but fails, but that's no problem—it's got time on the lease and merrily sets up a TCP/IP stack atop an Ethernet card that's not attached to anything. The user dials up and now the computer has *two* IP stacks—one that actually goes somewhere, via the modem, and one that doesn't do anything. Some services bind to the useless Ethernet card and the user experiences either failures or slow service. One answer: Tell the user to disable the Ethernet card. Another answer: Tell the user to type **ipconfig /release** before shutting down the laptop at work. But the easier answer is to enable this

feature—shutdowns lead to DHCP lease releases. (This would also bedevil users with Ethernet connections at home, so it's a good practice in that case also.)

The third option lets you modify the default metric of DHCP-supplied gateways. I'm honestly not sure where this would be useful.

Click Microsoft Windows 2000 Options, and you'll get the same three options. Click Microsoft Windows 98 Options, and you won't see any options—apparently Microsoft has hard-coded the vendor class into 98 but didn't do much with it. Again, you cannot create new vendor classes of your own.

### **Prebuilt User Classes**

Next, click the User Class drop-down list, and you'll see three prebuilt user classes: Default BOOTP Class, Default User Class, and Default Routing and Remote Access Class. Here's where you'll see each of the classes:

**Default BOOTP Class** All of your Windows 2000, XP, and 2003 systems will be members of this class.

**Default User Class** The class that a system reports if it lacks class (finds belching in public funny, blue screens just for the heck of it, that kind of thing) or, more likely, has a DHCP client that simply doesn't understand what a user class is in the first place—DHCP user classes weren't even a fully accepted RFC standard when Microsoft released Windows 2000. An NT 4 system, then, would end up with Default User Class.

**Default Routing and Remote Access Class** If you're connected via RRAS, then you're in this class. This is potentially a pretty useful class; for example, the DHCP Help for Windows 2000 shows you how to set the lease times for dial-in users—members of the Default Routing and Remote Access Class—to smaller values than for other users; that way, folks who typically only visit a site for a day end up with a day-long rather than a week-long lease.

You can see which user classes a system belongs to (there is no way to view the vendor classes for a system) by typing **ipconfig /showclassid \***; a sample run might look like the following:

```
C:\>ipconfig /showclassid *
```

```
Windows IP Configuration
```

```
DHCP Class ID for Adapter "Local Area Connection":
  DHCP ClassID Name . . . . . : Default
    ↳Routing and Remote Access Class
  DHCP ClassID Description . . . . : User
    ↳class for remote access Clients
  DHCP ClassID Name . . . . . : Default BOOTP Class
  DHCP ClassID Description . . . . : User class for BOOTP Clients
  DHCP ClassID Name . . . . . : Laptop
  DHCP ClassID Description . . . . : Identifies laptops
```

Here, this computer is a member of three user classes—Default BOOTP Class (it's a Windows 2000 computer), Default Routing and Remote Access Class, and a class called Laptop (which I created).

*Note*, however, that you may get different results from an `ipconfig /showclassid *` if you try it on different OSES; for some reason I sometimes get different class IDs when running this on 2000 machines than I do on XP or 2003 machines.

**User-Defined User Classes**

How did I define my own user class? In two steps. First, I told the DHCP server about the new user class and, second, I told some of my workstations that they were members of the class.

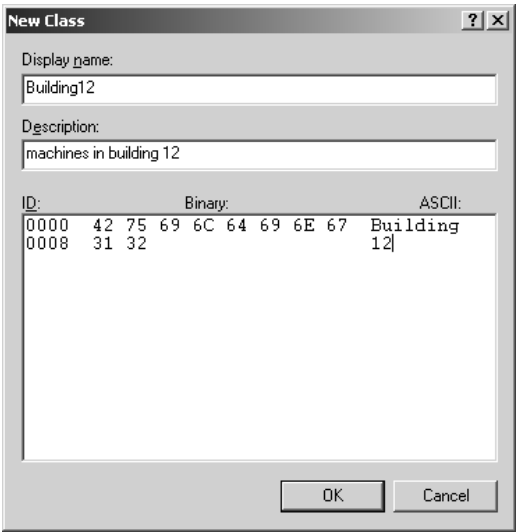

You create a new user class in the DHCP snap-in. Right-click the server's icon and choose Define User Classes, and you'll get a dialog box like the one in Figure 7.17.

**FIGURE 7.17**  
DHCP user classes

This dialog box doesn't show the Default User Class; however, your DHCP server—*every* 2000-based and later DHCP server, in fact—has it. Let's create a new user class and use it. Suppose I want all of the people in building 12 to have the domain suffix `b12.bigfirm.biz`. To create the new user class, I click Add. Then in Display Name I fill in **Building12**, and in Description I fill in **Machines in Building 12**, as you see in Figure 7.18.

**FIGURE 7.18**  
New user class for Building 12

The only non-straightforward part of filling out the dialog box was the ID part; it's not obvious, but you've got to click the mouse in the empty area below the word *ASCII* to be able to type in the class identifier. You can't have blanks in the identifier. Click OK and Close to return to the DHCP snap-in. Now right-click Server Options again and choose Configure Options, click Advanced, and notice that under User Class, there is now a class called Building12. (Case matters—as you'll see in a minute, this won't work unless you add the client machines to a class spelled "Building12" exactly—case and all.) Choose Building12 under User Class. Now you want to assign a particular DNS suffix to the Building12ers, and that's in the default options, so for Vendor Class just choose DHCP Standard Options. Look for the line 015 DNS Domain Name, choose it, and in the Date Entry/String Value field, enter **b12.bigfirm.biz.** and click OK. You're ready on the server side. Don't worry about the hex on the left side; it's just an alternative way of entering the data.

Next, find a machine and make it a member of the Building12 user class. Open a command line and type this:

```
ipconfig /setclassid "Local Area Connection" Building12
```

Then type **ipconfig /renew** and you should get an output something like this:

```
Windows 2000 IP Configuration
Ethernet adapter LAN:

    Connection-specific DNS Suffix  . : b12.bigfirm.biz.
    IP Address. . . . . : 192.168.0.2
    Subnet Mask . . . . . : 255.255.255.0
    Default Gateway . . . . . : 192.168.0.1
    DHCP Class ID . . . . . : Building12
```

Two notes on this:

First, notice in the `ipconfig /setclassid` line where I have "Local Area Connection" in quotes. That is the *name* of your network adapter. Didn't know that it *had* a name? Recall that you saw that in Chapter 6. To see it, right-click My Network Places and choose Properties. The page that results will have an icon for a LAN connection and the name next to it. The default name is *Local Area Connection*, but you can rename it. If you have more than one NIC, then you'll have a different name.

If this doesn't work the first time that you do it, don't be surprised—this often behaves a bit flakily the first time you use it—I have no idea why. Try an `ipconfig /release` after you do the `/setclassid` command before the `ipconfig /renew`.

The DHCP user class will survive reboots; to clear the user class info, type this:

```
ipconfig /setclassid "Local Area Connection"
```

And if your NIC has a different name than Local Area Connection, then substitute that, of course.

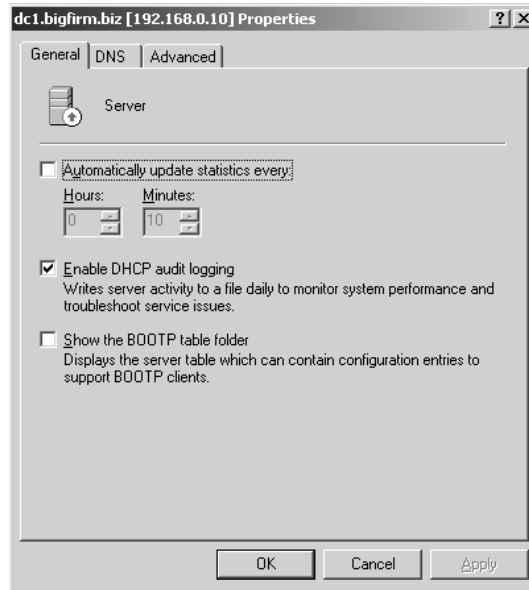

If you script your installs, then you can also set an adapter's class ID by adding this parameter to its [MS\_TCPIP parameters] section:

```
DHCPClassId = name
```

### ADVANCED SERVER CONFIGURATION

Before leaving configuration, let's take a look at some overall server configuration items—in particular, logging and DNS client registration. In the DHCP snap-in, right-click the server and choose Properties. You'll see a page with three tabs. The first is named General, as you see in Figure 7.19.

**FIGURE 7.19**  
General server  
configuration page

The main thing to notice here is the logging option. It's a default option, so don't worry about having to check it. But where is the log kept? Well, for one thing, there are seven logs, one for each day of the week—that makes finding a record for an action on a particular day easier. The logs are in simple ASCII format, so you can examine them with Notepad, although it would be nicer if the DHCP snap-in would go get them for you. They're in `\winnt\system32\dhcp` in files whose names include the day of the week. Part of one log looks like the following:

```
63,07/03/99,00:44:30,Restarting rogue detection,,,
51,07/03/99,00:45:30,Authorization succeeded,,win2ktest.com,
11,07/03/99,00:47:09,Renew,206.246.253.135,
PC400.win2ktest.com,00105A27D97A
10,07/03/99,00:48:00,Assign,206.246.253.2,
PC400.win2ktest.com,5241532000105A27D97A000000000000
10,07/03/99,00:48:00,Assign,206.246.253.3,
PC400.win2ktest.com,5241532000105A27D97A000001000000
63,07/03/99,01:51:51,Restarting rogue detection,,,
51,07/03/99,01:52:52,Authorization succeeded,,win2ktest.com,
```

*Rogue detection* is a process whereby the DHCP server seeks to find unauthorized DHCP servers. To entrap these dastards, the DHCP server craftily pretends it is just a PC looking for an IP address. It gets offers from other DHCP servers, and the DHCP server then checks their IP addresses against

the list of authorized DHCP servers in the Active Directory. If it finds a scoundrel, then it reports that in the Event Viewer.

On the third line, you see that the machine at 206.246.253.135 has “renewed” its IP address—that is to say, it has said to the DHCP server, “You once gave me this IP address and the lease is running out. May I extend the lease?” The two “assign” statements give the .2 and .3 addresses to PC400 to then hand out—you see, PC400 is a RAS server and needs IP addresses to give away to dial-in clients. RAS has given those two addresses for PC400 to use.

The properties page has another interesting tab, the DNS tab. Click it, and you’ll see a screen like the one in Figure 7.20.

**FIGURE 7.20**

Configuring the dynamic DNS client from DHCP

Although DNS is a topic for later in this chapter, let me jump ahead a bit and explain briefly how it works. DNS is a database of machines and names: My local DNS server is the machine that knows there’s a machine named `dc1.bigfirm.biz` with an IP address of `192.168.0.10`. But how does it *know* that? With DNS under NT 4, I’d have to start a program called the DNS Manager and hand-enter the information. But with the DNS client built into Windows 2000 and later OSes, `dc1.bigfirm.biz` is smart enough to talk to its local DNS server and say, “Listen, I don’t know if you knew this, but I’m a machine on the network, my name’s `dc1.bigfirm.biz`, and my IP address is `192.168.0.10`.” Additionally, the DNS server—which is running Server 2003, although any DNS server on Windows 2000 Server or later will work—is smart enough to *hear* this information; older DNS servers wouldn’t be expecting machines to register themselves with their local DNS server, and the local DNS server wouldn’t have a clue about what to do with the information anyway. But post-1998 DNS servers have a feature called *dynamic DNS*, which enables them to accept this name/address (*name registration*) information from other machines rather than having to have a human type the information in.

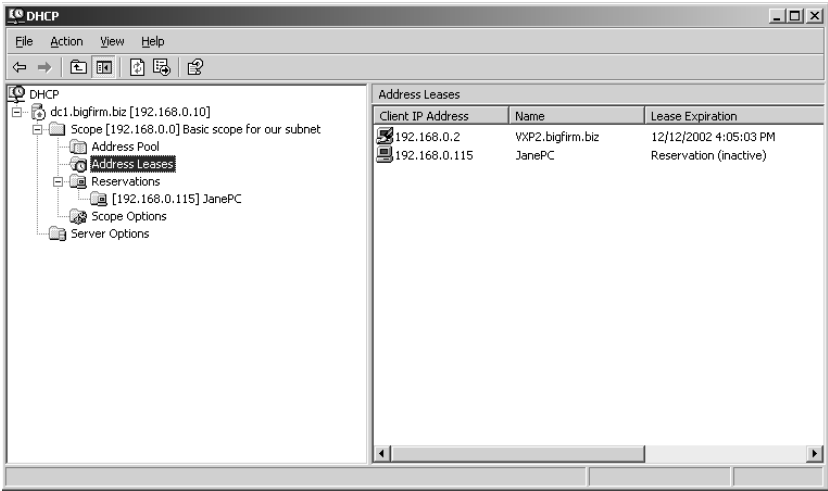

There are two important points to notice in the preceding paragraph. First, the DNS server's got to be smart enough to listen to and act upon the name registrations when they come from the clients. Second, the clients have to be smart enough to *issue* name registration information! If my workstation's running NT 4 rather than Windows 2000 or later, then it hasn't been programmed to offer name/address information to its DNS server because the whole dynamic DNS technology didn't even exist in 1996 when Microsoft wrote NT 4! From the point of view of the state-of-the-art DNS server running on the Windows 2000 or Server 2003, then, the old Windows 9x, Windows for Workgroups, and NT clients are just plain dumb. Or, more exactly, from the point of view of the DNS server, those clients *don't even exist*. There's no way that the DNS server could figure out they are there.

That's what the dialog box in Figure 7.20 accomplishes. This DHCP server will notice when it's handing out an IP address to a machine that doesn't know about dynamic DNS; although the DHCP server cannot modify the code running on the older client, it can fill in for the older client's lack of knowledge, and register the client's name/address with DNS for it. Notice the option labeled Dynamically update DNS A and PTR records for DHCP clients that do not request updates; that's the feature I've been discussing here. Make sure that box is checked, and DHCP will handle the DNS registrations for the older systems.

### Monitoring DHCP

Once you've got a DHCP server set up and running, you may want to find out how many leases remain, who's got those leases, and the like. Open the **Address Leases** folder and you'll see something like Figure 7.21.

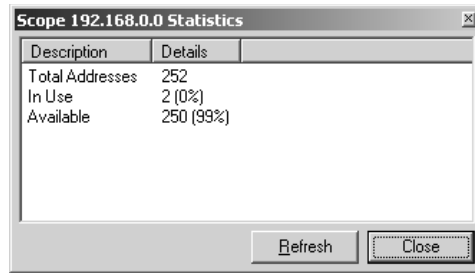

**FIGURE 7.21**  
Assigned leases

This folder displays all of the leases that DHCP has currently outstanding, which machine (by name) has them, as well as the machine's MAC address.

But how many addresses are left? Right-click any scope and choose **Display Statistics**, and you'll see a message box like Figure 7.22.

**FIGURE 7.22**  
Lease statistics

Description	Details
Total Addresses	252
In Use	2 (0%)
Available	250 (99%)

Refresh Close

With just a few clicks, you can bring up this message box and find out whether your network's hunger for IP addresses is being met.

### Rebuilding a Damaged DHCP Server

Once in a while, something goes wrong and you lose a DHCP server. The scopes, reservations, classes...all go poof! and you're in for an hour or two of configuration, assuming that you kept good documentation. If you didn't, well, then it'll take longer...

You can avoid that with just one command. Server 2003 lets you get your DHCP server just so, just as you like it, and then lets you back up the DHCP server's configuration with just one command:

```
netsh dhcp server dump
```

Or, if you're not sitting at the server,

```
netsh dhcp server ipaddress dump
```

That spews line after line of configuration information to your screen. Save it by redirecting it to an ASCII file:

```
netsh dhcp server dump > dhcpbackup.txt
```

Then, if the DHCP server falls apart, all you have to do is to put the DHCP server service on some other machine, copy over your backup file, and use `netsh exec`, like so:

```
netsh exec dhcpbackup.txt
```

You won't get back the lease information, but you'll get everything else—classes, options, scopes, reservations, etc.

### DHCP on the Client Side

Now that you've set up DHCP on a server, how do you tell clients to use that DHCP? Simple. Any Microsoft operating system from Windows for Workgroups to Windows 9x to NT 3.x to NT 4.x to Windows 2000 all have DHCP configuration as an installation option, although some of those clients refer to it as "automatic" configuration rather than DHCP configuration. (By the way, the Microsoft Client software for DOS and Windows supports DHCP as well.)

Once a system has gotten an IP address, you can find out what that address is by going to that system, opening a command line, and typing **ipconfig /all**. On a Windows 95 workstation, click Start/Run, and then type **winipcfg** and press Enter. Windows 98 supports both IPConfig and WINIPCFG. Windows NT only supports IPConfig. IPConfig's useful for other DHCP client-fiddling, as well. You can force a DHCP client to abandon its DHCP-supplied IP address and look for a different one by typing first **ipconfig /release** and then **ipconfig /renew**.

Windows XP, Server 2003, and later Windows versions support an all-in-one command to rebuild an IP connection:

```
netsh int ip reset filename
```

where *filename* is a file that reports the command's progress. I highly recommend learning this command if you've got XP or 2003 (and if you didn't have 2003 then I'm not sure why you'd be reading this book); it's more reliable than the pair of **ipconfigs**.

## DHCP in Detail: How DHCP Works

That's setting up DHCP. But how does it work, and unfortunately, how does it sometimes *not* work?

DHCP supplies IP addresses based on the idea of *client leases*. When a machine (a DHCP client) needs an IP address, it asks a DHCP server for that address. (*How* it does that is important, and I'll get to it in a minute.) A DHCP server then gives an IP address to the client, *but only for a temporary period of time*—hence the term *IP lease*. You might have noticed you can set the term of an IP lease from DHCP; just right-click any scope and choose Properties, and it's one of the settings in the resultant window.

The client then knows how long it's got the lease. Even if you reboot or reset your computer, it'll remember what lease is active for it and how much longer it's got to go on the lease.

### FINDING THE CLIENT LEASE INFORMATION

On a Windows 3.x machine, lease information is kept in DHCP.BIN in the Windows directory. On a Windows 95 machine, it's in HKEY\_LOCAL\_MACHINE\System\CurrentControlSet\Services\VxD\DHCP\Dhcp-infoxx, where xx is two digits. And if you want to enable or disable the error messages from the DHCP client on a Windows 95 machine, it's the value PopupFlag in the key HKEY\_LOCAL\_MACHINE\System\CurrentControlSet\Services\VxD\DHCP; use "00 00 00 00" for false, or "01 00 00 00" for true. Alternatively, opening a command line and typing **ipconfig /release** will erase this information. To find the place in the Registry holding DHCP lease information on an NT machine, run REGEDIT and search for DHCPIPAddress in HKEY\_LOCAL\_MACHINE\System\CurrentControlSet. The key or keys that turn up are the location of the DHCP lease info. On a Windows 2000 system, it's probably `hkey_local_machine\system\currentcontrolset\services\TCPIP\parameters\Interfaces`; within there you'll find GUIDs (Global Unique IDs, the things that look like {CE52A8C0-B126-11D2-A5D2-BFFE72FC}) for each adapter and potential RAS connection. There's a DHCPIPAddress value in each adapter that gets its addresses from DHCP. On Windows XP systems, it's just HKEY\_LOCAL\_MACHINE\SYSTEM\CurrentControlSet\Services, and you'll notice those keys with GUID names right up top; each of those keys has a Parameters\TCPIP key within it. Delete the GUID's key and you eliminate any settings for that adapter. As to figuring out which GUID goes with which adapter, ummm, well, that's a matter of trial and error.

So, if your PC had a four-day lease on some address and you rebooted two days into its lease, then the PC wouldn't just blindly ask for an IP address; instead, it would go back to the DHCP server that it got its IP address from and request the particular IP address that it had before. If the DHCP server were still up, then it would acknowledge the request, letting the workstation use the IP address. If, on the other hand, the DHCP server has had its lease information wiped out through some disaster, then either it will give the IP address to the machine (if no one else is using the address), or it will send a *negative acknowledgment* (NACK) to the machine, and the DHCP server will make a note of that NACK in the Event Log. Your workstation should then be smart enough to start searching around for a new DHCP server. In my experience, sometimes it isn't.

Like BOOTP, DHCP remembers which IP addresses go with what machine by matching up an IP address with a MAC (Media Access Control—that is, Ethernet) address.

Normally a DHCP server can send new lease information to a client only at lease renewal intervals. But DHCP clients also “check in” at reboot, so rebooting a workstation will allow DHCP to reset any lease changes such as subnet masks and DNS services.

**GETTING AN IP ADDRESS FROM DHCP: THE NUTS AND BOLTS**

A DHCP client gets an IP address from a DHCP server in four steps:

1. A *DHCPDISCOVER* broadcasts a request to all DHCP servers in earshot, requesting an IP address.
2. The servers respond with *DHCPOFFER* of IP addresses and lease times.
3. The client chooses the offer that sounds most appealing and broadcasts back a *DHCPREQUEST* to confirm the IP address.
4. The server handing out the IP address finishes the procedure by returning with a *DHCPACK*, an acknowledgment of the request.

**Initial DHCP Request: DHCPDISCOVER**

First, a DHCP client sends out a message called a DHCPDISCOVER saying, in effect, “Are there any DHCP servers out there? If so, I want an IP address.” Figure 7.23 shows this message.

**FIGURE 7.23**  
DHCP step 1:  
DHCPDISCOVER

You might ask, “How can a machine communicate if it doesn’t have an address?” Through a different protocol than TCP—UDP, or the *User Datagram Protocol*. It’s not a NetBIOS or NetBEUI creature; it’s all TCP/IP-suite stuff.

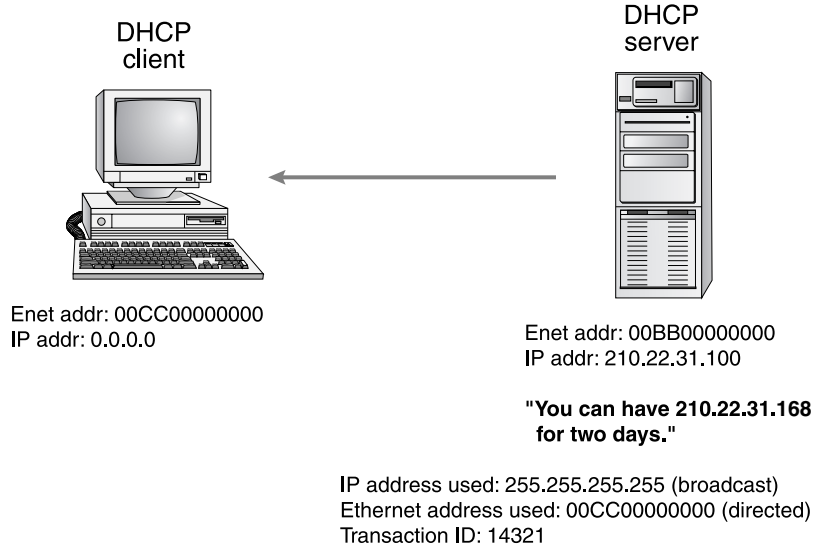

Now, to follow all of these DHCP messages, there are a couple of things to watch. First of all, I’m showing you both the MAC addresses (the 48-bit unique Ethernet addresses) and the IP addresses because, as you’ll see, they tell somewhat different stories. Also, there is a *transaction ID* attached to each DHCP packet that’s quite useful. The transaction ID makes it possible for a client to know when it receives a response from a server exactly *what* the response is responding to.

In this case, notice that the IP address the message is sent to is 255.255.255.255. That’s the generic address for “anybody on this subnet.” Now, 210.22.31.255 would also work, assuming that this is a class C network that hasn’t been subnetted, but 255.255.255.255 pretty much always means “anyone who can hear me.” If you set up your routers to forward broadcasts, then 255.255.255.255 will be propagated all over the network; 210.22.31.255 would not. Notice also the destination Ethernet address, FFFFFFFF. That’s the Ethernet way of saying, “Everybody—a broadcast.”

#### **DHCP Offers Addresses from Near and Far**

Any DHCP servers within earshot—that is, any that receive the UDP datagram—respond to the client with an offer, a proposed IP address, like the one shown in Figure 7.24. Again, this is an offer, not the final IP address.

**FIGURE 7.24**  
DHCP step 2:  
DHCPOFFER

This offering part of the DHCP process is essential because, as I just hinted, it’s possible for more than one DHCP server to hear the original client request. If every DHCP server just thrust an IP address at the hapless client, then it would end up with multiple IP addresses, addresses wasted in the sense that the DHCP servers would consider them all taken, and so they couldn’t give those addresses out to other machines.

**Side Note: Leapfrogging Routers**

Before going further, let's consider a side issue that may be nagging at the back of your mind. As a DHCP client uses *broadcasts* to find a DHCP server, where do routers fit into this? The original UDP message, "Are there any DHCP servers out there?" is a broadcast, recall. Most routers, as you know, do not forward broadcasts—which reduces network traffic congestion and is a positive side effect of routers. But if DHCP requests don't go over routers, then that would imply that you have to have a DHCP server on every subnet—a rather expensive proposition.

The BOOTP standard got around this by defining an RFC 1542, a specification whereby routers following RFC 1542 would recognize BOOTP broadcasts and would forward them to other subnets. The feature must be implemented in your routers' software, and it's commonly known as *BOOTP forwarding*. Even if you live in a one-subnet world, by the way, that's worth remembering, as it's invariably a question on the Microsoft certification exams: "What do you need for client A to communicate with DHCP server B on a different subnet?" Answer: The router between A and B must either "be RFC 1542-compliant" or "support BOOTP forwarding."

Okay, so where do you *get* an RFC 1542-compliant router? Well, most of the IP router manufacturers, such as Compatible Systems, Cisco, and Bay Networks, support 1542. New routers probably already support it; older routers may require a software upgrade. Another approach is to use a Windows 2000 or NT system as a router, as Windows 2000 and NT routing software includes 1542 compliance. But what if you've got dumb routers, or router administrators who refuse to turn on BOOTP forwarding? Then you can designate an NT, Windows 2000, or Server 2003 machine as a *DHCP relay agent*.

A DHCP relay agent is just a computer that spends a bit of its CPU power listening for DHCP client broadcasts. The DHCP relay agent knows there's no DHCP server on the subnet (because you told it), but the relay agent knows where there *is* a DHCP server on another subnet (because you told it). The DHCP relay agent then takes the DHCP client broadcast and converts it into a directed, point-to-point communication straight to the DHCP server. Directed IP communications can cross routers, of course, and so the message gets to the DHCP server.

What do you need to make a DHCP relay agent? Well, with NT 4, you could use any NT machine—workstation or server. For some annoying reason, Windows 2000 and Server 2003 only include software to make a DHCP relay agent with Server.

To make an NT machine into a DHCP relay agent, just open the Control Panel, then the Network applet. Click the Protocols tab and double-click the TCP/IP protocol. In the resulting dialog box, you'll see a tab labeled DHCP Relay. Click it, and you'll see a dialog box like the one shown in Figure 7.25.

To make this work, just click the Add button and fill in the IP address of a DHCP server or servers. The dialog box is simple, but there are two things that confuse people about making a computer into a DHCP relay agent, so let me note them in the following tip and warning.

**TIP** *The NT DHCP relay agent can run on any NT system; the system needn't be a router.*

Under no circumstances should you make a DHCP server into a DHCP relay agent. The net effect will be for the DHCP server to essentially "forget" that it's a DHCP server and instead just forward every request that it hears to some other DHCP server. This prompts me to wonder why the silly DHCP relay agent function isn't grayed out altogether on a DHCP server—certainly the Obtain an IP Address from a DHCP Server option is.

**FIGURE 7.25**

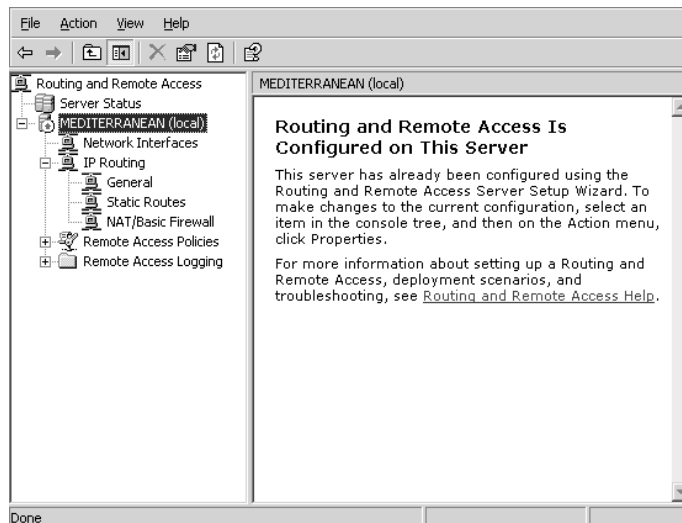

Configuring an NT 4 computer to be a DHCP relay agent

To make a Windows 2000 Server or Server 2003 system—remember, Server only—into a DHCP relay agent, you’ve got to use Routing and Remote Access Service. Basically any RRAS configuration will do; you needn’t enable WAN routing or dial-in. Look back to Chapter 6 to see how to configure an RRAS system—again, click Start/Administrative Tools/Routing and Remote Access, then right-click the server’s name and choose Configure and Enable Routing and Remote Access to start the wizard, then choose Custom Configuration, click Next, check the box next to LAN Routing, and finish the wizard. You’ll see a screen like the one in Figure 7.26.

**FIGURE 7.26**

RRAS main screen

Open the IP Routing object (click the plus sign) and one of the objects you'll see inside it will be a folder labeled General. Right-click the General folder and choose New Routing Protocol to see another dialog box. One of the options offered will be DHCP Relay Agent; choose it and click OK. Back in the RRAS snap-in, you'll now have an object under IP Routing named DHCP Relay Agent, as you see in Figure 7.27.

**FIGURE 7.27**  
RRAS console  
with DHCP  
Relay Agent  
highlighted

Right-click the DHCP Relay Agent object and choose Properties and you'll see a dialog box like the one in Figure 7.28.

**FIGURE 7.28**  
Relay agent config-  
uration screen

You configure the agent by telling it where to find DHCP servers. Enter the IP address of the DHCP server and click Add to add a server to the list. Finally, you've got to enable the agent to listen on the local network for DHCP requests to forward. Right-click DHCP Relay Agent and choose New Interface. Choose Local Area Connection and the agent will then be active on the network.

Discussion of relay agents and 1542-compliant routers leads me to yet another question. What if a DHCP server from another subnet gave an IP address to our client? Wouldn't that put the client in the wrong subnet? If a DHCP server serves a bunch of different subnets, how does it know which subnet an incoming request came from? DHCP solves that problem with BOOTP forwarding.

Assuming that your routers implement BOOTP forwarding, then a client's original DHCP request gets out to all of them. But how do you keep a DHCP server in an imaginary subnet 200.1.2.z from giving an address in 200.1.2.z to a PC sitting in another imaginary subnet, 200.1.1.z? Simple. When the router forwards the BOOTP request, it attaches a little note to it that says, "This came from 200.1.1.z." The DHCP server then sees that information, and so it only responds if it has a scope within 200.1.1.z.

Notice that although to the higher-layer protocol (UDP) this is a broadcast, the lower-layer Ethernet protocol behaves as though it is not, and the Ethernet address embedded in the message is the address of the client, not the FFFFFFFF broadcast address. Notice also that the transaction ID on the response matches the transaction ID on the original request. End of side trip, let's return to watching that client get its address from DHCP.

### **Picking from the Offers**

The DHCP client then looks through the offers it has and picks the one that's "best" for it, or so the Microsoft documentation says. In my experience—and I've done a bunch of experiments—"best" means "first." It seems that the first server that responds is the one whose offer it accepts. Then it sends another UDP datagram, another broadcast, shown in Figure 7.29.

**FIGURE 7.29**

DHCP step 3:  
DHCPREQUEST

It's a broadcast because this message serves two purposes. First, the broadcast *will* get back to the original offering server if the first broadcast got to that server, which it obviously did. Second, this broadcast is a way of saying to any *other* DHCP servers who made offers, "Sorry, folks, but I'm taking this other offer."

Notice that both the Ethernet and the IP addresses are broadcasts, and there is a new transaction ID.

### ***The Lease Is Signed***

Finally, the DHCP server responds with the shiny brand-new IP address, which will look something like Figure 7.30.

**FIGURE 7.30**

DHCP step 4:  
DHCPC

It also tells the client its new subnet mask, lease period, and whatever else you specified (gateway, WINS server, DNS server, and the like). Again, notice it's a UDP broadcast, but the Ethernet address is directed, and the transaction ID matches the previous request's ID.

You can find out what your IP configuration looks like after DHCP by typing **ipconfig /all**. It may run off the screen, so you may need to add **more** to the line. This works on DOS, Windows for Workgroups, and NT machines. You can see a sample run of **ipconfig /all** in Figure 7.31. Windows 95 machines have a graphical version of IPConfig called WINIPCFG.

### ***Lost Our Lease! Must Sell!***

What happens when the lease runs out? Well, when that happens, you're supposed to stop using the IP address. But you're not likely to lose that lease—Windows DHCP client software is pretty vigilant about keeping its DHCP leases as long-lived as is possible.

When the lease is half over, the DHCP client begins renegotiating the IP lease by sending a DHCP request to the server that originally gave it its IP address. The IP and Ethernet addresses are both specific to the server.

**FIGURE 7.31**  
Run of IPConfig

```

C:\>ipconfig /all

```

The DHCP server then responds with a DHCPACK. The benefit of this is that the DHCPACK contains all of the information that the original DHCPACK had—domain name, DNS server, and so on. That means you can change the DNS server, WINS server, subnet mask, and the like, and the new information will be updated at the clients periodically, but no more than 50 percent of the lease time.

Now, if the DHCPACK doesn't appear, then the DHCP client keeps resending the DHCP request out every two minutes until the IP lease is 87.5 percent expired. (Don't you wonder where they get these numbers from?) At that point, the client just goes back to the drawing board, broadcasting DHCPDISCOVER messages until someone responds. If the lease expires without a new one, the client will stop using the IP address, effectively disabling the TCP/IP protocol on that workstation.

But if you've messed with the DHCP servers, then the renewal process seems to get bogged down a bit. It's a good idea in that case to force a workstation to restart the whole DHCP process by typing **ipconfig /renew** or, better, **ipconfig /release** followed by **ipconfig /renew**; that will often clear up a DHCP problem.

Even with an infinite lease, however, a DHCP client checks back with its server whenever it boots. Therefore, you can often change from infinite to fixed leases by just changing the lease value at the server. Then stop and restart the DHCP service.

## Designing Multi-DHCP Networks

Clearly the function of the DHCP server is one that shouldn't rest solely on the shoulders of one server (well, okay, servers don't have shoulders, but you know what I mean). So, how can you put two or more DHCP servers online to accomplish some fault tolerance?

Microsoft seems a bit confused about how to go about providing multiple DHCP servers for a given subnet and has offered different advice at different times.

In one document, *Windows NT 3.5 Family Upgrade Course*, it said several things. First, "There is no mechanism in DHCP that allows two or more DHCP servers to coordinate the assignment of IP addresses from overlapping IP address pools."

No argument there. If you had two different DHCP servers on the same subnet, and they both thought that they could give out addresses 202.11.39.10 through 202.11.39.40, then there would be nothing keeping the first server from giving address 202.11.39.29 to one machine while simultaneously the other server was giving out that same 202.11.39.29 address to another machine. (It's almost as if helpful Tom has returned!)

Then, it goes on (pages 147 and 148) to demonstrate two different machines running DHCP server and each machine having a different scope. Both scopes are, however, taken from a single subnet.

In contrast, the NT Resource Kit (version 3.5, but 3.51 has no updates on the matter) takes issue with the idea of more than one scope referring to a subnet like so: "Each subnet can have only one scope with a single continuous range of IP addresses."

What this boils down to is this: I don't know what the official Microsoft approach to DHCP fault tolerance *is*. I *do*, however, know what works and what has worked for me. Like many people, I came up with an approach such as the one in the NT training guide. I just run DHCP on multiple machines and create multiple scopes that refer to the same subnet. I make absolutely sure that the ranges of addresses in the scopes do not overlap at all, and everything seems to work fine.

I guess I should note for the sake of completeness that you can provide fault tolerance for DHCP servers by putting your DHCP server on a cluster of two or more machines. A perfectly valid answer, but not a very cheap one.

## Name Resolution in Perspective: Introduction to WINS, NetBIOS, DNS, and Winsock

Consider the following two commands, both issued to the same server:

```
ping server01.bigfirm.com
```

and

```
net use * \\server01\mainshr
```

In the ping command, the server is referred to as server01.bigfirm.com. In the `net use` command, that same server is called server01. The difference is important for these reasons.

Ping relies upon a traditionally Internet-oriented programming interface called *Winsock*, and any program running Ping generally needs access to something called a *DNS server* in order to execute the ping command.

`net use` relies upon a traditionally Microsoft networking-oriented programming interface called *NetBIOS*, and any program running `net use` generally needs access to something called a *WINS server* to execute the `net use` command.

Let's do a bit of background work in order to understand Winsock, DNS, NetBIOS, and WINS.

### Two Different Lineages, Two Different Names

The ping command is clearly a TCP/IP/Internet kind of command. You can't run it unless you're running TCP/IP, and as a matter of fact, it's a valid command on a Unix, VMS, Macintosh, or MVS machine so long as that machine is running a TCP/IP protocol stack.

In contrast, `net use` is a Microsoft networking command. You can do a `net use` on an NT network no matter what protocol you're running, but the command usually wouldn't be valid on a Unix, VMS, Macintosh, or whatever kind of machine; in general, Microsoft networking is pretty much built to work on PCs. (Yes, I know, NT is in theory architecture-independent, so you could find an Alpha machine using `net use` commands, but on the whole, NT is an Intel x86 operating system at this writing—and I haven't seen announcements of an NT/390 for the IBM mainframe world, NT VAX for the Digital world, or NT SPARC for the Sun world.)

## Application Program Interface = Modularity

The difference is in the network application programming interface (API) that the application is built atop. API? What's that?

Well, years ago, most PC software had no understanding of networks at all. But that's not true anymore; there are many "network-aware" programs around. For example, the software that lets a Server 2003 system be a file server is network aware; what good would a file server be without a network? Other network-aware server software includes Web servers such as Internet Information Server or e-mail servers such as Exchange.

Desktop machines—*clients*—use network-aware software as well. The program that lets you browse file servers with My Network Places on Windows 2000 and later systems, browse Network Neighborhood on Windows 9x and NT 4 systems, or do command-line commands such as `net view` (which lets you view the servers in a workgroup or the shares on a server) or `net use` is generically called a "client for Microsoft networking" and is network aware. So also is a Web browser (the client software for a Web server, like Internet Explorer) or an e-mail client.

But the programmers who build network-aware applications such as file server clients or Web browsers aren't generally the programmers who write the rest of the networking software—the NIC drivers, the protocols, and so on. Different pieces of network software are usually designed to fit together in a modular fashion. But the only way that the folks who write the Web browsers can remain compatible with the folks who write the TCP/IP code is if the application developers and the protocol developers agree on an interface, a kind of "software connector" between the two pieces of software. More and more, designers build software to be modular specifically so that the Web browser people don't have to coordinate closely with the TCP/IP protocol-writing people.

The interface between a protocol and the applications that rely on it is called the *application programming interface* (API). Think of an API as being something like the controls you use when driving a car. Your car's steering wheel, accelerator, and other controls form the interface that you see, and you learn to use them to operate the car. You might have no idea while you're driving what's under your car's hood—you just push down the accelerator and the car goes faster. If someone snuck into my garage tonight and replaced the internal combustion engine in my Honda with a magic engine that didn't use gas, I would have no idea, nor would I care until I eventually noticed that the gas gauge seemed to be broken. As a driver, I really don't have to know anything at all about engines—all I've got to know is that the pedal on the right makes the car go faster. So long as the magic engine makes the car go vroom-vroom when I push down the right pedal, I'm happy.

The "automobile API" consists of a few "primitive" commands: Brake the car, accelerate the car, shift the car's transmission, and so on. There is no command "back the car out of the driveway," and yet I can still back a car out of a driveway by just assembling several of the primitive commands into the actual action of backing a car out of a driveway. The best part about this generic automobile

API is that once you learn how to drive one car, you can instantly use another. In other words, you are an “application designed for the car driver controls API.”

In contrast, consider how private pilots learn to fly. They have two pedals on the floor of their plane, but the left pedal turns them left and the right pedal turns them right. Someone trained as a private pilot would be an “application designed for the private plane API.” Taking someone who can fly a plane and plunking him down in a car without any other training wouldn’t work too well. In the same way, if an application is built for *one* network API, then it won’t work on another. But if you built a car whose controls acted like an airplane’s, airplane pilots could drive the car without any trouble.

## NetBIOS and Winsock

I’m stretching a point a bit here, but I could say that cars and planes are just different ways of solving the same problem: transportation. In the same way, various network vendors over the years have tackled the same problem and come up with different solutions. In particular, Microsoft has, since 1985, built its network applications atop a network API called the Network Basic Input-Output System (NetBIOS) that first appeared on a product from a company called Sytek and that was later promoted and expanded by IBM and Microsoft. The Internet world, on the other hand, has used a different network API called *sockets*. In the Microsoft world, we call our special version of sockets *Winsock*.

Recall that the value of an API is that it separates your network applications from your network vendor—you needn’t buy your network operating system from the same people you bought your network fax software from. For example, if you buy a network fax application designed for a network API named NetBIOS, you should be able to run that network fax application on any network at all, so long as the network supports the NetBIOS API. Over time, we’ve seen a number of seemingly dissimilar networks that all sported NetBIOS as their API, including Lantastic, OS/2 LAN Server, LAN Manager, HP’s LM/UX, Digital’s PathWorks, Windows for Workgroups, and the NT family. Code written for one of these networks could run with little or no changes on any of the others.

Similarly, at one time there were several vendors selling a version of TCP/IP for Windows for Workgroups back in 1992–1994. If the Winsock implementations on each of those TCP/IP versions were built right, then you should have been able to run the exact same copy of Eudora Light (a free Internet e-mail program) or Netscape Navigator on any of them.

Can your network live with just Winsock or NetBIOS programming interfaces? Probably not. You want to run the NetBIOS-based programs because anything written for Microsoft networks prior to Windows 2000 was written to run on NetBIOS. And you want to run Winsock-based programs because so many Internet-type applications exist—the Web and e-mail stand out, but there are many more—and they’re built to work with Winsock.

In fact, one of the major changes in NT wrought by Windows 2000 (and later OSes) was that almost all of Windows 2000’s networking will work fine on Winsock and doesn’t need NetBIOS at all. (Not everything; for example, some Exchange 2000 configurations need NetBIOS, and server clusters need NetBIOS, as does the ability to restrict users to only logging onto specific workstations.) But any Windows 9x, Workgroups, or NT system needing to access data on Windows 2000 or Server 2003 servers will do so via NetBIOS. Similarly, any pre-Windows 2000 applications running on a Windows 2000 system can only run atop NetBIOS, even if all of the systems in the network are Windows 2000 systems. The result is that virtually all Windows 2000 systems need a complete NetBIOS infrastructure.

## Name Resolution Defined

Something that both NetBIOS and Winsock have in common is that they both want to support easy-to-work-with machine names. Yes, every machine on the Internet and on virtually all Server 2003 networks has a unique IP address, but no one wants to use that to identify servers: Opening My Network Places should show servers with names such as `\\PERSONNEL` rather than `220.10.99.32`, and Amazon wants to be able to tell you to shop for books at `www.amazon.com` rather than `208.216.182.15`. So we need some kind of database server around that can translate `www.amazon.com` to `208.216.182.15` and `\\PERSONNEL` to `220.10.99.32`. This problem of converting a name into an IP address is called *name resolution*. For NetBIOS and Winsock, it's the same problem but with two different solutions. NetBIOS looks for its name resolution from a Windows Internet Name Service (WINS) server; Winsock looks for its name resolution from a Domain Name System (DNS) server.

NetBIOS versus Winsock still not clear? Then consider one more analogy. Think of the APIs as communications devices. Telephones and the mail service are communications devices, also, so I'll use them in an analogy. Ping's job is to communicate with some other PC, and `net use` also wants to communicate with some PC. But Ping uses Winsock (the telephone) and `net use` uses NetBIOS (the mail). If you use the telephone to call a friend, then that friend's "name" as far as the phone is concerned may be something like (707) 555-2121. As far as the mail is concerned, however, the friend's "name" might be Paul Jones, 124 Main Street, Anytown, VA, 32102. Both are perfectly valid "names" for your friend Paul, but they're different because different communications systems need different name types. In the same way, `server01.bigfirm.com` and `\\server01` are both perfectly valid but different names for the same server.

## Handling Legacy and NetBIOS Names: The Windows Internet Name Service

Anyway, for those of you NT 4 vets hoping that WINS would bite the dust in Windows 2000 or *certainly* by Server 2003, I've got to report that sorry, looks like we've still got to support it. So let's see how to support this "legacy name resolving system." (*Legacy* is computer industry-ese for "crappy old stuff that we hate and that's why we upgraded in the first place, but we can't seem to get rid of all of it and so now we have to support both the new incomprehensible stuff *and* the crappy old stuff." But *legacy* sure makes it sound better, at least to me.)

## NetBIOS atop TCP/IP (NBT)

The NetBIOS API is implemented on the NetBEUI, IPX/SPX, and TCP/IP protocols that Microsoft distributes. That makes Microsoft's TCP/IP a bit different from the TCP/IP you find on Unix (for example), because the Unix TCP/IP almost certainly won't have a NetBIOS API on it; it'll probably only have the TCP/IP sockets API on it. (Recall that as with all PC implementations of TCP/IP, Microsoft's TCP/IP form of sockets is called the Winsock API.)

NetBIOS on the Microsoft implementation of TCP/IP is essential, again to make older operating systems and applications happy. And NetBIOS over TCP (which is usually abbreviated NBT or NetBT) needs a name resolver.

Now, basic old NetBIOS converted names to network addresses by just broadcasting—"Hey, I'm looking for `\\AJAX`; if you're out there, `\\AJAX`, tell me your IP address!"—but clearly that's not going to be the answer in a routed environment; all of those "name resolution shouts" will stop dead at the routers. If `\\AJAX` is across a router from us, our software will never find `\\AJAX`.

NetBIOS name resolution over TCP/IP is, then, not a simple nut to crack. Many people realized this, and so there are two Internet RFCs (Requests for Comment) on this topic, RFC 1001 and 1002, published in 1986.

### **B NODES, P NODES, AND M NODES**

The RFCs attacked the problem by offering options.

The first option was sort of simplistic: Just do broadcasts. A computer that used broadcasts to resolve NetBIOS names to IP addresses is referred to in the RFCs as a *B node*. To find out who server01 is, then, a PC running B node software would just shout out, “Hey! Anybody here named server01?”

Simple, yes, but fatally flawed: Remember what happens to broadcasts when they hit routers? As routers don’t rebroadcast the messages to other subnets, this kind of name resolution would only be satisfactory on single-subnet networks.

The second option was to create a name server of some kind and to use that. Then, when a computer needed to resolve a name of another computer, all it needed to do was send a point-to-point message to the computer running the name server software. As point-to-point messages *do* get retransmitted over routers, this second approach would work fine even on networks with routers. A computer using a name server to resolve NetBIOS names into IP addresses is said to be a *P node*.

Again, a good idea, but it runs afoul of all of the problems that DNS had. *What* name server should be used? Will it be dynamic? The name server for NetBIOS name resolution is, by the way, referred to as a NetBIOS name server, or NBNS.

The most complex approach to NetBIOS name resolution over TCP/IP as described in the RFCs is the *M node*, or *mixed* node. It uses a combination of broadcasts and point-to-point communications to an NBNS.

### **MICROSOFT FOLLOWS THE RFCs, ALMOST**

When Microsoft started out with TCP/IP, it implemented a kind of M node software. It was “point-to-point” in that you could look up addresses in the HOSTS file, or a file called LMHOSTS, and if you had a DNS server, then you could always reference that; other than those options, Microsoft TCP/IP was mainly B node-ish, which limited you to single-subnet networks. (Or required that you repeat broadcasts over the network, clogging up your network.) Clearly, some kind of NBNS was needed, and the simpler it was to work with, the better. As the RFCs were silent on the particulars of an NBNS, vendors had license to go out and invent something proprietary and so they did—several of them, in fact, with the result that you’d expect: None of them talk to each other.

That’s where WINS comes in.

WINS is simply Microsoft’s proprietary NBNS service. What makes it stand out from the rest of the pack is Microsoft’s importance in the industry. They have the clout to create a proprietary system and make it accepted widely enough so that it becomes a *de facto* standard.

Microsoft’s NetBIOS-over-TCP client software not only implements B, P, and M nodes, it also includes a fourth, non-RFC node type. Microsoft calls it an H, or Hybrid, node.

But wait a minute; isn’t *M node* a hybrid? Yes. Both M nodes and H nodes (and note well that at this writing, M nodes are RFCed and H nodes aren’t) use both B node and P node, but the implementation is different:

- ◆ In M node, do a name resolution by first broadcasting (B node) and then, if that fails, communicate directly with the NBNS (P node).
- ◆ In H node, try the NBNS first. If it can’t help you, then try a broadcast.

### M NODE VERSUS H NODE

“Hmmm,” you may be saying, “Why would anyone want to first broadcast, *then* look up the answer in the name server? Why clutter up the network cable with useless broadcasts when we could instead go right to the source and reduce network chatter?”

The answer is that it’s a matter of economics. Recall that the RFCs on NetBIOS over TCP were written back in the mid-1980s, when a typical PC had perhaps an 8MHz clock rate and a 5MHz internal bus. An Ethernet full of XTs would have had a lot of trouble loading the network enough for anyone to even notice. The bottleneck in networks in those days was the CPU or disk speed of the network server. But if the network includes routers—and if it doesn’t, then broadcasting is all you need—then consider what the routers are connected to: wide area network links, probably expensive 9600, 14,400, or 19,200bps leased lines. In a network like this, the LAN was a seemingly infinite resource, and wasting it with tons of broadcasts was of no consequence. In contrast, creating more traffic over the WAN by having every machine ask for NetBIOS names (presuming the NetBIOS Name Server was across the WAN link) could greatly reduce the effectiveness of that expensive WAN. Besides, the reasoning went, the vast majority of the time a PC only wanted to talk to another PC on the same LAN, so broadcasts would suffice for name resolution most of the time. The result? M nodes.

The economic picture in 1994, when Microsoft was inventing WINS, was another story entirely: LANs were clogged and WAN links were far cheaper—so H nodes made more sense.

You can force any DHCP client to be a B, P, M, or H node. One of the options that you can configure via DHCP is the WINS/NBNS Node Type. You give it a numeric value to set the client’s NetBIOS name resolution technique. A value of 1 creates a B node, 2 is used for a P node, 4 for an M node, and 8 for an H node, the recommended node type.

### UNDERSTANDING THE NBT NAMES ON YOUR SYSTEM

A major part of the NetBIOS architecture is its lavish use of names. A workstation attaches up to 16 names to itself. Names in NetBIOS are either group names, which can be shared—workgroups and domains are two examples—or normal names, which can’t be shared, like a machine name. As you’ll soon see that WINS keeps track of all of these names, you may be curious about what all of them *are*—so let’s take a minute and look more closely into your system’s NetBIOS names.

You can see the names attached to your workstation by opening a command line from a Windows for Workgroups, Windows 95, NT, Windows 2000, or XP machine and typing **nbstat -n**. You get an output like this:

Node IpAddress: [192.168.0.41] Scope Id: []

NetBIOS Local Name Table

Name	Type	Status
-----	-----	-----
GX240	<00> UNIQUE	Registered
WIN2KTEST	<00> GROUP	Registered
GX240	<03> UNIQUE	Registered
GX240	<20> UNIQUE	Registered
WIN2KTEST	<1E> GROUP	Registered
MM100	<03> UNIQUE	Registered

In this example, the WIN2KTEST group names are my workgroup and domain. GX240 is my machine’s name, and MM100 is my name—notice that NetBIOS registers not only the machine name, but the person’s name as well. You can see the list of registered names on any computer in your network by typing **nbstat -A <ip address>**, where the **-A** *must* be a capital letter.

But why is there more than one GX240? Because each different part of the Microsoft network client software requires names of its own, so they take your machine name and append a pair of hex digits to it. That’s what the <00>, <20>, and the like are—suffixes controlled by particular programs. For example, if some other user on the network wanted to connect to a share named STUFF on this computer, she could type **net use \* \\gx240\stuff**, and the redirector software on her computer would then do a NetBIOS name resolution on the name GX240<00>, as the <00> suffix is used by the redirector. Table 7.1 summarizes suffixes and the programs that use them.

TABLE 7.1: EXAMPLES OF MACHINE NAMES

UNIQUE NAMES	WHERE USED
<computername>[00h]	Workstation service. This is the “basic” name that every player in a Microsoft network would have, no matter how little power it has in the network.
<computername>[03h]	Messenger service. Used for administrative alerts or pop-up messages; NET SEND messages use this name. Without this, you can’t get NET SEND messages. (Or the irritating online spam that some people do with this service.)
<computername>[06h]	RAS Server service.
<computername>[1Fh]	NetDDE service; will only appear if NetDDE is active or if you’re running a NetDDE application. (You can see this by starting up Network Hearts, for example.)
<computername>[20h]	Server service; name will only appear on machines with file/printer sharing enabled.
<computername>[21h]	RAS Client service.
<computername>[BEh]	Network Monitor agent.
<computername>[BFh]	Network Monitor utility.
<username>[03h]	Messenger service; any computer running the Messenger service (which is just about any MS networking client) would have this so that NET SEND commands to a user could be received.
<domain name>[1Bh]	This system is the primary domain controller (or PDC emulator, if the domain is Active Directory). There is only one of these per domain.
<domain name>[1Ch]	This says that this machine is a domain controller on this domain. In NT 4 domains it means that it could be either a BDC or the PDC. This is, therefore, not a unique name; more than one DC can exist, so more than one system can have this name.

Continued on next page

TABLE 7.1: EXAMPLES OF MACHINE NAMES (continued)

UNIQUE NAMES	WHERE USED
<domain name>[1Dh]	Master browser.
<domain name>[00h] or <workgroup name>[00]	Domain name; indicates that the computer is a member of the domain and/or workgroup. If a client is a member of a workgroup whose name is different from a domain, then no domain name will be registered on the client.
<domain name>[1Eh] or <workgroup name>[1Eh]	Used in browser elections, indicates that this computer would agree to be a browser. Will only show up on servers. (Potential browser.)
MSBrowse	Domain master browser.

No matter what kind of computer you have on a Microsoft enterprise network, it will have at least one name registered—the <computer name>[00] name. Most computers also register <workgroup>[00], which proclaims them as a member of a workgroup. Those are the only two names you would see if you had a DOS workstation running the old LAN Manager network client without the Messenger service or a Windows for Workgroups 3.1 (not 3.11) workstation that had file and printer sharing disabled.

Most modern client software would also have the Messenger service enabled and so would have the <computer name>[03] and <username>[03] names registered, as well.

Adding file and/or printer sharing capabilities to a computer would add the <computer name>[20] name. Servers all agree to be candidates for browse master by default, so unless you configure a machine to *not* be a candidate for browse mastering, then the <workgroup name>[1E] name will appear on any machine offering file or printer sharing. If the machine happens to be the browse master, it'll have <workgroup name>[1D] as well. Workstations use the [1D] name to initially get a list of browse servers when they first start up: They broadcast a message looking to see if the [1D] machine exists, and if it does, then the [1D] machine presents the workstation with a list of potential browsers.

Browse masters get the network name [01][02]\_\_MSBROWSE\_\_[02][01] as well—it's a group name, and only the *master* browsers are members. Master browsers use that name to discover that each other exists.

Name Resolution before WINS: LMHOSTS

Clients written prior to WINS, or clients without a specified WINS server, try to resolve a NetBIOS name to an IP address with several methods. The tools they'll use, if they exist, are:

- ◆ A HOSTS file, if present
- ◆ Broadcasts
- ◆ An LMHOSTS file, if present
- ◆ A DNS server, if present

You met HOSTS before—it's just a simple ASCII file. Each line contains an IP address, at least one space, and a name. LMHOSTS works in a similar way to HOSTS. And yes, you'd do well to

understand LMHOSTS, as it solves many name resolution problems with pre-Windows 2000 servers and perhaps even Windows 2000 Servers or Server 2003 machines in an enterprise with both Windows 2000– and NT 4–based domains.

Let me stress that: Don't skip this section. It's not a history lesson; it can sometimes be the only way to fix a networking problem even with Server 2003, believe it or not.

## Introducing LMHOSTS

Recall that HOSTS is an ASCII file that lists IP addresses and Internet names, such as the following:

```
100.100.210.13 ducky.mallard.com
211.39.82.15 jabberwock.carroll.com
```

Microsoft reasoned that if a simple ASCII file could supplement or replace DNS to resolve Winsock names, why not create an ASCII file to hold NetBIOS names? The result is the LMHOSTS file. LMHOSTS consists of pairs of IP addresses and names, like HOSTS, but the names are 15-character *NetBIOS* names, not Internet-type names:

```
100.100.210.13 ducky
211.39.82.15 jabberwock
```

I assumed in the previous example that the NetBIOS name is identical to the leftmost part of the Internet name, although that's not necessary, as you may recall from the earlier discussion in the previous chapter about setting up TCP/IP on a system.

## REPRESENTING HEX SUFFIXES IN LMHOSTS

But how to handle the nonprinting characters in a NetBIOS name, the <1B> used by the primary domain controller, the <1C> used by all domain controllers? Recall that the hex suffixes are always the 16th character in a NetBIOS name, so write out a suffixed NetBIOS name like so:

- ◆ Enclose the name in quotes.
- ◆ Add enough spaces to the end of the name so that you've got 15 characters in the name.
- ◆ After the spaces, add \0x followed by the hex code.

For example, suppose I had a domain named CLOUDS and a domain controller named \\CUMULONIMBUS at address 210.10.20.3. I'm creating an LMHOSTS file that I can put on systems around the network so that they can find \\CUMULONIMBUS and recognize it as the primary domain controller for CLOUDS. The LMHOSTS file would look like this:

```
210.10.20.3 cumulonimbus
210.10.20.3 "clouds          \0x1B"
```

This indicates that the machine at IP address 210.10.20.3 has two names (or at *least* two names). As CLOUDS is a six-letter word, I added nine spaces to the end of it.

## USING HEX SUFFIXES TO SOLVE AUTHENTICATION PROBLEMS

Suppose you have a system that absolutely cannot find a domain controller; no matter what you do, you get "no domain controller found." Or suppose you have an Active Directory domain and an NT 4

domain that you are trying to build a trust relationship between, but the AD seems unable to find the NT 4 domain or vice versa.

In this case, you need desperate measures. You need LMHOSTS.

I'm going to show you a trick whereby you can take a particular system and "nail" it to a particular DC. Do this trick on a balky workstation and you do a couple of things. First, you force the workstation to use a particular DC when logging in—no ifs, ands, or buts. Second, you remove all of the workstation's normal methods of finding DCs...so the DC that you designate in LMHOSTS had better be up and running!

Systems connecting to NT 4-type networks or, for that matter, Active Directories in mixed mode (again, apologies, we'll explain all of the ins and outs of domains in the next chapter) query NetBIOS for a machine with a name equal to the domain's name, suffixed with a "1C." As you just learned, you can create a LMHOSTS entry that does this very thing by adding enough spaces so that there are 15 characters between the open double quote and where the \0x part starts. So let's suppose that I had a difficult system that seemed unable to see I had a DC named SATURNV in a domain named BOOSTERS. Let's also say that SATURNV is the PDC of that domain, and its IP address is 10.10.100.2. I'd create the following LMHOSTS entries:

```
10.10.100.2 saturnv
10.10.100.2 "boosters      \0x1C" #PRE
10.10.100.2 "boosters      \0x1B" #PRE
```

All three entries refer to the same computer. The first says that its name is saturnv, the second says that it is a domain controller of a domain named boosters, and the last says that it is not only *a* domain controller of boosters, it is *the* primary domain controller of that domain. I'll explain the #PRE in a few paragraphs.

#### A SPECIAL SUFFIX FOR DOMAIN CONTROLLERS: #DOM

In most cases, the only hex suffix you'll care about is <1C>, the suffix indicating a domain controller. You can create an entry for it as previously, with a \0x1C suffix, or you can use a special meta-command that Microsoft included in LMHOSTS: #DOM.

To indicate that a given entry is a domain controller, enter a normal LMHOSTS entry for it, but add to the end of the line #DOM: and the name of the domain controller. In the CUMULONIMBUS example, you could register CUMULONIMBUS's name and the fact that it is a domain controller for CLOUDS like so:

```
210.10.20.3 cumulonimbus #DOM:clouds
```

But \x01C and #DOM behave a bit differently, in my experience. If you enter a \x01C entry in an LMHOSTS, then NT will use it and only it, ignoring WINS or any other information—so if you're going to use an \0x1C entry, make sure it's right! Furthermore, if you try to tell NT about more than one domain controller in a given domain using the \0x1C suffix, it will only pay attention to the *last* one mentioned in the LMHOSTS file.

#### "LISTEN TO ME!": THE #PRE COMMAND

This is a bit out of order, as I haven't taken up WINS in detail yet, but as long as I'm discussing LMHOSTS, it kind of fits. As you'll learn later, a normal H node type of client will first send a name

resolution question to a WINS server before consulting its local LMHOSTS file, if one exists. Only if the WINS server returns a failure, saying, “I’m sorry, I can’t resolve that name,” does the client look in its LMHOSTS file. But sometimes you want to tell a PC, “I have a particular entry here in LMHOSTS that is more important than anything that WINS tells you. If you need to look up this particular NetBIOS name, use the LMHOSTS entry rather than looking at WINS.” For those entries, you can use the `#PRE` metaccommand. In the case of CUMULONIMBUS, the previous line would look like:

```
cumulonimbus #DOM:clouds #PRE
```

`#PRE`’s job is this: If WINS and LMHOSTS offer conflicting answers to the question, “What’s the IP address of CUMULONIMBUS?” then in general the client listens to WINS rather than LMHOSTS—in other words, by default WINS, uh, wins. But `#PRE` gives an LMHOSTS entry precedence over anything that WINS has to say.

### CENTRALIZED LMHOSTS: `#INCLUDE`, `#ALTERNATE`

LMHOSTS is powerful but can require a fair amount of running around because for a user’s PC to benefit from LMHOSTS, *the LMHOSTS file must be on the user’s PC*. Yuck. That means you’d have to go out Amongst The Users, a happy time for some but a—ummm—mixed blessing for others. Every time you changed LMHOSTS, you’d have to walk around replacing the old LMHOSTS file with a new one on every single machine—ugh, double yuck. Is there a better way?

Sure. You can put a small LMHOSTS file on a user’s machine with just one simple command: “Go to this server to read the ‘main’ LMHOSTS file.” Even better, you can specify as many backups for this server as you like. You do it with the `#INCLUDE` and `#ALTERNATE` metaccommands. Here’s a sample LMHOSTS:

```
#BEGIN_ALTERNATE
#INCLUDE \\shadows\stuff\lmhosts
#INCLUDE \\vorlons\stuff\lmhosts
#INCLUDE \\centauri\stuff2\lmhosts
#END_ALTERNATE
```

You can use `#INCLUDE` without the `#ALTERNATE`s, but it seems to me that if you’re going to go to all the trouble of having a central LMHOSTS, you might as well add some fault tolerance, right? And I would hope that it would go without saying that either `\\SHADOWS`, `\\VORLONS`, and `\\CENTAURI` would have to be on the same subnet as the client PC, or you should add a few lines above the `#BEGIN ALTERNATE` to tell the PC where to find those three servers.

```
#INCLUDE also takes local filenames:
#INCLUDE D:\MORENAME
```

LMHOSTS is a pretty powerful tool, and it still makes sense in today’s NetBIOS-using networks because, as you’ll see, WINS is not without its flaws.

## WINS: A NetBIOS Name Service for Windows

You’ve seen that the world before WINS was a rather grim place, where everyone shouts and many questions (well, resolution requests) go unanswered. Now let’s look at what happens with WINS.

## WINS Needs NT or Later Server

To make WINS work, you must set up an NT 4 or later Server (it won't run on anything else, including NT Workstation) to act as the WINS server. The WINS server then acts as the NBNS server, keeping track of who's on the network and handing out name resolution information as needed.

## WINS Holds Name Registrations

Basically, when a WINS client (the shorthand term for “any PC running some kind of Microsoft enterprise TCP/IP network client software designed to use WINS for NBT name resolution”) first boots up, it goes to the WINS server and introduces itself, or in WINS-speak, it does a name registration. (In fact, as you recall, most machines have several NetBIOS names, so clients register each of those names with WINS.) The client knows the IP address of the WINS server either because you hard-coded it right into the TCP/IP settings for the workstation or because the workstation got a WINS address from DHCP when it obtained an IP lease.

You may recall that the client actually gets *two* IP addresses, one for a “primary” and one for a “secondary” WINS server. The client tries to get the attention of the primary and register itself on that machine. But if the machine designated as a primary WINS server doesn't respond within a certain amount of time, the client next tries to register with the secondary WINS server. If the secondary will talk to the client and the primary won't, the client registers with the secondary. You can tell that this has happened by doing an `ipconfig /all` at the client. Among other things, this reports the address of the primary WINS server. If that address is the *secondary's* address, then you know that the primary was too busy to talk—and that turns out to be an important diagnostic clue, as you'll see later when I discuss how to design multiserver WINS systems.

In the process of registering its name with a WINS server, the workstation gets the benefit of ensuring that it has a unique name. If the WINS server sees that there's another computer out there with the same name, it will tell the workstation, “You can't use that name.” The name registration request and the acknowledgment are both directed IP messages, so they'll cross routers. And when a workstation shuts down, it sends a “name release” request to the WINS server telling it that the workstation will no longer need the NetBIOS name, enabling the WINS server to register it for some other machine.

## WINS Client Failure Modes

But what if something goes wrong? What if you try to register a name that some other workstation already has, or what if a workstation finds that the WINS server is unavailable?

Duplicate names are simple—instead of sending a “success” response to the workstation, the WINS server sends a “fail” message in response to the workstation's name request. In response, the workstation does not consider the name registered and doesn't include it in its NetBIOS name table; an `nbstat -n` will not show the name.

But if a workstation can't find the WINS server when it boots up, then the workstation simply stops acting as a hybrid NBT node and reverts to its old ways as a Microsoft modified B node, meaning that it depends largely on broadcasts but will also consult LMHOSTS (and perhaps HOSTS, if configured to do so) if they're present.

## It's My Name, but for How Long?

Like DHCP, WINS only registers names for a fixed period of time called the *renewal interval*. By default, it's 6 days (144 hours), and there will probably never be a reason for you to change that. Forty minutes seems to be the shortest time that WINS will accept.

In much the same way that DHCP clients attempt to renew their leases early, WINS clients send “name *refresh* requests” to the WINS server before their names expire—*long* before. According to Microsoft documentation, a WINS client attempts a name refresh very early after it gets its names registered—after one-eighth of the renewal interval. (My tests show that it's actually *three-eighths*, but that's not terribly important.) The WINS server will usually reset the length of time left before the name must be renewed again (this time is sometimes called the *time to live*, or TTL). Once the client has renewed its name *once*, however, it doesn't renew it again and again every one-eighth of its TTL; instead, it only renews its names every one-half of the TTL. (My tests agree with that.)

## Installing WINS

Installing WINS is much like installing all the other software that we've installed elsewhere in this chapter and in the book.

When you're planning how many WINS servers you need and where to put them, bear in mind that you need not put a WINS server on each subnet (which is one of the great features of WINS). It is a good idea to have a second machine running as a secondary WINS server, however, just for fault tolerance's sake. Remember that if a workstation comes up and can't find a WINS server, it reverts to broadcasting, which will limit its name resolution capabilities to just its local subnet and will cause it to do a lot of shouting, which adds traffic to the subnet. Why would a WINS client not find a WINS server if there's a working WINS server?

Well, normally the client would find the server just fine, but in some small percentage of the cases, the WINS server might be too busy to respond to the client in a timely fashion, causing the client to just give up on the server. That will probably only happen rarely, unless you're overloading the WINS server. Unfortunately, a very common way to overload a WINS server is to put the WINS server function on the same machine that's also acting as a domain controller. Think about it: When is a WINS server busiest? First thing in the morning, when everyone's booting up and registering names. When's a domain controller busiest? First thing in the morning, when everyone's logging in. That leads to a warning.

If possible, don't put the WINS server function on a domain controller. Or a system with more than one NIC.

*That's* where a secondary is useful. If you have a backup domain controller, then put a WINS server on that machine as well. The WINS software actually does not use a lot of CPU time, so it probably won't affect your server's performance unless you have thousands of users all hammering on one WINS server. If *that's* the case, I'd dedicate a computer solely to WINS-ing.

To get a WINS server set up, follow these steps:

1. Open the Control Panel (Start/Control Panel/Add or Remove Programs).
2. Click Add/Remove Windows Components and wait a bit while the Windows Components Wizard dialog appears.
3. Click Networking Services and then the Details button.

4. Click the check box next to Windows Internet Name Service.
5. Click OK to return to Windows Components.
6. Click Next to install the service. The system will say that it is “Configuring Components” for a while, probably a few minutes. A bit later, the screen labeled Completing the Windows Components Wizard appears.
7. Click Finish to end the wizard.
8. Click Close to close Add or Remove Windows Components.

No reboots needed anymore—thanks, Microsoft—and you’ll see in Start/Administrative Tools that you’ve got a new snap-in to control WINS. Start it up, click the plus sign next to the server, and it will look like Figure 7.32.

**FIGURE 7.32**  
The initial WINS  
manager screen

No need to authorize WINS servers, in case you’re wondering. The first thing you should do on your WINS server is inform it of the machines on your subnet that are not WINS clients but use NetBIOS on TCP/IP. There won’t be many of them, but they may exist; for example, you may have some old pre-1995 Microsoft Windows machines around. Machines with hard-coded IP addresses don’t need to be entered, so long as they use WINS: If they know the address of a primary or secondary WINS server, they will register their names with that server. If you *do* have an old system requiring a static mapping, right-click Active Registrations and choose New Static Mapping. You then see a dialog box like the one shown in Figure 7.33.

Alternatively, if you have an existing LMHOSTS file, you can click Action at the top menu, then Import Hosts, and the program will take that information to build a static-mapping database.

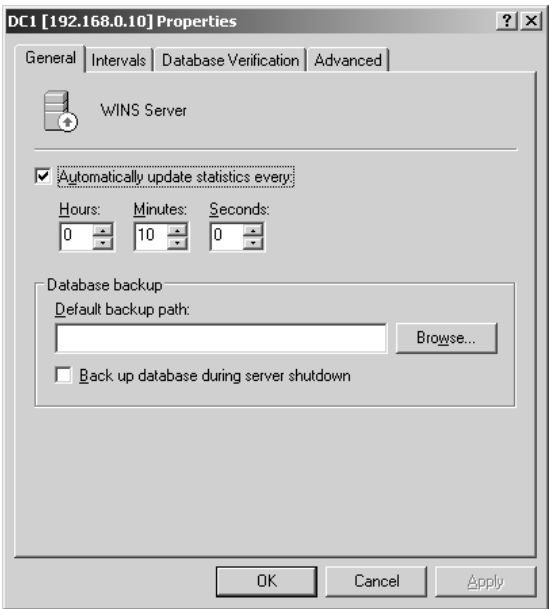

**FIGURE 7.33**  
The Static  
Mapping table

**Configuring a WINS Server**

Right-click the server in the left pane of the WINS snap-in, and choose Properties. You'll see a properties page like the one in Figure 7.34.

**FIGURE 7.34**  
Server configuration  
properties page

WINS will regularly back up its database—a good disaster recovery step—if you fill in a directory name in Default Backup Path. You can even use a UNC, such as `\\ajax\central\wins` or the like. A check box allows you to tell WINS to also do a backup specifically when the server is shut down.

Click the Database Verification tab, and you'll see a page like Figure 7.35.

**FIGURE 7.35**

Configuring WINS verification

This is a real improvement in WINS over NT 4's WINS service. WINS has always had trouble as a distributed database: Name records get transmitted around the network and databases get corrupted. The corruption spreads and before you know it, you're erasing your WINS databases and starting all over. The option at the top of the screen tells your WINS server to periodically check its records against those of any other server in your enterprise. It's a good idea. If you enable it, I'd let it check every 24 hours, as is the default, and to check against the *owner* rather than a random server. *Owner* in WINS terminology means "the WINS server that generated the original name record." Thus, it could be in a multi-WINS server world that I registered my PC's name with WINS Server 1, which then told WINS Server 2 about me. (This happens automatically, recall—you needn't do anything to get your system registered with WINS except to specify a WINS server in your TCP/IP settings.) WINS Server 2 might run into some kind of trouble and corrupt the record about my machine. But checking with WINS Server 1 would point out the problem, and WINS Server 2 would be set straight.

Click the Advanced tab and you'll see a page like the one in Figure 7.36.

The first interesting thing here is logging. You can leave logging enabled, but think twice about logging detailed events. Basically, if you enable this, then WINS adds a lot of chatter to the Event Viewer, and WINS gets *really* slow. It's not a bad idea if you're trying to get some insight into what WINS does on a small network, but I've had it freeze a WINS server right up on me.

**FIGURE 7.36**  
Advanced WINS  
server configuration

Enable Burst Handling is a work-around to handle an old WINS problem. WINS is busiest first thing in the morning, when everyone's logging on and trying to register their system names. Before registering a name, however, WINS must check its database to ensure that there's no duplication, that no one's trying to register a computer name that already exists. But that takes time, so WINS cheats.

The chances are good that early morning (the busy time) registrations are simply reregistrations, so WINS goes into burst mode, meaning it pretty much agrees to every registration request. It then says, "Come back and reregister in a few minutes," which gives it a chance to *really* check a registration when things are slower. It only shifts into burst mode when it has a lot of outstanding registration requests in its queue. How many? That's what the radio buttons are for—to set how soon WINS goes into burst mode. The default is probably fine, but if you're getting a lot of refused registrations—where WINS simply doesn't respond—then set the threshold to Low.

## Designing a Multi-WINS Network

Thus far, I've discussed a situation where you have one WINS server and a bunch of clients. I've *also* mentioned the notion of a secondary WINS server, suggesting that at least one additional WINS server would be in order. How should you set up this second WINS server? And how about the third, fourth, and so on? And while we're at it, how many WINS servers should you have?

### FROM MANY SERVERS, ONE DATABASE

The theory with multiple WINS servers is that you might have one in Europe, one in Africa, and one in North America. Europeans do their registrations with the European server, Africans with the African server, and Americans with the North American server. Then, on a regular basis, the three WINS servers get together and create a master worldwide list of WINS records, a kind of sort/merge amalgamating three different databases. But how to do it? We certainly don't want to have to transmit—*replicate*

is the WINS term—the entire African name serving database over WAN links to Europe and America, particularly because the database probably hasn’t changed all that much since yesterday.

As a result, WINS time-stamps and sequence-numbers name records so that it can take up less WAN bandwidth. That’s great in theory, but in practice it means that WINS servers that are being asked to *do* all that sorting and merging will be pretty occupied CPU-wise, which will of course mean that they’re falling down on the job as name resolvers. It also means that it might be a good idea to designate a relatively small number of servers—say, perhaps *one*—to essentially do nothing but the sort/merges.

### MINIMIZING THE NUMBER OF WINS SERVERS

People assume that as with domain controllers, it’s a great idea to have a local WINS server, and lots of them. But it’s not, and in fact you should strive to keep the WINS servers to an absolute minimum.

A local WINS server would be great because it could quickly perform NetBIOS name resolutions for nearby machines. And in fact it would be great if you could install a WINS server in every location that only did name resolutions—but remember that every WINS server does *two* things: name resolutions and name registrations. This, in my opinion, is the crux of why multiple WINS networks can be a pain. If you could simply say, “Go to local machine X for name resolutions, but for those infrequent occasions when you need to do a name *registration*, go across the WAN to the central WINS server named Y,” then WINS would be more trouble free. Sure, a morning logon would get a bit slower, as the registration would happen over the WAN, but you’d not get the corrupted WINS databases that are sadly so common in big WINS installations.

Why this happens is easy to understand. Merging two WINS databases and “boiling them down” to one database is simple. Merging three is harder, and merging 100 could be, well, a lot of work, perhaps more than WINS’s database engine is capable of. That’s why for years, Microsoft has maintained that no enterprise on the entire planet needs more than 14 WINS servers. More than that, and database corruption becomes far more likely.

People want a local WINS server for name resolution, but actually they’re not getting much for it. If your WINS server were across the WAN from you, how much time would a name resolution take? Well, an entire name resolution request and response is only 214 bytes. Let’s see, at 56Kbps that would be, hmmm, three-hundredths of a second. Here’s a case where the wide area network will *not* be the bottleneck! WINS may have its drawbacks, but one thing that it was designed to do, and designed well, is to respond to name resolution requests quickly. Even a 66MHz 486 running NT 4’s WINS server can handle 750 resolution requests per minute—so when it comes to WINS servers, remember: Less is more.

### Adding the Second WINS Server

Of course, having said that, a *second* WINS server isn’t a bad idea.

When setting up a Microsoft TCP/IP client, you’re prompted for both a primary and a secondary WINS server address. When your PC boots up, the PC goes to the primary WINS server and tries to register the PC’s NetBIOS name with that WINS server. If it’s successful, it never even tries to contact the secondary WINS server unless a subsequent name resolution attempt fails.

What that implies is important: Suppose you’ve been a good network administrator and created a backup WINS server, and then you’ve pointed all of your workstation’s Secondary WINS Server fields to that backup. The primary goes down. Where are you?

Nowhere very interesting, actually. You see, that secondary WINS server doesn’t know much, as no one has ever registered with it. If a WINS client successfully registers with its primary server, it does not try to register with the secondary server.

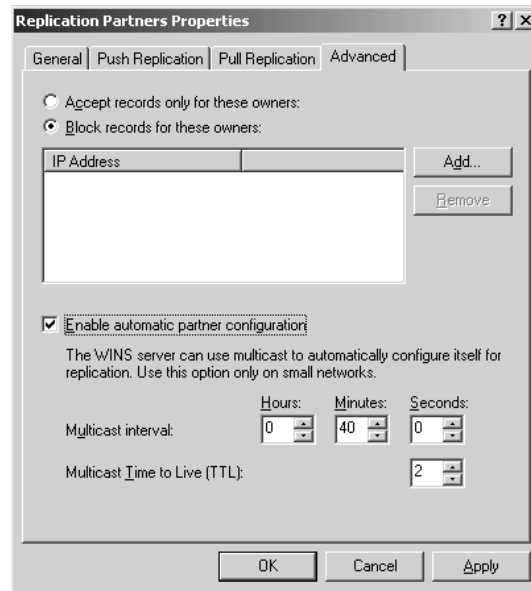

If the primary goes down and everyone starts asking the secondary to resolve names, the secondary will end up just saying, “Sorry, I can’t answer that question.” So you’ve got to convince the primary to replicate to the secondary. Fortunately, there’s an easy way: *push/pull partners*.

## Keeping the Second Server Up-to-Date

In general, you’ve got to configure two WINS servers to be push/pull partners, but it’s possible to have them discover each other with a setting in the WINS snap-in. Right-click the **Replication Partners** folder, choose Properties and click the Advanced tab, and you’ll see a screen like Figure 7.37.

**FIGURE 7.37**

Choosing automatic discovery of replication partners

Here, I’ve checked the box **Enable Automatic Partner Configuration**, which will cause the WINS server to periodically broadcast (well, actually it will *multicast*) to find other WINS servers and from there automatically replicate. This will, however, only work for WINS servers on the same subnet, as most routers don’t pass IP multicasts. On a big network, this is a bad idea, but for a small network it’ll save the administrator a bit of time and trouble.

Alternatively, you’ve got to introduce the replication partners. WINS database replications transfer data from a push partner to a pull partner. Those terms *push* and *pull* aren’t *bad* terms description-wise, but they need a bit of illumination. Suppose for the purposes of the example that you have two machines named Primary and Secondary. Suppose also that Primary is the machine that gets the latest information, as it is the *primary* WINS server, and that all you really want to do with Secondary (the name of the machine that is the secondary WINS server) is have it act as a kind of backup to Primary’s information. Thus, Secondary never really has any information to offer Primary. In that case, you’d have to set up Primary to *push* its database changes to Secondary.

You can tell a WINS server to create a push, pull, or push/pull relationship with another WINS server by right-clicking the folder labeled **Replication Partners** and choosing **New Replication Partner**. You’re prompted for the IP address of the WINS server with which you want to establish a replication relationship.

In a push/pull relationship, data gets from Primary to Secondary in one of two ways. First, Secondary (the pull partner) can request that Primary (the push partner) update Secondary, telling Secondary only what has changed in the database. Alternatively, Primary can say to Secondary, “There’s been a fair amount of changes since the last time I updated you. *You really should request an update.*” I italicized the last sentence to emphasize that it’s really the pull partner that does most of the work in initiating the database replication updates. All the push partner really “pushes” is a suggestion that the pull partner get to work and start requesting updates.

Having said that, could I just tell Secondary to be a pull partner with Primary, without telling Primary to be a push partner for Secondary? Wouldn’t it be sufficient to just tell Secondary, “Initiate a replication conversation with Primary every eight hours”? It would seem so, as there wouldn’t any longer be a need for Primary to do any pushing—but there’s a catch. If Secondary starts pulling from Primary, Primary will refuse to respond to Secondary’s pull request unless Primary has been configured as a push partner with Secondary, because WINS servers are configured by default to refuse replication requests from all machines but partners, remember?

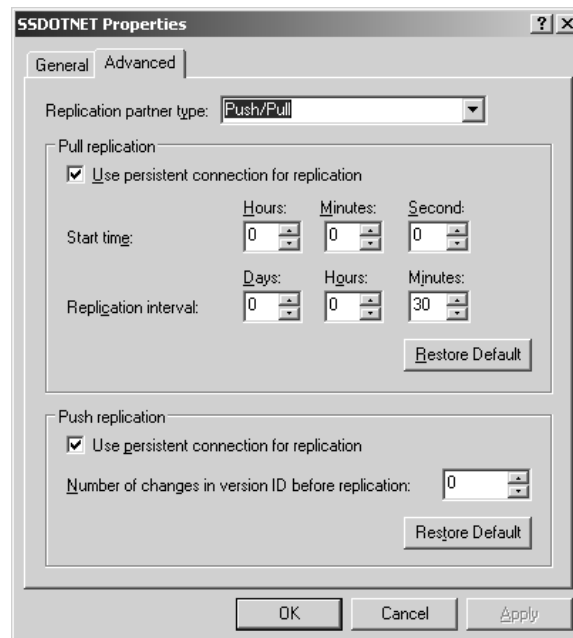

WINS services are totally independent of Active Directory domain security, as is DHCP. A WINS server can serve workstations throughout your network. In fact, if your network is connected to the Internet and doesn’t have a firewall, you could actually publish your WINS server address, and other networks across the Internet could share browsing capabilities! (Whether you’d want to do that is another issue.)

### CONTROLLING REPLICATION

So now you see that the right thing to do is to make Secondary a pull partner with Primary and make Primary a push partner with Secondary. What triggers the replication? What kicks off the process of WINS database replication? To see, right-click any server listed in the **Replication Partners** folder, choose Properties, and click the Advanced tab. You’ll see a screen like the one in Figure 7.38.

**FIGURE 7.38**

Configuring WINS replication

Well, recall that either the push partner or the pull partner can start the conversation. In the case of the former, you configure a push partner to tap its partner on the shoulder and suggest a replication session based on the number of database changes. You can tell Primary, “Notify Secondary whenever 50 changes have occurred to the WINS database on Primary,” or whatever number you like, so long as you like numbers above 19; 20 is the minimum number of changes that NT will allow you to use to trigger replication. (You can alternatively trigger replication from the WINS snap-in.) The default, zero, essentially turns off push triggers.

A pull partner, in contrast, can’t possibly know how many changes have occurred and so needs another way to know when to request updates. So pull partners request updates based on time—you configure a pull partner to contact its partner every so many minutes, hours, or days.

The bottom line, however, is that most of us will just set up our WINS replication relationships to the defaults, particularly if we set up our WINS enterprise as a hub-and-spoke design, as you’re about to read. You *might* want to set your partners to replicate less often in a large enterprise.

### WINS REPLICATION DESIGN

Now that Microsoft has had years of experience supporting big clients using WINS, some Microsofties have recommended a push/pull partner architecture to me, something like a hub-and-spoke design. You see it pictured in Figure 7.39.

**FIGURE 7.39**

Suggested primary/  
secondary WINS  
server configuration

The goal of this design is to keep WINS servers responsive while still handling replication. In the picture, you see three different networks, each served by a WINS server labeled Primary WINS. In each network, each workstation points to the local WINS server as its primary server and the central machine labeled Secondary WINS as its secondary. In other words, then, every machine in the enterprise designates that one central machine as their secondary WINS server and a closer machine as

their primary WINS server. This works because every WINS server hears about a particular machine from only one WINS server, instead of from several replication partners. Result? No confusion.

The main job of the central WINS server is to gather the three primary servers' databases, aggregate them into one enterprise-wide WINS database, and replicate that database out to the local primaries. Each primary WINS server, then, designates the central WINS server as its sole push/pull partner.

Many firms implement a mesh-type structure, where every WINS server designates every other WINS server as a push/pull partner. The result is a nightmare of corrupted WINS databases and lost records. To add another WINS server, just make sure that it has some kind of connectivity to the central WINS server and make it a push/pull partner of that machine. If you end up with too many WINS servers for one central machine, just put hubs and spokes on the ends of the hubs and spokes, building a hierarchy.

No matter what kind of WINS replication architecture you create, ensure that there are no loops in your replication. For example, if WINS server A replicated to B, which replicated to C, which replicated to A, then records can be replicated and re-replicated, causing WINS problems.

## Avoiding WINS Problems

Sources inside Microsoft tell me that WINS generates more support calls than any other of NT's "core" network technologies. That won't be surprising to anyone who's ever tried to track down a WINS problem. Here are a few tips to save you some time and help you avoid having to pay Microsoft more money to keep the product that you bought from them working.

### WINS SERVERS SHOULD POINT TO THEMSELVES AS A PRIMARY WINS SERVER ONLY

When you're configuring the TCP/IP stack on a WINS server, do not fill in a value for a secondary WINS server, and in the Primary field, fill in the server's own value. This avoids a situation wherein the WINS server is busy but needs to reregister its own address. As it is busy, however, it cannot—believe it or not—respond quickly enough to *itself*. As a result, the WINS client software on the WINS server seeks out another WINS server, and so WINS server A's name registrations end up on WINS server B. The result is WINS instability, as the WINS server software is built assuming that each WINS server's name is registered on its own database.

### BE CAREFUL REPLICATING TO "TEST" WINS SERVERS

Don't set up a "test" WINS server, register a few names on it, have a "production" WINS server pull the names from the test server, and then shut off the test WINS server for good. WINS will refuse to delete names that it got from another server, no matter how old and expired they are, until it can do a final double-check with the WINS server that it got the names from originally; if you shut off the test and never turn it back on, those records will never go away without a bit of operator intervention!

To remove all of the records created by a defunct WINS server, go to one of its replication partners and start the WINS snap-in. Right-click the **Active Registrations** folder, then choose **All Tasks/Delete Owner**. That allows WINS to finally purge the old owner's records.

### DON'T MAKE A MULTIHOMED PC A WINS SERVER

A PC with more than one NIC can hear communications from several subnets. That's gotten WINS in trouble when a WINS server is multihomed, as WINS sometimes gets confused about where a

name registration came in from. Several service packs have claimed to fix it, but each service pack brings more trouble reports. My suggestion: Don't make a multihomed machine a WINS server.

By the way, the same advice goes for PDCs. Multihomed PCs shouldn't be PDCs. The reason is that the PDC ends up being the master browser in a domain, and again, having workgroup announcements coming in from several different network segments causes problems for the browser software.

### **DON'T MAKE A DC A WINS SERVER**

As explained earlier, both the domain controller and WINS functions are at their busiest at the same time. Mixing DC and WINS responsibilities on a single machine will make a mediocre DC and a mediocre WINS server. (Of course, on a small network this isn't the case; if you have 25 users, feel free to make one machine your domain controller, WINS, DHCP, DNS, and file server—but be sure you know how to do disaster recovery on it!)

### **Deleting, Tombstoning, and Purging WINS Records**

You'll eventually look at your WINS name database and realize that there are a bunch of old, useless records that you'd like to get rid of. Some of those records may be, as mentioned earlier, garbage left over from an old, now-defunct WINS server. Those are easy to get rid of—just choose the Delete Owner function, as described earlier.

For other records, though, the approach is a bit different.

Consider how a record gets created and propagated around an enterprise. A machine named TRAY (what server doesn't have a tray?) registers itself with WINS Server 1. That generates a record in WINS Server 1's database. WINS Server 1 is said to be the "owner" of that record.

Now suppose WINS Server 1 replicates TRAY's name record (or more likely, records) to WINS Server 2. WINS Server 2 now contains copies of those records, but it also knows that WINS Server 1, not itself, originated—"owns"—those records. Even if WINS Server 2 were to replicate this record to yet another WINS server, then WINS Server 2 wouldn't "take credit for" this record; it would say to this new WINS Server, "Hey, just in case you don't know about this, here's a record for the TRAY computer—but I didn't discover TRAY, WINS Server 1 did. *It* owns TRAY's name record."

Now let's suppose we decommission the TRAY server. Working at WINS Server 2, you (an administrator) notice that the TRAY record is still in the WINS database, and so you delete the TRAY record. (In **Active Registrations**, right-click a record and choose Delete.) That causes the WINS snap-in to raise a dialog box asking whether you want to do one of two things:

- ◆ Delete the record only from this server, or
- ◆ Replicate deletion of the record to other servers (tombstone).

If you were to choose the first option, then TRAY would disappear from WINS Server 2's WINS snap-in...for a while. The next time that WINS Server 1 and WINS Server 2 replicated, then WINS Server 1 would say to WINS Server 2, "My goodness, why don't you have a TRAY record?" and quick as a wink, TRAY is *baaaaack*.

How, then, to stomp TRAY for good? With the alternative to deleting—tombstoning. When you tombstone a record, you don't remove it from the database; rather, it marks it as being in a *tombstone state*.

The purpose of the tombstone is this: WINS Server 2 has already written TRAY off, but it knows that the rest of the enterprise doesn't know that TRAY is history, because WINS Server 1 owns the

TRAY record. So the next time WINS Server 1 replicates a TRAY record to WINS Server 2, WINS Server 2 may be tempted to insert a new record in its database for a machine named TRAY—but then it sees the tombstone record with TRAY’s name and so can say, “Ah, I should just ignore that record; I have more up-to-date information than WINS Server 1 does.” When WINS Server 2 next replicates to WINS Server 1, it’ll tell WINS Server 1 that TRAY is tombstoned, and so WINS Server 1 will tombstone TRAY in its database as well. Eventually TRAY will be marked as tombstoned in the entire WINS enterprise.

By the way, tombstoned entries don’t get purged from a WINS database until WINS runs a *scavenging operation*. That happens every three days by default, or you can initiate a scavenging operation from the WINS Manager by right-clicking a server, then choosing Scavenge Database.

If for some reason you stop the WINS service more often than every three days, your WINS database will never be scavenged. If that’s the case, manually initiate scavenging from the WINS Manager.

A badly designed WINS replication structure may need a bit of tombstoning help, and here Server 2003’s graphical WINS Manager is of assistance. When you click Delete Mapping, you get an option—delete or tombstone? You use tombstone *always* if you want to delete a record on server X but you’re working from server Y. You typically delete rather than tombstone if you’re sitting right at the server that owns the record that you’re about to delete. And if you find that you’ve been trying to get rid of a record but it keeps coming back, you tombstone it.

## WINS Proxy Agents

Using an NBNS (NetBIOS naming server) such as WINS can greatly cut down on the broadcasts on your network, reducing traffic and improving throughput. But, as you’ve seen, this requires that the clients understand WINS; the older network client software just shouts away as a B node.

WINS can help those older non-WINS-aware clients with a *WINS proxy agent*. A WINS proxy agent is a regular old network workstation that listens for older B node systems helplessly broadcasting, trying to reach NetBIOS names that (unknown to the B node computers) are on another subnet.

To see how this would work, let’s take a look at a simple two-subnet intranet, as shown in Figure 7.40.

**FIGURE 7.40**  
An example of a  
two-subnet intranet

Here, you see two class C subnets, 1.1.1.0 and 1.1.2.0. There’s a router between them. On 1.1.1.0, there are two workstations. One is a WINS-aware client named HELPFUL, which is also running a WINS proxy agent. The other is an old B node client named HOPELESS, which is not WINS-aware. On 1.1.2.0, there are a couple of servers, a machine acting as a WINS server and a regular old file server.

When HOPELESS first comes up, it'll do a broadcast of its names to ensure that no one else has them. The machine that it really should be talking to, of course, is WINSERV, but WINSERV can't hear it. HELPFUL, however, hears the B node broadcasts coming from HOPELESS and sends a directed message to WINSERV, telling it that there's a workstation named HOPELESS trying to register some names.

WINSERV looks up those names to ensure that they don't already exist. If they *do* exist, then WINSERV sends a message back to HELPFUL, saying, "Don't let that guy register those names!" HELPFUL then sends a message to HOPELESS, saying, "I'm sorry, but *I* already use the name HOPELESS." That keeps HOPELESS from registering a name that exists on another subnet.

Assuming that HOPELESS names do *not* currently exist in the WINSERV database, however, WINSERV does *not* register the names; putting a WINS proxy agent on 1.1.1.0 doesn't mean that the non-WINS clients will have their names registered with WINS. That means that it's okay to have the same NetBIOS name on two different computers, so long as they are both B node clients and are on different subnets.

Suppose then that HOPELESS does a `net use d: \\fileserv\files`—in that case, the name `\\fileserv` must be resolved. Assuming that HOPELESS does not have a HOSTS or LMHOSTS file, HOPELESS will start broadcasting, saying, "Is there anyone here named FILESERV? And if so, what's your IP address?" HELPFUL will intercede by sending a directed IP message to WINSERV, saying, "Is there a name registered as FILESERV, and what is its IP address?"

WINSERV will respond with the IP address of FILESERV, and HELPFUL will then send a directed message back to HOPELESS, saying, "Sure, I'm FILESERV, and you can find me at 1.1.2.5." Now HOPELESS can complete its request.

Make sure there is only one WINS proxy agent per subnet! Otherwise, two PCs will respond to HOPELESS, causing—how do the manuals put it? Ah yes—"unpredictable results."

## Name Resolution in More Detail

Now that you know how to configure DHCP and WINS, you may be faced with a troubleshooting problem in reference to name resolution. Perhaps you try to FTP to a site inside your organization, but you can't hook up. Even though you know that `ftp.goodstuff.acme.com` is at one IP address, your FTP client keeps trying to attach somewhere else. You've checked your DNS server, of course, and its information is right. Where else to look?

### Review: Winsock versus NBT

Remember first that there are two kinds of name resolution in Microsoft TCP/IP networking, Winsock name resolution and NetBIOS name resolution. A `net view \\somename` needs NetBIOS-over-TCP name resolution, or NBT name resolution. In contrast, because FTP is, like Ping, an Internet application, it uses Winsock name resolution. So, to troubleshoot a name resolution problem, you have to follow what your client software does, step by step.

### DNS/Winsock Name Resolution

I type `ping lemon`, and get the response "unknown host lemon." But I suspect there's a lemon out there, and I'm not talking about a computer from a certain Texas computer company. How did Server 2003 decide that it couldn't find lemon? It certainly takes long enough to decide that it can't

find lemon, after all—usually on the order of 20 to 30 seconds on a 400MHz system. *Something* must be going on.

When faced with a question such as this, I turned to the Microsoft documentation for help, but there wasn't much detail. So I ran a network monitor and issued ping commands to computers that didn't exist, to see the sequence of actions that the network client software tried in order to resolve a name. The HOSTS and LMHOSTS files do not, of course, show up in a network trace, so I inserted information into those files that didn't exist on the DNS or WINS servers and then tried pinging again, to demonstrate where the HOSTS and LMHOSTS files sit in the name resolution hierarchy. (And if you think about it, LMHOSTS and WINS should have nothing at all to do with a Winsock resolution. Perhaps in a non-Microsoft world, but not in any version of Windows created after 1995.) Pinging for a nonexistent apple, I found that the name resolution order proceeds as shown in Figure 7.41.

Before I get into the details here, let me warn you that Microsoft has changed how their OSes resolve DNS names; in particular, Windows 2000 and later (XP, 2003) are a bit different, and I'll explain that as we go along. Step by step, it looks like this:

First, consult the HOSTS file, if it exists. If you find the name you're looking for, stop.

Next, look in the DNS cache. This only applies to Windows 2000 and later systems, and I'll cover this later, but basically all Win2K and later systems remember previously successful DNS name resolutions. So if I successfully looked up apple in DNS a moment or two ago, then my system would pull that successful resolution out of cache, and it'd be done. Note that this happens *after* the HOSTS lookup, contrary to some sources. You can, if you like, clear the DNS cache by typing **ipconfig /flushdns**. You can see the current contents of the DNS cache by typing **ipconfig /displaydns**.

Next, if there's a specified DNS server or servers, then query them. Most Microsoft OSes recognize that a name like apple clearly isn't a complete DNS name, as DNS names usually have parts to them like apple.bigfirm.biz or the like. In a case like that, the system adds its DNS suffix to the query. For example, if I were sitting at a workstation named mypc.bigfirm.biz and typed **ping apple**, then my workstation wouldn't query DNS for apple, it would query for "apple.bigfirm.biz." You can, if you like, add even more DNS suffixes for your system to try when presented with a too-short DNS name; look in TCP/IP Advanced Properties, the DNS tab, and you'll see where you can add them. By the way, Windows 95 systems seem to not add the DNS suffix; a Win95 system would actually ask DNS to resolve apple in my theoretical case. If DNS finds the name, then stop.

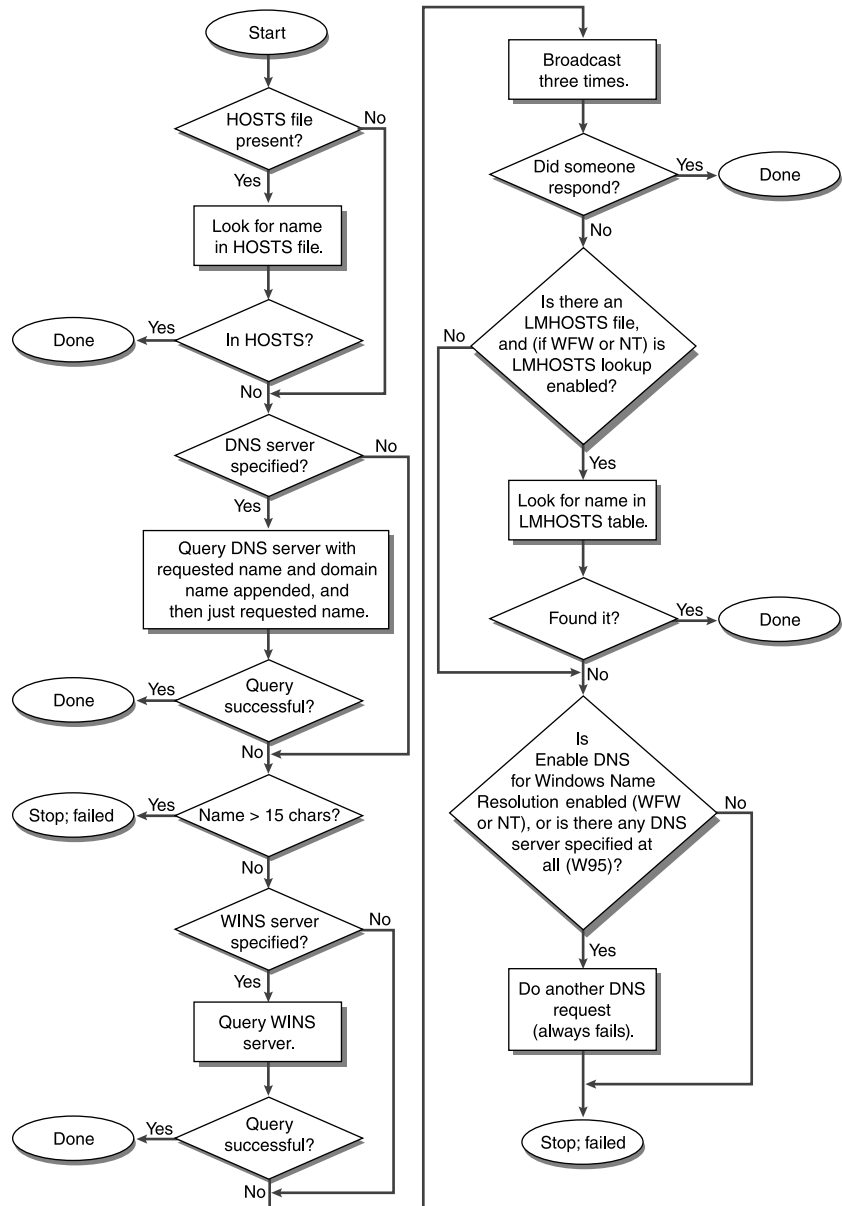

You would think that would be it for DNS name resolution, and indeed for most OSes it is—look in HOSTS, look in DNS and if there's no luck, then just stop looking. That's also how a Windows 2000 or later system works, if you have disabled NetBIOS over TCP/IP. (Almost no one does nowadays. But one day, when we're free of WINS...) Assuming that you're running NBT, though, Microsoft takes it further and involves its *NetBIOS* lookup engine as well. So if your system still hasn't gotten an answer to a name query...

If there's a specified WINS server or servers, then query the WINS server(s). The name WINS looks for is apple <00>, the name that *would* be registered by the Workstation service, if the apple machine existed.

If that fails, then do three broadcasts looking for a machine with NetBIOS name apple <00>, requesting that it identify itself and send back its IP address. Again, this would succeed with a workstation running some NetBIOS-over-TCP/IP client, even a relatively old one, as it would have registered the apple <00> name already, if only on its own name table. Unfortunately, this only works if the machine is on the same subnet.

**FIGURE 7.41**

The name resolution order

If the name still hasn't been resolved, then NT 4 and earlier systems next read the LMHOSTS file, unless configured to ignore LMHOSTS. Windows 2000 and later systems do *not* use LMHOSTS to assist in DNS/Winsock name resolution, whether configured to use LMHOSTS or not.

If the system still hasn't succeeded, then under some circumstances a pre-Win2K system will do yet another DNS lookup which will, of course, fail.

Summarizing, then, a Windows 2000 or later system first looks in its DNS cache, then its HOSTS file, then asks a DNS server, then a WINS server, and finally broadcasts. If you disable NetBIOS over TCP/IP then Win2K and later systems just look in the DNS cache, then HOSTS, and then ask the DNS server.

Why the broadcasts and the WINS lookup? I'm not sure, but I guess Microsoft just threw them in for good measure. The broadcasts are a pain because they waste network bandwidth, but they *would* be of benefit when you tried to execute a TCP/IP command on a computer in your network but wanted to use the shorter NetBIOS name rather than the longer DNS name, such as apple instead of apple.mmco.com.

Getting back to an earlier question, what happened on that workstation that could not access the FTP site? There was an old HOSTS file sitting in the `Windows` directory that pointed to a different IP address, an older IP address for the FTP server. HOSTS is read before anything else, so the accurate information on the DNS or WINS servers never got a chance to be read. So be very careful about putting things in HOSTS if they could soon become out-of-date!

There is an explicit Enable DNS for Windows Name Resolution check box in Windows for Workgroups and NT 3.51 clients, but how do you control whether DNS gets into the act on a Windows 95 client? You can't, at least not entirely; where Workgroups and NT 3.51 separate the options about whether to specify a DNS server and whether or not to use that DNS server as a helper when resolving NetBIOS names (that's what Enable DNS for Windows Name Resolution means), Windows 95 seems not to do that.

## Controlling WINS versus DNS Order in Winsock

Now, what I just showed you is the order of events by default in NT, Windows 9x, or later clients. But if you feel like messing around with the way that Winsock resolves names, you can. As usual, let me take this moment to remind you that it's not a great idea to mess with the Registry unless you know what you're doing.

Look in the Registry under `HKEY_LOCAL_MACHINE\System\CurrentControlSet\Services\Tcpip\ServiceProvider` and you see `HostsPriority`, `DnsPriority`, and `NetbtPriority` value entries. They are followed by hexadecimal values. The lower the value, the earlier that HOSTS, DNS (and LMHOSTS), and WINS (and broadcasts) get done. For example, by default DNS's priority is 7D0 and WINS's is 7D1, so DNS goes before WINS. But change DNS's priority to 7D2, and WINS does its lookup and broadcast *before* the client interrogates the DNS server.

Again, I'm not sure *why* you'd want to do this, but I include it for the sake of completeness and for the enjoyment of those who delight in undocumented features.

## NetBIOS Name Resolution Sequence

Readers send me many questions about networking Microsoft OSes, but unfortunately I usually can't help much, usually because the problem boils down to either some hardware or software that I'm not familiar with, so all I can do is to make a few suggestions to help them try to smoke the problem out on their own. Of all of the troubleshooting suggestions that I make, however, here's the most common one.

Many problems sound like “I can’t get X machine to connect to and communicate with Y machine,” as in “I have a file server named ABEL that workstation BAKER can’t access.” Most people don’t realize the very important fact there are *two* problems to troubleshoot here:

- ◆ First, you must have IP connectivity.
- ◆ Second, you must have proper name resolution—and “proper” means DNS/HOSTS if the application is Winsock-based, or WINS/LMHOSTS if the application is NetBIOS-based.

I know I’ve touched on this elsewhere, but I really want to hit home with this point. First, make sure that the two systems can ping each other. Do a ping from each side to the other. Without the ability to transfer IP packets back and forth, your network can go no further—“don’t mean a thing if you ain’t got that ping,” y’know.

Once you’re sure that you have IP connectivity, check that your systems can resolve each other’s names. Here’s where I find that readers sometimes go wrong. Someone will tell me that workstation \\ABEL can’t contact server \\BAKER, “even though I pinged BAKER from ABEL.” In other words, the reader typed `ping baker` or something similar while sitting at ABEL. But Ping doesn’t use NetBIOS to resolve the name “baker,” of course—it uses DNS. That’s no help, although it *does* demonstrate that there’s IP connectivity. We need to test that ABEL can resolve the name \\BAKER via *NetBIOS*, not DNS. I’m not sure why, but Microsoft doesn’t include a NetBIOS-based ping in any versions of NT and later OSes, and I wish it did. It’d make life a lot easier. About the closest thing that you can get to a NetBIOS-based ping is probably a `net view` command, as in `net view \\baker`. That command will list the shares on the BAKER server, but it’s not a great test, as other irrelevant factors can cause it to fail.

To really chase down a NetBIOS name resolution problem, you’ve got to understand what’s going on under the hood, exactly how the “WINS client”—the word for the piece of software that runs on your workstation and resolves NetBIOS names—operates.

I’ll assume for this discussion that you haven’t modified the way that the WINS client resolves NetBIOS names—that is, that you haven’t told the client to disable the LMHOSTS file—and that you are using WINS. (Come to think of it, that’s an important troubleshooting step: Make sure that all of the communicating parties are connected either to the same WINS server, or to WINS servers that replicate to each other.)

Summarized, the name resolution sequence appears in Figure 7.42.

The NBT name resolver uses the following steps; if any succeed, then it stops looking:

- ◆ The resolver caches the result of NetBIOS-name-to-IP-address resolutions that have succeeded in the past 30 seconds, and looks first in that cache. You can see the current state of your NetBIOS name cache by typing `nbtstat -c`. You can clear and reload the cache by typing `nbtstat -R`.
- ◆ If the client is a Windows 98, Me, NT 4, Windows 2000, or later system, then the first thing to check is whether the name to the right of the \\ is either an IP address or a recognizable DNS name—that is, that it has a period in its name. If the name is just an IP address, as in a command like `net use * \\199.33.29.15\\Stuff`, then forget the name resolution and just go to that IP address. If it’s a DNS name, like `net use * \\myserver.region8.acme.com\\files`, then resolve the name using the *DNS* client, not the *WINS* client (and you’ll read about how DNS resolves names in the remainder of the chapter).

**FIGURE 7.42**  
Name resolution  
sequence under  
NetBIOS

- ◆ If the name wasn't IP or DNS—or the client was too old to be able to respond to that—then the next part is the WINS client, if the client software is WINS aware. If WINS is disabled under Windows 95, or if there is no WINS server specified in Workgroups or NT 3.51, then the client skips this step.

- ◆ If WINS isn't being used, then the client does three broadcasts. For example, `net view \\apple` causes three broadcasts looking for a workstation with the name apple registered rather than apple.mmco.com or the like.
- ◆ Next, if LMHOSTS is enabled—and it appears that LMHOSTS is *always* enabled on Windows 95/98/Me/2000/XP clients but must be enabled with the Enable LMHOSTS check box for NT 3.51 and Workgroups—then the client looks up the name in LMHOSTS. Surprised? When doing NBT name resolutions, LMHOSTS gets consulted *before* HOSTS, a reversal over Winsock name resolutions. Recall that LMHOSTS only contains 15-character NetBIOS names, not longer DNS-like names.
- ◆ If you've checked Enable DNS for Windows Name Resolution in Workgroups or NT 3.51, or if you have specified a DNS server in Windows 95/98/Me/2000/XP, then the workstation's client software will look at HOSTS, and if HOSTS can't help, it will interrogate the DNS server (or servers, as you can specify up to four DNS servers).

The NT/Workgroups clients and the 9x clients use DNS differently. The NT/Workgroups clients do a DNS query for the name with the domain name appended to it and then a DNS query of just the name. For example, if your domain is acme.com and you're doing a `net view \\myserver`, then an NT workstation will ask DNS first to resolve the name myserver.acme.com—it automatically adds the domain name for the first resolution. Then, if the DNS server can't resolve the name with the domain name attached, the client will request that the DNS server just resolve myserver.

In contrast, the Windows 9x client software only asks the DNS server to resolve the name with the domain name appended; in my example, a Windows 9x workstation would ask DNS to resolve myserver.acme.com but would not ask about myserver.

Then there's a final step in NetBIOS name resolution—it's an odd one. If the client software is the NT client (not the Workgroups or Win9x clients), and if it has been unsuccessful so far, then it goes back and does it all over again, I suppose in the hope that it'll work the second time.

## DNS: Name Central in Active Directories

Windows 2000 or, more precisely, Active Directory turned names in Microsoft networking on its head, and it's stayed that way in XP and 2003. From 1985's MS-Net through the versions of LAN Manager through Windows for Workgroups, Windows 9x, and NT 3.x and 4.x, NetBIOS reigned supreme and anyone running a TCP/IP-based network needed WINS or, before WINS's appearance, LMHOSTS files to support NetBIOS names, as you've just read. DNS, where it existed, was something of an afterthought.

With Active Directory-based networks, all of that changes. The heart of naming in AD is DNS. As you've already read, in a network of *only* Windows 2000 and later systems and applications united through an Active Directory domain, WINS would be completely unnecessary. And no matter what kind of domain you've got, DNS is important, as you need it to find things on the Internet.

DNS is, for those just joining us, a name resolution system invented in 1984 for the Internet. It enables you to point your Web browser to a "friendly name" such as `www.continental.com` when you want to look up Continental Airlines' flight schedule rather than having to know that Continental's

Web server is at IP address 208.229.128.54. It makes e-mail work smoother through its MX records (which you'll read about later) and has proven itself to be an easily expanded way of maintaining names in the largest network in the world. DNS's ability to grow—its *scalability*—is a real plus for the Active Directory, as Microsoft hopes that the AD will be the basis of some very large networks.

## Why DNS Matters to Active Directory

Why is DNS a big deal all of sudden? After all, in truth NT 4 experts could get away with knowing basically nothing *about* DNS, and in fact you could probably even have passed the NT 4 TCP/IP elective exam without answering any of the DNS questions. So why did it become so important with the advent of Windows 2000 and later implementations of NT?

DNS is significant for several reasons, but here's the main one: DNS is now the central name repository for Active Directory, replacing WINS's role in NT 4. Yes, WINS will be around for a good time longer—so long as you have pre-2000 operating systems and application software running anywhere on your network—but WINS is in its twilight years. Or so we hope, anyway. It sometimes seems that the two truths about WINS are

- ◆ #1: WINS, your days are numbered!
- ◆ #2: Unfortunately for the rest of us, that number is *really* big.

WINS is on its way out because although basic NT 4 services accessed the network via NetBIOS, which relies upon WINS for name resolution, Windows 2000 and later instead accesses the network via Winsock, which uses DNS for its name resolution.

To see how the importance of names has shifted from WINS to DNS, consider this example: Both NT 4-based domains and Active Directory domains use a set of machines called *domain controllers* to act as the keepers of the enterprise's user accounts. When one domain controller learns something new about a user, such as a new password, that machine must pass that information on to the other domain controllers. But how does it *find* those domain controllers? Well, an NT 4 DC would find another DC via WINS. But an AD DC would find another DC via DNS. Similarly, before your workstation can log you in first thing in the morning, that workstation must find a DC—which it needs in order to log you in—with DNS. So where DNS access was a kind of “nice to have” feature of NT 4 domains, in Active Directory DNS is really a “need to have” feature—no DNS, no logon.

DNS, then, is now a basic service, no less important than electricity, at least as far as your network is concerned.

## Anatomy of a DNS Name

DNS has rules for naming computers, rules that are in some senses actually more restrictive than the ones that we lived with under NetBIOS.

### DNS NAMES ARE SEGMENTED

DNS names are arranged in pieces separated by periods so that, for example, a PC name such as mypc.test.minasi.com has four pieces to it. Each piece can't exceed 63 characters in length, and the entire name can't exceed 255 characters total. The only acceptable characters in a DNS name (according to RFC 1123—as you'll see, Microsoft bends this rule in its Active Directory names) are A–Z, a–z, 0–9, and a “-” (that is, a hyphen or a dash—no underscores allowed under RFC 1123).

That's worth keeping an eye on if you're upgrading systems from pre-Windows 2000 operating systems. NetBIOS lets you use considerably more characters than DNS does.

### THE COMPUTER NAME IS THE LEFTMOST PART

When picking apart a DNS name, the leftmost piece is the computer name, and the remaining pieces to the right are the computer's DNS domain or DNS suffix. (Some sources call it a *DNS domain*, others a *DNS suffix*. I think the Microsoft literature favors *DNS suffix* because it's easy to get confused between *DNS* domains and *Active Directory* domains.) So, for example, in the machine mypc.test.bigfirm.biz, visualize two pieces:

mypc + test.bigfirm.biz, or  
machine name + DNS domain name/suffix

Now that I've pointed out that the leftmost part is the machine name, let me answer a question that might be in the minds of those who've used NT. I said a couple of paragraphs back that each piece of a DNS name can be up to 63 characters long. Is that *really* true when it comes to the leftmost piece—can I *really* assign a machine name that is that long?

Well, it depends. Windows 2000, XP, and 2003's NetBIOS software is only really aware of the leftmost part of the name, so from NetBIOS's point of view, mypc.test.bigfirm.biz would simply be named \\mypc. But NetBIOS doesn't like computer names longer than 15 characters, so any Windows 2000 or later system with a machine name longer than 15 characters but shorter than 64 characters (and remember, we're talking about just the leftmost piece here—mypc, not mypc.test.bigfirm.biz) would be able to communicate from a Windows 2000 PC to a Windows 2000 or later PC, but pre-2000 systems would not be able to see a computer with a 16+ character name, so Windows 2000, XP, and 2003 keep a *truncated* NetBIOS name in that case. That might not be a problem—but if two systems with long computer names both truncated to the same name, as would be the case with a system named marksfavoritepc0001 and marksfavoritepc0002—then the NetBIOS software on one of those systems would simply shut itself down, as duplicate names are a no-no for NetBIOS, and thus pre-2000 systems would not be able to access that second system.

### The DNS Namespace: The Key to DNS

The huge size of networks that DNS can handle naming for is downright amazing. Given the name of any computer on the Internet, it can give you the IP address of that computer, and usually in just a few seconds. How many computers *are* there on the Internet—how big is the database that DNS is searching for you when it resolves a name? Honestly, I don't know the exact number of machines on the Internet, but I'm sure that “hundreds of millions or more” is a reasonable guess. The database of machine names for the entire Internet is a *big* database, and it changes all the time—but it works. From any computer on the Internet, you can find the address of any other computer on the Internet, using the worldwide DNS hierarchy or “namespace.” Furthermore, you can get that information relatively quickly, usually in a few seconds.

How does a DNS hierarchy or namespace work? You need to know this for a couple of reasons. First, even if you create a DNS hierarchy that *isn't* connected to the public DNS hierarchy, you still need to create a hierarchy, and the tiniest DNS namespace works exactly the same as the public DNS namespace, it's just smaller. Second, if you *do* decide to build your DNS so that it's a part of the public DNS hierarchy, then you'll need to know how that hierarchy works. (And, I suppose,

the third reason would be that it's just interesting to understand how this essential part of the Internet works. Interesting to me, at least, but then I don't get out much.)

You'll see people use the term *namespace* and *hierarchy* when referring to DNS. I'll tend to use *hierarchy* here, but if you read something that refers to a *DNS namespace*, then just substitute *DNS hierarchy* and you'll be correct.

### INTRODUCING THE HIERARCHY: BACK TO LEFT-TO-RIGHT

As I suggested in the first paragraph of the last section, you read DNS names left to right, whether they're names in the worldwide DNS hierarchy or in your own private four-computer private DNS hierarchy. But what are you reading? Let me explain this in some detail and use it as my vehicle to introduce how the DNS hierarchy works.

To rephrase a question I posed a couple of paragraphs ago, "How on Earth could a database as large, widespread, and ever-changing as the DNS machine-name-to-IP-address database be managed and maintained and yet still offer reasonable query times?" Well, as you'll see later in this chapter, the *only* reason that it's possible is because no one person or organization must keep track of those names. Instead, the responsibility for keeping track of the name-to-IP-address relationship is maintained locally—if you point your browser to `www.minasi.com` and your local DNS server then tries to figure out the IP address of `www.minasi.com`, then your local DNS server is soon going to be talking to *my* local DNS server to resolve that name. That means that it's *my* job to make sure that you can find the `www` machine in the `minasi.com` domain because `minasi.com` is *my* domain. If by contrast you go looking for `www.acme.com` and *Acme* drops the ball on keeping track of *their* domain, then it only affects the people trying to get to the Acme systems—you wouldn't be hampered at all in trying to find a computer in the `minasi.com` domain.

Let's consider a PC whose full name is `mypc.test.minasi.com` in order to start examining how the hierarchy works. What do the placements of the periods in the name—the parts of the name—tell us?

First, we know that its machine name is `mypc`. Second, we know that its domain is `test.minasi.com`.

But what *is* `test.minasi.com`? Well, reading left to right, you see that *test* is a subdomain or child domain (RFCs use both terms, so I don't think one is the "official" name) of another domain named `minasi.com`. That means that whoever created the `test.minasi.com` domain needed the permission of whoever's in charge of the `minasi.com` domain in order to create the `test.minasi.com` domain.

Next, let's move to the right, and consider *minasi.com*. What is this domain? It is a child domain of a domain named, simply, `com`. (Yes, there is such a domain.) To create the `minasi.com` domain, someone (well, *me*, actually) needed to contact the people in charge of the `com` domain and get permission to create a subdomain of `com` named "minasi" or, in other words, "`minasi.com`." That's what you do when you visit `www.networksolutions.com` to try to register a new "dot-com" domain.

But where did the `com` domain come from? Is it a child of some other domain? Well, if it weren't for a very common bit of sloppiness, then it'd be more obvious. You see, `mypc.test.minasi.com` isn't, strictly speaking, a complete DNS name—instead, `mypc.test.minasi.com` *is*. What's the difference? Look again—the correct one ends with a period. The `com` domain is actually a child domain of a domain named just "." that is, by the way, pronounced "dot" and is called the *root* of the DNS hierarchy. And as long as I'm introducing terminology, the phrase *complete DNS name* isn't really correct—the Internet-speak phrase is *fully qualified domain name* (FQDN).

Now you know why I've been calling the way that DNS stores names a "hierarchy"—DNS distributes responsibility. To create the com domain only required the permission—granted *once*—of whomever owned the root (.) domain. (Originally it was the U.S. government, but that responsibility has moved to a nonprofit group called the Internet Corporation for Assigned Names and Numbers, or ICANN. They're doing a terrible job, apparently, and the Feds are threatening to take the root back.) I got to register minasi.com because I provided some information and a credit card number to the people who run the com domain, Network Solutions. (They're a division of a for-profit firm named VeriSign.) Now, if someone were to come to me and ask to create a domain named thisistheplace.minasi.com, she wouldn't have to talk to ICANN or VeriSign—she'd only have to talk to me.

Let me underscore that. To create minasi.com, I only needed the permission of the people who run the .com domain. I didn't have to get permission from other .com companies, such as microsoft.com, ibm.com, or saralee.com—I just needed the OK from the .com parent domain, which is controlled by Network Solutions. Nor did Network Solutions have to ask the ICANN guys—once ICANN (the root people) delegated control of the com. directory to the Network Solutions folks, then ICANN doesn't care who Network Solutions delegates to. In the same way, if I wanted to create a subdomain of minasi.com, such as hq.minasi.com, then I not only needn't tell microsoft.com, ibm.com, or saralee.com, I also needn't tell Network Solutions.

### WHY BUILD THE DNS HIERARCHY THIS WAY?

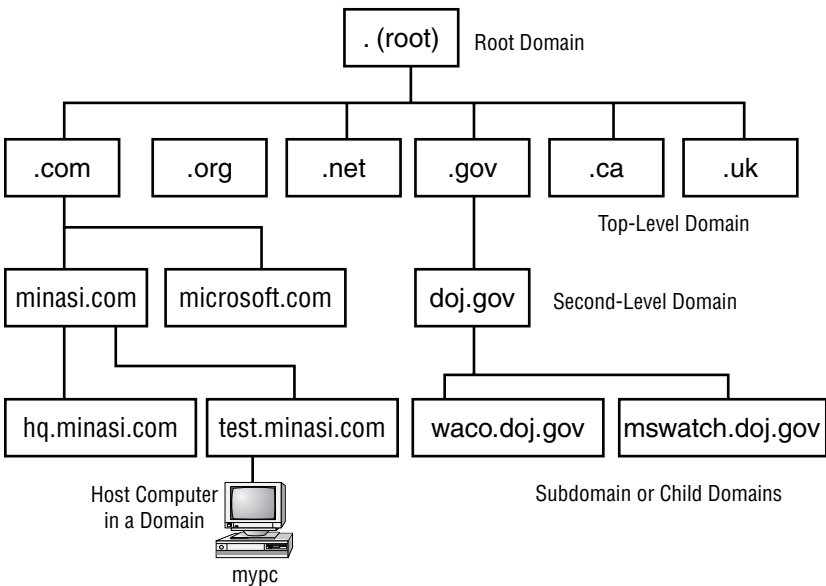

Let's back up for a bit and see what led to DNS looking as it does today. In the TCP/IP world, anything with an IP address is called a *host*. Back in the early '80s, when the Internet (which wasn't yet *called* the Internet—it was the ARPAnet then) consisted only of a few hundred computers, a server on MIT's campus held a file that listed the names and IP addresses of those few computers. That file was named HOSTS because it listed all of the hosts on the Internet. When someone at some distant site added a computer to their local network and attached that computer to the ARPAnet, then he or she would just contact someone at MIT, who'd update the HOSTS file, and once a day everyone would attach to that MIT server and download the latest HOSTS file.

As you know, the HOSTS file still exists, although in a much less important role. But why not keep running things the old way, with one big central HOSTS file? Well, let's see: Assume 200 million computers on the Internet, and about 40 characters per HOSTS line; that'd be about 8 gigabytes. So every day you'd have to connect to some location and download 8 gigs—yuck. Even worse, every single time you put a computer on your network, adding pc0012 to acme.com, you'd have to tell someone at the one worldwide central repository of the HOSTS file and hope that they'd update the file in a timely fashion. And when you add a new system to your network, or perhaps assign a name to a different IP address—such as when you move www.acme.com from one machine to another, changing an IP address in the process—then you better hope that everyone out there in Internetland who you'd *like* to be able to find your Web server is working from the latest HOSTS file—ugh, double and triple yuck.

### THE ROOT, TOP-LEVEL, SECOND-LEVEL, AND CHILD DOMAINS

Having explained how the hierarchy *doesn't* work, let's look at how it *does* work. Take a look at Figure 7.43.

**FIGURE 7.43**  
The public DNS  
hierarchy

**Top-Level Domains**

Below the root are hundreds—yes, hundreds—of *top-level* domains. Most of the ones we tend to think of around the world are .com, .net, and .org, as they’ve become sort of the worldwide “catch-all” domains. Then, each country has its own top-level domain—the United States has .us, Canada .ca, the United Kingdom .uk, and so on. Some countries have decided to offer their top-level domain for registrations, as in the case of the Cocos Keeling Island, the owners of the .cc top-level domain that many are using as an alternative to .com, .org, or .net. The island has a total population of 604 and in 1995—the last year I could find data for—their main export was copra. Who knows, perhaps nowadays they’re all sharing the wealth from being the “kings of dot-cc.” In another example, the somewhat-larger (population 10,000) island nation of Tuvalu ended up with the top-level domain with the salable name of .tv. Top-level domains .gov, .mil, and .edu tend to point to U.S. government, military, and educational institutions—remember who invented the Internet—although I guess in theory, groups of those types in other countries might register names under those top-level domains as well.

In November 2000, ICANN created several new top-level domains. I don’t exactly get why they did some of them, but they are presented in Table 7.2.

**TABLE 7.2: NEW TOP-LEVEL INTERNET DOMAINS**

DOMAIN	PURPOSE	CONTROLLING ORGANIZATION
.aero	Aerospace-oriented firms, including airlines	Societe Internationale de Telecommunications Aeronautiques (Belgium)
.biz	Basically an “expansion area” for .com	JVTeam, LLC

*Continued on next page*

TABLE 7.2: NEW TOP-LEVEL INTERNET DOMAINS (continued)

DOMAIN	PURPOSE	CONTROLLING ORGANIZATION
.coop	Business cooperatives	National Cooperative Business Association
.info	Information sources	Afilias, LLC
.museum	Museums, clearly	Museum Domain Management Association
.name	People’s names (see text)	Global Name Registry (the U.K.)
.pro	Various professional groups—doctors, lawyers, accountants, that sort of thing	RegistryPro (Ireland)

The top-level domains .biz and .info are both wide-open domains that anyone can register names in. If you’re Acme Termite Inspection service and acmetermite.com, acmetermite.net, and acmetermite.org are taken, then you might still be able to get acmetermite.biz or acmetermite.info. The domain .pro is *not* wide open; there are people running various subdomains there. For example, you couldn’t (as far as I can see) just register engineer.pro; rather, someone would administer engineer.pro and you’d get a name below that, like janesconstruction.engineer.pro. (As I write this, there’s already a cpa.pro, medical.pro, and legal.pro.) The idea behind the .name domain is that someone would create an overall registry of people whose last name was Minasi and therefore control the minasi.name domain. I’d then get a subdomain under that called mark.minasi.name.

Different organizations control different top-level domains. For example, clearly Ottawa designates who hands out registrations under .ca, and the .tv sellers couldn’t be doing those sales without the permission of the Tuvalans. The top-level domains that are biggest by far, however, are of course .com, .net, and .org, all administered by a company called Network Solutions, based in northern Virginia—but you may hear this company referred to by several names. Before the late ’90s, a consortium of U.S. government agencies called the InterNIC controlled the entire DNS naming hierarchy, and they contracted with Network Solutions, a private firm, to handle the nuts and bolts of keeping the .com, .org, and .net top-level domains working. As a result, people have a tendency to use the terms *Network Solutions* and *the InterNIC* interchangeably, although they’re not the same thing, and the InterNIC has become pretty irrelevant now that the U.S. has ceded control of the public DNS hierarchy to ICANN. Network Solutions is also not the same as ICANN—ICANN worries about *all* of the top-level domains. You might even see people refer to Network Solutions as VeriSign, the e-commerce security folks; that’s because VeriSign bought Network Solutions in 1999.

**Roll-Your-Own Top-Level Domains: For Internal Use Only!**

Before I move to second-level domains, I want to toss in something that I’ll be covering in detail later. Although the public Internet only uses a handful of top-level domains (TLDs in geek-speak), that doesn’t mean you can’t create others of your own sometimes. As you’ll see, I strongly recommend that the DNS servers that support your Active Directory *not* be visible on the public Internet, if you can avoid it. You can, as you’ll learn, create a DNS server that is perfectly capable of resolving names on the public Internet, but that also hosts a domain that is “invisible” to the public Internet. (You’d do this for security’s sake.) You can accomplish this in several ways, but one simple way

is just to use a domain name with a nonstandard TLD. For example, suppose your company's publicly visible Internet domain name were `acme.com`; you might choose to create an Active Directory domain name of `acme.local`. Never heard of a domain called `something-dot-local`? No wonder—there's no such TLD on the Internet. But you can do anything you like on your *intranet*, creating domains with any TLD that you like. So I guess I *could* have an e-mail name of `mark@minasi`—but only people inside my company could use it! Again, we'll cover more on this later, but I wanted to plant that idea in your head now so I can expand on it later.

There was a proposed standard working its way through the RFC process that would have suggested a reserved internal-only top-level domain of `“.pri”` for “private” but it appears to have gone nowhere.

### **Second-Level Domains: Searching the Hierarchy**

Sadly, ICANN's not about to give me my own `.minasi` top-level domain, so I guess I won't be able to change my e-mail address to `mark@minasi` any time soon. So the second-level domains are the more interesting ones for most of us.

As you just read, you can create a second-level domain with the permission of the owner of the parent domain. To create your second-level domain, the parent domain only has to do one thing: “delegate” name responsibility for your second-level domain to some machine. That's an important concept, and I'll get to it in a minute. But first, let's see how DNS uses its hierarchical nature with an example.

Suppose you point your browser to `www.minasi.com`. Your browser needs to know the IP address of the `www.minasi.com` machine, so it asks your local DNS server to resolve `www.minasi.com` into an IP address. (This is a simplified example—we'll consider a more complete one later.) Where should your local DNS server go to ask the IP address of the `www` machine in the domain `minasi.com`? Simple—it should go to the DNS server for `minasi.com`. That's a perfectly correct answer but not a very helpful one. How is your DNS server supposed to find the DNS server for `minasi.com`? Well, in general, you can find the address of a domain's DNS server by asking the domain's *parent's* DNS server—in other words, the DNS servers in the `com` domain can tell you the addresses of the DNS servers in the `minasi.com` domain.

But we're still not done, because *now* the question is, “What is the IP address of the DNS server (or servers) for the `com` domain?” Well, as you just learned, you get a domain's DNS server addresses from the DNS servers in that domain's parent's DNS server, so you'd get `com's` DNS server address from the DNS servers for `com's` parent, `“.”`—the root.

Hmmm...if you've been patient enough to follow this so far, then you've probably realized that we've run into a bit of a brick wall. You find the DNS servers for `minasi.com` by asking the DNS servers for `com`, and you find the DNS servers for `com` by asking the root, but who do you ask to find out the DNS servers for the root, as the root has no parent? (Hey, that'd be a great computer trivia question: Which is the only “orphan” DNS domain?)

The answer is, “you cheat.” Every piece of DNS server software that I've ever seen comes with a kind of a cheat sheet called the *root hints file*, which contains the name and IP addresses of the 13 root DNS servers. On a Microsoft OS-based DNS server, you'll find a file named `cache.dns`—an ASCII file that you can examine with Notepad—in `\winnt\system32\dns` (or perhaps `\windows\system32\dns`) on any server that you've installed the DNS server service on. Anyway, once your DNS server has located a root DNS server's address in its root hints file, it asks that root DNS server for the addresses

of the DNS servers for the com domain, then asks one of the com DNS servers for the address of the minasi.com DNS server, *then* asks the minasi.com DNS server for the address of the machine named www in the minasi.com domain and finally resolves the name for you. To summarize what happened when your local DNS server tried to resolve www.minasi.com:

1. First, your DNS server decided to find the minasi.com DNS server.
2. To find the minasi.com DNS server, your DNS server decided to look for the addresses of the com domain's DNS servers, as com is minasi.com's parent domain.
3. To find the com domain's DNS server, your DNS server decided to look for the root DNS servers.
4. It knew the IP addresses of the root DNS servers through its local root hints file.
5. Using the IP address of a root DNS server, it asked that root DNS server for the address of a DNS server for the com domain.
6. The root DNS server told your DNS server the addresses of the com domain's DNS servers.
7. Your DNS server then took one of those addresses and asked that com DNS server for the addresses of the minasi.com DNS servers.
8. That DNS server for the com domain told your DNS server the addresses of minasi.com's two DNS servers.
9. Your DNS server then asked one of minasi.com's DNS servers to resolve the name www.minasi.com.
10. The minasi.com DNS server resolved the address, returning the IP address of www.minasi.com.

### **Third Level, Child, or Subdomains: More on Delegation**

Now suppose I choose to divide my domain into subdomains or child domains. Suppose I create a subdomain named hq.minasi.com. What's involved? Delegation.

You saw from the previous example about resolving www.minasi.com that a DNS server resolves a name by working its way up the DNS hierarchy until it gets to the root, then works its way back down until it finally finds the DNS server that can answer its question. But, in some senses, *shouldn't* the root servers be able to resolve www.minasi.com? After all, www.minasi.com *is* in their domain, sort of. Or I could argue that the DNS servers for the com domain should be able to resolve www.minasi.com, as that address is inside the com domain, *sort of* "once removed," so to speak.

The answer is no, the root and com domains should *not* be able to resolve www in the minasi.com domain because they have *delegated* name resolution responsibility for minasi.com to a set of DNS servers, the minasi.com DNS servers. More specifically, the root domain contains records called NS (name server) records that delegate the responsibility for the com domain to the com DNS servers, and the com domain's DNS servers contain NS records that delegate name server responsibility for the minasi.com domain to the minasi.com servers. In fact, the people who maintain the database for the com zone *could* keep the name resolution record for www.minasi.com in the com database, but that would defeat the whole purpose of the hierarchy, and it would be a pain for me—if I ever moved the Web function from one of my computers to another, I'd have to bother the Network Solutions people and ask them to change the name resolution record for www.minasi.com.

So why would I create a subdomain of minasi.com? Perhaps I've got the same kind of problem that Network Solutions does—that is to say, perhaps I want to enable a group to use DNS names within my domain, but I don't want to have to do the maintenance on the DNS records. Suppose, for example, that I buy a company in Singapore, 12 time zones away from me. Now suppose they put a new machine online and need a name resolution record for that machine installed in the minasi.com DNS database. They can't call me when they need that, as it's not only a long way away, but also because I'm usually asleep while they're working. That gets kind of annoying and after a while they say, "Can't you just give us control of the name resolution for our own machines?" Well, I'm not particularly keen about giving them control of the whole minasi.com domain, but I'd like to grant their request for local control of their machine names. So I create a subdomain and call it test.minasi.com. Making their subdomain a reality requires two things:

- ◆ First, they'll need to make one of their computers into a DNS server for the test.minasi.com subdomain. That machine will, of course, need to be on the Internet persistently.
- ◆ Second, I'll need to tell the rest of the world to look at their server when resolving names in the test.minasi.com domain. I do that by delegating name server responsibility, by placing an NS record in my minasi.com DNS database that says, "There's a subdomain named test in the minasi.com domain, and if you want to look up any names in that, then don't ask me, ask this other DNS server, the one in Singapore."

You'll learn more about NS records a bit later, when I get more specific about building DNS zones, but in a nutshell that's all there is to delegation—it's a one-line command in a parent DNS server's database that says, "Hey, don't ask *me*—go talk to this other DNS server."

#### **DNS DEFINITION: "AUTHORITATIVE"**

Before moving on to my next DNS topic, let me define a term: *authoritative*. I've been telling you that to look up names in minasi.com you need to find minasi.com's DNS servers, and that you find minasi.com's DNS servers by asking the DNS servers in minasi.com's parent domain, com. The names of the minasi.com DNS servers that the com servers report to you are called the authoritative servers for minasi.com.

In other words, I could, in theory, have 50 DNS servers set up for minasi.com running on my network. (Don't ask me why I'd do that; I can't think of a reason offhand.) But if the com domain's DNS servers only know about three of those minasi.com DNS servers, then when people ask the com domain's servers for the names of the minasi.com servers, the com domain servers will only contain three NS records for minasi.com, so they will only report the three minasi.com DNS servers that they know about. In the same way, if my imaginary Singapore office ran 47 DNS servers but I had only entered one NS record in the minasi.com DNS database for test.minasi.com, then only the one DNS server named in that NS record would be authoritative for test.minasi.com.

#### **Exercise: Set Up a DNS Server and Work with *nslookup***

Time to leave the theory for a moment; let's set up a simple DNS server and do some name resolution. We will build upon this server as the rest of this chapter goes on, and then I'll use this server as the foundation of an example Active Directory that we'll build in the next chapter. I've integrated these examples for one reason: Active Directory will not work without the proper underlying DNS

infrastructure. I get tons of letters from readers who say that they've got a small AD set up and it isn't working. In my experience nine out of ten times, it's DNS that gets in the way. Without correct DNS setup, your systems cannot find each other to authenticate, and if one machine in a domain wants to talk to another machine in a domain then they must authenticate, or nothing happens. So I'll walk you through an example, step by step.

In this step, we'll just get the DNS server up and running.

### INTRODUCING BIGFIRM.BIZ

We're going to create a DNS domain and eventually an Active Directory for a mythical company called bigfirm.biz. To that end, we'll end up with two things. First, we'll have a DNS domain named bigfirm.biz, and this computer will be the authoritative DNS server for that domain. Second, we'll have an Active Directory named bigfirm.biz. And just to keep the number of machines that we'll need to a minimum, we'll also make this machine a domain controller for Bigfirm.

All I want right now, though, is the most basic DNS server possible, one that only knows how to go out on the Internet and answer queries. Let me stress that you do not need a Server 2003–based DNS server to run Active Directory; a Windows 2000 Server–based DNS server or for that matter many other vendors' DNS servers will do fine for AD. But this gives me an excuse to show you how to set up a Server 2003–based DNS server.

### WHAT YOU'LL NEED

I know that some of you will just read along and not actually try this out, but let me counsel you *not* to do that. People often ask me how to learn a product—what books, seminars, videos, Web sites, or the like should they use? My answer is always the same: get a good basic text or other starting point, get a computer whose hard disk you don't mind wiping clean and rebuilding, and then just install the software and play with it. (I'm hoping that you've decided that you've got that “good basic text” in your hands, but use whatever works.)

In any case, you do not need a big beefy machine just to play around with Server 2003; as I write this, my test machine is a 450MHz laptop with an 8GB drive and 196MB of RAM. I wouldn't use it to create the main DNS server for Earthlink, but it's fine for testing. Just make sure that the system is

- ◆ Running Windows Server 2003
- ◆ Has a connection to the Internet, and
- ◆ Keeps the same IP address throughout this exercise

In general, real honest-to-God DNS servers that enterprises rely upon will have either static IP addresses, or unchanging IP addresses delivered via a DHCP reservation. Ultimately I'll have you set this machine to some IP address, but for now it doesn't matter. But let me stress that (1) any machine that you intend to be a DNS server for your network must have a constant IP address, and (2) if you want that DNS server to be able to resolve addresses on the public Internet, then that DNS server must have an IP address that connects to the Internet. Note that it is perfectly fine for the machine's address to be in one of the nonroutable ranges of addresses—your machine could have a 192.168.x.x, 10.x.x.x, or 172.x.x.x address. As long as it can ping IP addresses to the public Internet, then it'll do just fine as a simple DNS server for this example.

No matter how you plan to do this, however, make sure you know your system's IP address: open a command line and type `ipconfig` and press Enter to find out. Keep that address handy.

Then I'll add a couple of nice, but not essential, characteristics to this server:

- ◆ Any domain controller for an Active Directory has to have a DNS suffix whose name matches the AD. Again, in the next chapter we'll create a domain named `bigfirm.biz`, so let's get ready and make sure that this DNS server—which will ultimately be a DNS server for `bigfirm.biz`—already has its DNS suffix set to `bigfirm.biz`. This isn't essential for these early examples, but let's get it out of the way now; besides, if DNS servers don't have any DNS suffix set at all, then you get some annoying warning messages in the DNS Server event log.
- ◆ Finally, let's agree on a machine name for this computer. Again, not essential, but it's nice if my screen shots look somewhat the same as yours. This machine will ultimately do a lot for `bigfirm.biz`, so let's call it `bigdog`.

In case you're not 100 percent sure how to name the system `bigdog` and give it a DNS suffix of `bigfirm.biz`, let's walk through that now.

#### CHANGING A SYSTEM'S NAME AND DNS SERVER SUFFIX

You change a system's name and DNS name in the Computer Name tab. More specifically:

1. Click Start, then right-click My Computer and choose Properties.
2. Click the Computer Name tab.
3. Click the Change button to raise a dialog box labeled Computer Name Changes.
4. In the Computer Name field, enter **bigdog**.
5. Click the More button.
6. In the DNS Suffix and NetBIOS Computer Name dialog box, fill the field labeled Primary DNS Suffix of This Computer with **bigfirm.biz**.
7. Click OK to return to the Computer Name Changes dialog.
8. Click OK to close the Computer Name Changes dialog.
9. That will raise a dialog box that warns that you've got to reboot to see these changes take effect. Click OK to clear the dialog.
10. Click OK to close the System Properties page.
11. Click Yes to reboot your computer.

Once the system has rebooted, try an `ipconfig /all` command. You should see that the Host Name is `bigdog` and the Primary DNS Suffix is `bigfirm.biz`.

#### CHECK IP ADDRESS AND CONNECTIVITY

While you've got the `ipconfig` output in front of you, make a note of the IP address. Then check that your system can ping the outside world. Open a command prompt and try typing `ping 164.109.1.3`, the address of a DNS server on a large ISP, or `152.163.159.232`, one of AOL's DNS servers. If you're not sure what I just said to do, *do not go any further*; please go back and review the previous chapter. (I promise, we won't go anywhere until you get back.)

### INSTALL THE DNS SERVER SOFTWARE

Now we're ready to get the DNS server running. The steps to installing DNS are exactly the same as for installing any of the other network services, like DHCP or WINS. Make sure you've got the Server CD around, or are connected to whatever set of I386 files you installed this system from, as it'll need to go out to the CD to find the DNS server software. Then do this to install the DNS server software:

1. Open Add/Remove Programs (Start/Control Panel/Add or Remove Programs).
2. Click Add/Remove Windows Components and wait a bit while the Windows Components Wizard starts up.
3. Click Networking Services and then the Details button.
4. Click the check box next to Domain Name System (DNS).
5. Click OK to return to Windows Components.
6. Click Next to install the service. The system will say that it is "Configuring Components" for a while, probably a few minutes, and may need the original Server installation CD. A bit later, the Completing the Windows Components Wizard screen appears. If you currently have an IP address from DHCP, then the wizard will stop and suggest that while it's not going to *make* you give this server a static IP address, it's a *really* good idea to set one. It then brings up the TCP/IP properties screen. In a real DNS production server you would always use either a static IP address or a DHCP reservation. But if you're just playing with a DNS server, then you can work with whatever random IP address your ISP's DHCP server (or for that matter the built-in DHCP server in your DSL/cable router, if that's how you connect) gives you. Just click OK three times and the wizard will leave you alone.
7. Click Finish to end the wizard.
8. Click the Close box in the Add/Remove Windows Components window.

### POINT THE DNS SERVER TO ITSELF

You're going to be sitting at the server while doing the sample DNS queries, so when the server wants to resolve a DNS query you want the server to ask *itself* (that is, the DNS server software running on it) to resolve names. Do that through the GUI as you saw in the last chapter—in Network Connections, right-click Local Area Connection or whatever your NIC's name is, choose Properties, click the General tab, then click Internet Protocol (TCP/IP) and the Properties button, and then click the radio button labeled Use the Following DNS Server Addresses and fill in the DNS server's IP address. So, for example, let's say that you've got your test machine, the one that you just put the DNS server software on. Suppose its IP address is 192.168.0.12. You must now go into TCP/IP Properties for that test machine and fill in the Preferred DNS Server field with its own IP address, 192.168.0.12.

You can alternatively set the preferred DNS server from the command line:

```
netsh int ip set dns name static ipaddress primary
```

where you replace *ipaddress* with the server's actual IP address and *name* with the first word from the NIC's name. So if your system had an IP address of 192.168.0.12 and a NIC named Local Area Connection, then you could set its preferred DNS server this way:

```
netsh int ip set dns local static 192.168.0.12 primary
```

If, on the other hand, the server's NIC were named Wireless Network Connection, then you'd replace "local" with "wireless," as in

```
netsh int ip set dns wireless static 192.168.0.12 primary
```

Why "wireless" and "local?" Because if you have more than one NIC, then netsh needs to know which NIC you're referring to. Each NIC has a name like "Local Area Connection," "Local Area Connection 2," "Wireless Network Connection," or the like. You can either write out the whole name, or just use the minimum number of letters necessary to make clear which you mean. Thus, if you had two network connections named "Local Area Connection" and "Wireless Network Connection" then you could just type "l" or "w" to tell netsh which you meant. You need quotes in the name when the name has spaces, as in "Local Area Connection."

Here's another example. If you had a system with a NIC named Local Area Connection and another NIC named Local Area Connection 2, then you'd have to specify the whole name in quotes, as in

```
netsh int ip set dns "Local Area Connection 2" static 192.168.0.12 primary
```

**TIP** That's a general rule—you should usually set up DNS servers to point to themselves for name resolution; specify the server's IP address in the Preferred DNS Server field. If you configure the server via a DHCP reservation, then you can specify the server's preferred DNS server address in the reservation as well.

Double-check that you've got this set up right by typing **ipconfig /all** at the command prompt. You should see the same IP address next to both "IP Address" and "DNS Servers" in that output. If they don't match, go back and reassign the preferred DNS server either in the GUI or with the netsh commands above.

### START THE DNS SNAP-IN

As with DHCP and WINS, you needn't reboot when you install the server software. Click Start/Administrative Tools/DNS and you'll see the DNS snap-in. You'll see an icon representing your server in the left pane; click the server and you'll see a screen like Figure 7.44.

**FIGURE 7.44**

Initial DNS snap-in screen

Notice the seemingly helpful message in the right pane offering to configure your DNS server. Take my advice:

**WARNING** *Never let Configure a DNS Server configure your DNS server.*

If you right-click the server's icon and choose Configure a DNS Server, then you start a wizard that has a tendency to make some bad assumptions about how you want your server set up. It's particularly good at mistakenly making your DNS server something called a "private root." (This is less of an issue in 2003 than it was in 2000, but I still advise against it.) It's not hard to fix private roots, but they're scary-looking when you've never seen one before. Trust me, I'll show you how to get it "configured" with no trouble (and no help from the Configure a DNS Server Wizard) in this chapter.

Before we leave the snap-in, let me direct your attention to a place that I hope to habituate you to looking at: the Event Viewer logs. Click the plus sign next to the server's icon and you'll see a folder labeled **Event Viewer**; inside that is a folder labeled **DNS Events**. Click that and you'll see entries in the right pane that offer information about how your DNS server is running. If you've followed my steps here, then you'll only have two events in your log. The first will be a lengthy Event ID 708, which basically just says, "Hmmm, it looks like this DNS server isn't holding onto any DNS information, so you must only want it to go resolve names from elsewhere—that is, to be a 'caching-only' server." It's just an information-only message and is nothing to worry about. The second will be an Event ID 2, which just says that the DNS Server service has started. So we had two information-only messages; was looking in the Event Viewer a waste of time? Not at all. It pays to take a look at it periodically...even if some of the messages that you'll come across *are* a bit cryptic!

### TRY A NAME RESOLUTION

Now that we've got a DNS server running and a computer relying on that DNS server (that is, the server itself), let's do the simplest thing in the world—just resolve a name. We'll resolve [www.minasi.com](http://www.minasi.com).

Then open a command prompt (unless you've still got one open) and type **nslookup** and press Enter. You'll probably see something like this:

```
C:\>nslookup
DNS request timed out.
        timeout was 2 seconds.
*** Can't find server name for address 206.246.253.12: Timed out
Default Server: UnKnown
Address: 206.246.253.12
>
```

Your IP address will be different, but otherwise you'll probably see something like this. Or you might see a somewhat less-scary set of output, like this:

```
C:\>nslookup
Default Server: ip68-106-120.hr.hr.cox.net
Address: 68.106.183.120
>
```

The only difference is in how some other DNS servers are set up. If you keep getting the "\*\*\* can't find server name for..." error, then ignore it. You'll see how to get rid of it later. Now, **nslookup**

is a bit impatient and complains about timeout messages if a DNS server doesn't respond to it in *two seconds*. Let's relax it a bit. Type

```
set timeout=10
```

Ten seconds seems a bit more reasonable.

Next, type

```
www.minasi.com
```

and again press Enter. You should see something like

```
Default Server: UnKnown
```

```
Address: 206.246.253.12
```

```
Non-authoritative answer:
```

```
Name:    cablenic.minasi.com
```

```
Address: 68.15.149.117
```

```
Aliases: www.minasi.com
```

```
>
```

Again, the exact text may vary because your DNS server uses a different IP address than mine does, and I might well have reconfigured the IP address on my Web server by the time you try this out. Here's the important thing: *it resolved a name on the Internet*. Not impressed, you say? Well, consider this: how much configuration did you do to the DNS server in order to "teach" it to resolve names on the public Internet? Answer: none.

That's *really* important. We're going to talk later about something called *forwarders*. Many people somehow get an idea that they need to configure forwarders for DNS servers in order for the DNS servers to be able to resolve addresses on the Internet. It's not true; all a DNS server needs is a connection to the Internet and the list of ICANN's 13 root servers. Again, the server's IP address needn't even be routable as long as there's a NAT/PAT router around. Try it—set up Internet Connection Sharing as we discussed in the last chapter and put a system on your internal network, the network that gets the 192.168.0.x addresses. Make the system a DNS server and try what we just did, and it'll still work fine, at least so long as my connection to my ISP is intact. (Try a name like [www.ibm.com](http://www.ibm.com) if mine doesn't work.)

So when you set up a DNS server, make it a habit to do a simple little troubleshooting step as soon as you've got DNS on the system—point a system to that DNS server, start `nslookup`, and try to resolve a name out on the public Internet.

### TROUBLESHOOTING THE SIMPLE DNS SERVER

If it doesn't work, what to do? Check the following things.

- ◆ Double-check that the DNS service is actually running. While sitting at the server that's running the DNS service, open the DNS snap-in and right-click the icon representing the DNS server and choose All Tasks, then look at the options offered. Toward the bottom of the options, you should see Stop, Pause, and Restart, rather than Start. If

you see Start, that means that the DNS server service isn't running; choose Start and it *should* start up. If it doesn't, or if it starts and then stops, look in the folder named **Event Viewer** in the DNS snap-in; there may be an error or warning message that can shed some light on the problem.

- ◆ Check that the DNS server points to itself: do an `ipconfig /all` and ensure that the IP address and the address of the DNS server are the same.
- ◆ Check that the server can route to the Internet. Try a ping to a few fairly reliable IP addresses like the ones that I mentioned a page or two back. If you can't ping to an IP address, then it's not a DNS problem, it's a router problem.
- ◆ Check that your network guys haven't installed some insanely paranoid firewall that's blocking your attempts to do DNS lookups. Type **nslookup**, press Enter, and then type **server 164.109.1.3** to point your system to that large ISP's DNS server. You should now be able to resolve `www.ibm.com` and the like. If not, then either you've got a really damaged copy of `nslookup` (something I've never seen) or your ability to communicate with the public Internet is being severely hampered by a firewall.
- ◆ Again, look in the **Event Viewer** folder. There are often *very* useful hints there.

With hope, by now you've successfully set up a DNS server and gotten a bit of hands-on with it. So it's time to return to some concepts and theory...

## Zones versus Domains (and More on Delegation)

I've been talking about how DNS servers maintain a database for a "DNS domain," but strictly speaking, DNS servers don't hold name information for domains, they hold them for *zones*. What, then, is a zone? It's a DNS-specific term that basically means "the range of Internet addresses that this DNS server will be concerned about." To see how this works, let's consider Acme Industries (`acme.com`), a firm familiar to any Warner Bros. cartoon fan. And, in the process, we'll also consider another example of delegation.

When Acme got its Internet connection, it set up a primary DNS server at its corporate headquarters in Chicago and gave DNS names to its machines. There are machines with names such as `jills-pc.acme.com`, `bigserver.acme.com`, `www.acme.com`, and so on.

As time went on, however, Acme began to feel the bite of competition from its hated and long-time rival, Apex Limited (`apex.com`). So it moved its Gadgets group—the guys who brought us Acme Instant Hole, Acme Rocket Sled, or Acme Spring-Powered Shoes—to Mexico in the hopes of lower prices. Meanwhile, Acme bought a munitions firm in Belgium and decided to close its other big domestic division, the Explosives group, and sell the Belgian explosives instead.

At this point, Acme has three loci of operation: the suits in Chicago, the gadgeteers in Mexico, and the demolitions folks in Belgium. The question for Acme's network engineers is, "How do we arrange our DNS?" They decide to create two child domains, `explosives.acme.com` and `gadgets.acme.com`. Although some machines will stay in the top `acme.com` domain—the Web server, `www.acme.com`, is an obvious choice—many machines will be either *machinename.explosives.acme.com* or *machine-name.gadgets.acme.com*. Why split up the domain into child domains? Any of several reasons, but one obvious one might be just simplicity—you can look at a machine's name and immediately figure out to which department it belongs.

**NOTE** Please note that I'm talking about DNS domains, not Active Directory domains. If I have an AD domain named *acme.com* then it'd be a really good idea to also give the DNS suffix *acme.com* to all of the machines in that domain; if my PC were named *mypc* then its full DNS name would be *mypc.acme.com*. But Microsoft says that you don't have to match DNS domain names with AD domain names, so in theory if my computer were named *mypc* in an AD domain named *acme.com*, then I could choose to give it a completely different DNS name, like *mypc.xyz.org*. I am told, however, that this leads to Kerberos problems (Kerberos is the protocol that accomplishes Active Directory authentications). I've tried to nail down exactly what the problem is but I haven't had much luck. Nevertheless, I've heard this enough that I'd think twice about giving a system a DNS suffix that didn't match its Active Directory domain.

Acme has two basic options for setting up its DNS, shown in Figures 7.45 and 7.46.

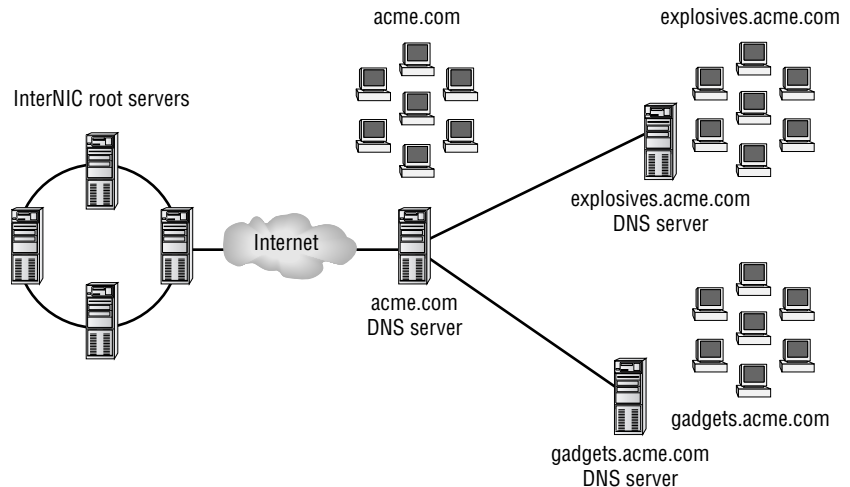

**FIGURE 7.45**

Acme with one DNS zone

**FIGURE 7.46**

Acme with three DNS zones

In Figure 7.45, Acme keeps things as they've been: There is one server that is the primary authority for all of Acme's machines. It's a perfectly fine answer, but not everyone may like it, as you'll probably guess if you recall my earlier example of my mythical Singapore office.

This is not, understand, a *wrong* answer; it's just one of several possible answers, and some may not like it. The folks in Belgium must rely on some network operators in Chicago to keep their

machines properly listed in the DNS database, and it may be that every time Belgium needs some new machines and IP addresses stuffed into the database, it's morning in Belgium and the middle of the night in Chicago, so the Belgians get to wait. And, as they're the explosives guys, that might weigh heavily on the minds of the suits in Chicago when the Belgians ask for their own DNS server. Mexico could experience the same kinds of long-distance administration problems as the ones that Belgium faces. That could lead to the setup shown in Figure 7.46.

In Figure 7.46, Explosives has its own DNS server, and Gadgets has one of its own as well. The acme.com DNS server in Chicago has a pretty sparse database—basically, it just names a few machines in Chicago and then contains a few records that say, “While I *am* the acme.com DNS server, don't ask me about anything with a name like something-dot-explosives.acme.com or something-dot-gadgets.com; rather, go ask these other machines.” Recall that in DNS terms, we'd say that the acme.com server has *delegated* name resolution for gadgets.acme.com to some DNS server in Mexico and delegated name resolution for explosives.acme.com to some other DNS server in Belgium.

Now, acme.com is still just one domain, but its DNS responsibilities—techies would say “DNS *namespace* duties”—have been spread out. What, then, to call these subsets of domains for which Acme's new DNS servers are authoritative? The term is *DNS zone* or *zone*. In Figure 7.45, Acme implemented its DNS as one zone. In Figure 7.46, Acme has three zones: its top-level acme.com zone, the explosives.acme.com zone, and the gadgets.acme.com zone.

How is this relevant to Active Directory? Well, if your network uses AD domains—and it will—then each domain requires a DNS zone of its own. So, for example, from the point of view of DNS in a no-AD world, Acme could implement acme.com, explosives.acme.com, and gadgets.acme.com as either one big zone, two zones, or three zones. Acme won't retain that flexibility if it creates Active Directory *domains* named acme.com, explosives.acme.com, and gadgets.acme.com; Active Directory would, in that case, require three separate zones.

### FORWARD AND REVERSE LOOKUP ZONES

Thus far, I've described DNS's main task as converting host names such as kiwi.fruit.com to IP addresses such as 205.22.42.19. But DNS can do the reverse as well; you can ask a DNS server, “What host name is associated with IP address 205.22.42.19?”

The process of converting a host name to an IP address is called a *forward name resolution*. The process of converting an IP address to a corresponding host name is called *reverse name resolution*.

DNS maintains information about a given domain such as fruit.com in files called *zone files*. Fruit.com, then, has a zone file that DNS can use to look up kiwi.fruit.com's IP address. But where does DNS go to look up the host name associated with IP address 205.22.42.19?

Well, recall that the Internet authorities hand out blocks of addresses. There's a DNS zone called a *reverse lookup zone* for each Internet network. So, assuming that fruit.com's working with a class C network 205.22.42.0, it's someone's job to keep a reverse lookup zone for 205.22.42.0.

The *name* of the reverse lookup zone is odd, though. To construct it, take the dotted quads that the Internet authorities gave you—drop the ones that you control—and reverse them, then add .in-addr.arpa to the end of the name. Thus, whoever is responsible for 205.22.42.0 would create a reverse lookup zone 42.22.205.in-addr.arpa. A few other examples:

- ◆ 164.109.0.0/16, a class B network, would drop the two zeroed quads and reverse the remaining two to yield a reverse zone name of 109.164.in-addr.arpa. Notice there were only two dotted numbers, as it's a B network and the owner controls the bottom two quads.

- ◆ 4.0.0.0/8, a class A network, would have reverse zone 4.in-addr.arpa. In the case of an A network, only the top quad is set, so there's only one number in the reverse zone.
- ◆ 200.120.50.0/24, a class C network, would drop the zeroed quad and reverse the numbers to get a reverse zone name of 50.120.200.in-addr.arpa.

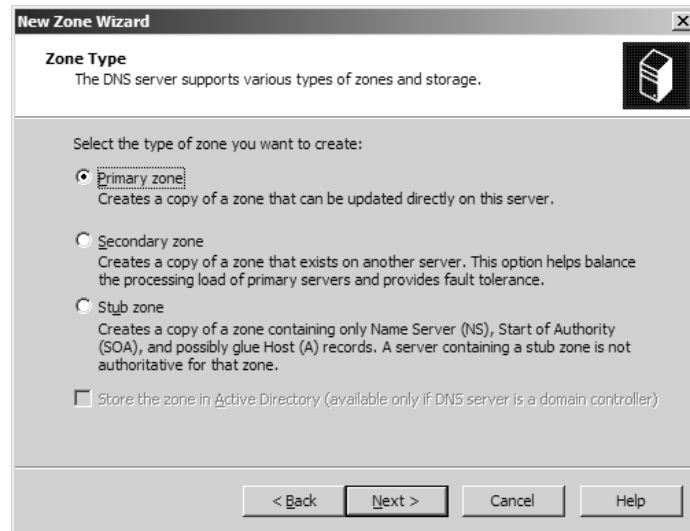

### EXERCISE: CREATING THE BIGFIRM.BIZ ZONE

Let's see what's involved with setting up new DNS domain, or, to adopt the techier talk that you'll hear most DNS experts use, a DNS zone. Let's make a zone for bigfirm.biz. As it's going to be a zone where you hand the DNS server a computer's name, like mypc.bigfirm.biz, and get back an IP address, this will be a forward lookup zone. Here's how to create the bigfirm.biz zone.

1. Open up the DNS snap-in, if it's not already open: Start/Administrative Tools/DNS.
2. Next to the icon representing the server itself—the icon named bigdog—click the plus sign to open up the server object. (If there's a minus sign then you needn't do anything.)
3. Under bigdog, you'll see three folders: Forward Lookup Zones, Reverse Lookup Zones, and Event Viewer. Right-click the Forward Lookup Zones folder and choose New Zone, which starts up the New Zone Wizard. Click Next to see a figure like 7.47.

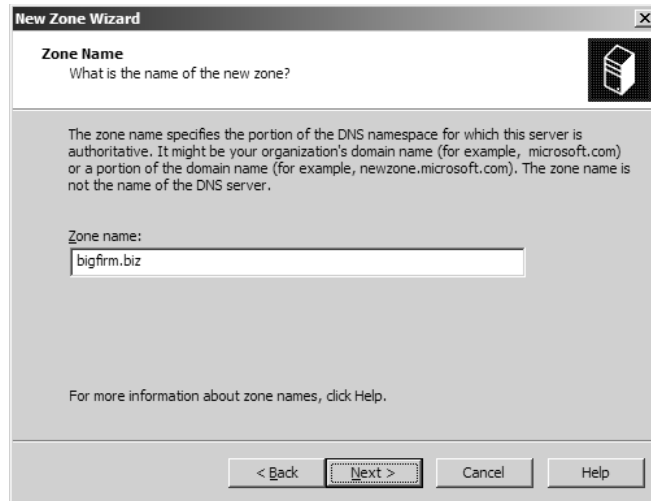

**FIGURE 7.47**

New zone options

4. Notice that you have three options for a zone—Primary, Secondary, and Stub. We'll use a primary zone, so select that—actually it's probably already selected—and click Next to see a screen like Figure 7.48.
5. As the page suggests, fill in the zone name, which is bigfirm.biz in this case. Click Next to see a screen like Figure 7.49.

**FIGURE 7.48**  
Name the zone

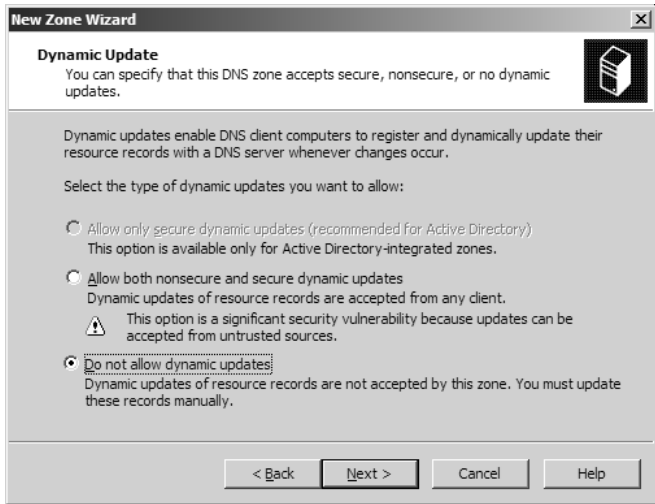

**FIGURE 7.49**  
What to name the zone file

6. Most varieties of DNS servers store their zone information in an ASCII text file and by default Server 2003's DNS server is no exception. ("By default" because, as you'll see later, you can choose to store the DNS information in Active Directory's database.) Unless you tell it otherwise, the DNS server creates a file named *zonename.dns*. The DNS server stores these files in `\windows\system32\dns`. This is actually pretty convenient, as it makes disaster recovery on DNS a snap. If bigdog croaked, then you could cook up a replacement in a twinkling, assuming that you've got a backup of *bigfirm.biz.dns*. Just set up another 2000 or 2003 server as a DNS server, then take the *bigfirm.biz.dns* file from the old server and copy it to `\windows\system32\dns` on the new server. Run the wizard as we're doing here, but at this page in the wizard choose *Use This Existing File* and point the wizard at *bigfirm.biz.dns*.

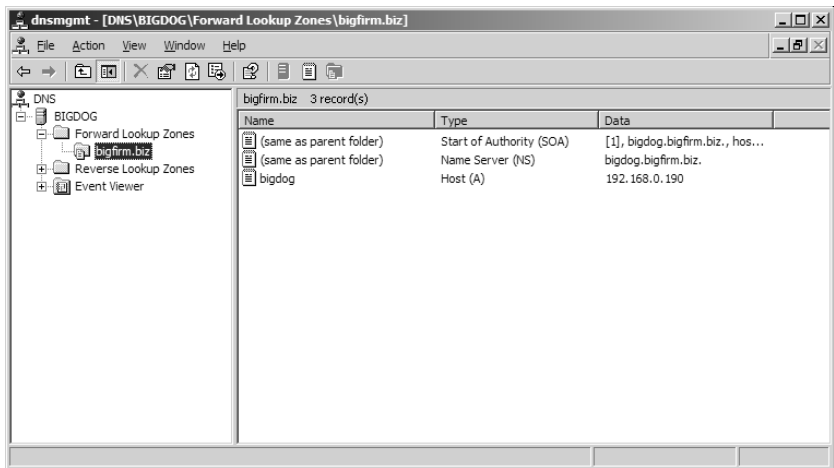

7. To continue creating the bigfirm.biz zone, click Next to see a screen like Figure 7.50.

**FIGURE 7.50**  
Dynamic update settings

8. You'll learn about dynamic DNS a bit later, but briefly, it lets systems register information about themselves in DNS automatically, as they can with WINS servers. DNS only got this ability a few years ago, so the wizard has it disabled by default. But we're going to find it useful, so click Allow Both Nonsecure and Secure Dynamic Updates—don't worry about the dire-sounding warning—and click Next and Finish to create the zone.
9. Open the Forward Lookup Zones folder and you'll see a bigfirm.biz folder; click that in the left pane and you'll see something like Figure 7.51.

**FIGURE 7.51**  
The bigfirm.biz zone, version 1

Notice that it's got three items in the right pane. They're called DNS records—"records" because it's a database—and notice that they're of three different "types"—something called an SOA, another called an NS, and a third called an A record. What's that all about? Read on.

**BIGFIRM.BIZ OVERVIEW**

I'd like to start introducing different types of DNS records and offer hands-on examples of them where possible in my mythical bigfirm.biz domain. So let's imagine that Bigfirm has a set of servers as depicted in Figure 7.52.

**FIGURE 7.52**

bigfirm.biz servers

Now I'm going to get a bit more serious about structuring this example, so I've got to specify IP addresses. I'm going to build bigfirm.biz assuming that it uses a nonroutable class C network at 192.168.0.1.

There are just a few machines important enough that they must have entries in DNS:

- ◆ As I've mentioned before, it's convenient to name the router at 192.168.0.1.
- ◆ The mail server for bigfirm.biz is a machine named postoffice.bigfirm.biz, at 192.168.0.4.
- ◆ The Web server for bigfirm.biz is a machine named www.bigfirm.biz, at 192.168.0.5.
- ◆ That same 192.168.0.5 machine is also the FTP server, and we want it to respond to the name ftp.bigfirm.biz.
- ◆ The bigdog.bigfirm.biz machine that we've built already will, again, act both as a domain controller (once we set up AD in the next chapter) and as the primary DNS server. Please give it a static IP address of 192.168.0.2.
- ◆ There's another DNS server that also acts as a file server at ns2.bigfirm.biz with address 192.168.0.3.

**SOME IMPORTANT NOTES ABOUT THIS EXAMPLE**

As I've said, I've assigned addresses for these machines in the 192.168.0.0 range, which is a range of nonroutable addresses. (Recall that you learned about nonroutable addresses and Network/Port Address Translation in the previous chapter.) This implies a few things:

- ◆ If you set up this example with a few machines of your own, then these machines will be unable to access the public Internet, *unless* your router is a NAT/PAT router. Just set up the machine or machines with one of the IP addresses in the example and set the subnet mask to 255.255.255.0 and the default gateway to 192.168.0.1.

- ◆ You may recall from the previous chapter that Windows 2000 and later operating systems can act as NAT routers and that there's a kind of simplified NAT router called ICS that you can set up with just a click or two. ICS is set up to use addresses 192.168.0.1–192.168.0.254, which is one reason I designed this example with those addresses. Where I've got a hardware router pictured in Figure 7.52, you could be running a Windows 2000 or later system acting as the ICS router. In that case, you needn't set its IP address to 192.168.0.1 because, as you learned in the last chapter, enabling ICS automatically sets the IP address on the Ethernet card on the intranet side of the router to 192.168.0.1. Or, alternatively, your NAT/PAT router might simply be an existing corporate router or a DSL/cable modem dedicated router.
- ◆ Recall that systems with nonroutable addresses accessing the Internet via a NAT/PAT router such as ICS have the ability to *initiate* communications to the public Internet and systems on the public Internet can respond to queries from the systems with the nonroutable addresses, but systems on the public Internet cannot *initiate* conversations with nonroutable addresses. That means that these servers can only serve computers in their 192.168.0.x network. Systems on the public Internet could not access the Web or DNS servers, for example, unless you configured the NAT/PAT router to map ports on the publicly visible router to particular ports on servers in the 192.168.0.x network, or if you had extra routable IP addresses that you could then use the NAT/PAT router to assign to particular systems in the 192.168.0.x network. You saw in the previous chapter how to do that.

### CHANGING BIGDOG'S IP ADDRESS

Previously, I said that you could give bigdog.bigfirm.biz any IP address that you wanted but, again, now I need to ask you to change its IP address to a static 192.168.0.2. You can do that from the GUI, as you learned in the last chapter, or from the command line with a `netsh` command:

```
netsh int ip set address name static 192.168.0.2 255.255.255.0 192.168.0.1 2
```

That command's all one line, even though it broke on the page. Either replace *name* with the full name of your NIC surrounded by quotes, as in

```
netsh int ip set address "Local Area Connection" static
    ↪192.168.0.2 255.255.255.0 192.168.0.1 2
```

Or you can just specify the first part of the NIC's name without quotes, as in

```
netsh int ip set address local static 192.168.0.2 255.255.255.0 192.168.0.1 2
```

Then change its preferred DNS server, again as you've seen how to do it. If your NIC's name is Local Area Connection and there are no others, then this command would do it:

```
netsh int ip set dns local static 192.168.0.2 primary
```

As before, do an `ipconfig /all` and ensure that the value next to IP Address and DNS Servers is 192.168.0.2. Then restart the DNS server:

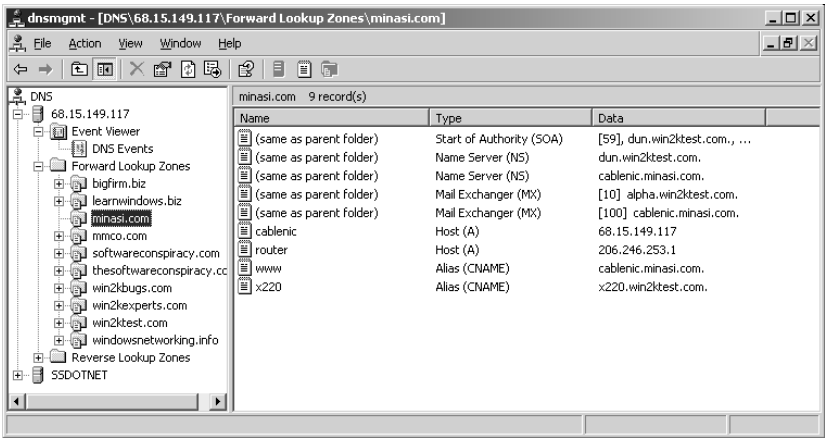

```
net stop dns & net start dns
```

If you've got the DNS snap-in running, close it and open it to ensure that it refreshes properly. You should see the bigdog A record report an IP address of 192.168.0.2.

Basic DNS Record Types

I’ve been referring vaguely to “DNS databases.” Now let’s consider in more detail exactly what these databases look like and what’s in them. DNS databases contain several kinds of database records—there’s more there than just names and IP addresses. Take a look at Figure 7.53, and you’ll see a listing of some DNS records at the minasi.com domain. You’ve seen the DNS snap-in earlier; this is what it looks like with a real-live zone or two running on it.

**FIGURE 7.53**  
Sample DNS records  
for a domain

This is like the bigfirm.biz screen that you saw in Figure 7.51, but with a greater range of record types.

A RECORDS (HOSTS)

The simple record that says that cablenic.minasi.com is at IP address 68.15.149.117, the record that relates names to IP addresses, is called an *A* record or *host record*. (It’s called an *A* record because DNS’s internal database, a set of ASCII files called *zone files*, uses an *A* to indicate that a record is a host record.) Host records are usually the most numerous, although in this zone there are just two—the one for cablenic and the one for router. The router entry, by the way, does indeed point to the network’s router. Giving the router a name isn’t necessary; it just makes pinging it easier.

**NOTE** I know I’m calling them *A* records even though the graphical UI doesn’t call them that. But I’m doing it because, again, zone files use the *A* designation—cablenic’s record in a zone file might look like `cablenic A 68.15.149.117`—and I believe that you’ll agree by the end of the chapter that you can get a lot done with zone files, from both an administration and troubleshooting standpoint. So throughout this section, I’ll be presenting the records both as Server 2003’s DNS refers to them and as zone files refer to them.

Back in our simple bigfirm.biz example, notice that you have an *A* record—bigdog.bigfirm.biz. And because I’ve introduced information from an actual Internet domain (minasi.com), let me add the following important warning.

**WARNING** *This is very important. Please note that minasi.com and win2ktest.com are domains that I host. I use sample screen shots from them, but please do not use the domain name win2ktest.com or minasi.com in your network. If you're live on the Internet, that will make your system attempt to log in to my domain controllers and register records in my win2ktest.com or minasi.com zones (and that's just not polite, if you know what I mean!). That goes for other names that you'll see in this chapter as well, such as the acme.com references that you'll see around the book in examples. Someone owns that domain and would view attempts to log in to his domain or add records to his DNS servers as hostile acts, and take action accordingly. (After all, what would you do if you found some stranger taking up residence in your front room?) I've specifically driven many of my examples around a domain named bigfirm.biz because I own that domain, and honestly only bought it so that I'd have a nice example domain that I knew wouldn't cause anyone any heartburn. I strongly suggest when you're playing around with DNS zones that you ensure that you're not connected to the Internet, that you register a DNS domain name with the proper DNS name authorities such as www.network-solutions.com, or that you set up "split-brain DNS," which I'll describe later. That will ensure that you're a "good Internet citizen." Thanks!*

### EXERCISE: ENTERING A OR HOST RECORDS

If you're following along in the bigfirm.biz example, then it's time to punch in records for each our servers:

- ◆ router.bigfirm.biz for 192.168.0.1
- ◆ ns2.bigfirm.biz for 192.168.0.3
- ◆ postoffice.bigfirm.biz for 192.168.0.4
- ◆ www.bigfirm.biz for 192.168.0.5

To create the first A record for router, right-click the **bigfirm.biz** folder and choose New Host (A) to see a dialog like the one in Figure 7.54.

**FIGURE 7.54**

Creating a host (A) record

The screenshot shows a 'New Host' dialog box with the following fields and values:

- Name (uses parent domain name if blank):** router
- Fully qualified domain name (FQDN):** router.bigfirm.biz.
- IP address:** 192 .168 .0 .1
- Create associated pointer (PTR) record:** ☐ (unchecked)

Buttons at the bottom: Add Host, Cancel.

I've typed in router and entered the IP address 192.168.0.1; all I've got to do now is click Add Host, and I've got the record. Notice the Create Associated Pointer (PTR) Record check box; I

would use this if I wanted to add not only my A record, which says, “If you ask me router.bigfirm.biz’s address, I will tell you that it’s 192.168.0.1,” but also a *reverse* record, which says, “If you ask me what 192.168.0.1’s name is, I will tell you that it’s router.bigfirm.biz.” A “reverse A record” is called a PTR record, and you put them in *reverse* lookup zones, which we discussed earlier. I haven’t checked the box because I don’t have a reverse zone set up, so there would be nowhere to put the PTR record.

Click Done, and DNS stores the record and confirms that it created the record. DNS then leaves the dialog up, making it simple to punch in more Host records. Enter the ns2, postoffice, and www records in the same way. When you’ve got them all in, click Done and the New Host dialog goes away.

### **CHEAP “CLUSTERS”: BUILDING FAULT TOLERANCE WITH MULTIPLE A RECORDS AND ROUND-ROBIN DNS**

This isn’t a record type, but as long as I’m talking about A records, let me explain a great (and free!) way to handle a lot of Web traffic.

#### **How Round Robin Works**

Suppose I’ve got a Web server at IP address 206.246.253.100. I’ve named it www.minasi.com because, well, that’s what people expect the Web server at minasi.com to be named. But now let’s suppose that several thousand people all decide at the same time to hit my Web site to find out how to hire me to speak at their next engagement. (Hey, it could happen.) At that point, my poor Web server’s overloaded, lots of people get some kind of “server is too busy to respond to you” message, and I lose lots of potential business. That would be bad. Really bad.

Alternatively, I could set up three more machines with IIS on them, at IP addresses 206.246.253.101 through 206.246.253.103. *Then*—and here’s the clever part—I just enter host name records, A records, for each of them and name *all* of them www.minasi.com.

Now that I’ve got all four machines, each named www.minasi.com, suppose someone points her browser to www.minasi.com. My DNS server is then asked by *her* DNS server to resolve the name www.minasi.com. So my DNS server looks at the four addresses that have www.minasi.com and responds with the four IP addresses, saying, “You can find www.minasi.com at 206.246.253.100, .101, .102, and .103.” Then, seconds later, someone else’s DNS server asks my DNS server what IP address goes with www.minasi.com. My DNS server then responds with the same information, but in a different order, offering first 206.246.253.101, then .102, .103, and finally .100. The DNS client will usually take the first address offered first, so the first visitor will tend to go to .100, and the second to .101. The third person to ask about www.minasi.com gets the four addresses in the order of .102/.103/.100/.101, the fourth as .103/.100/.101/.102, and then for the fifth, DNS cycles back to .100/.101/.102/.103.

This process, called *round-robin DNS*, spreads out the load on a machine. If I had these four Web servers set up, they each would get roughly one-fourth of the incoming Web requests. In that way, I could build a “scalable” Web site. Now, understand that this *isn’t* a replacement for Enterprise Edition and multisystem clusters. DNS has no idea what’s going on with the various Web servers, and if one of them goes down, DNS knows nothing of the problem and just keeps giving out the bad server’s IP address to every fourth inquirer. But it’s a free way of doing load balancing and worth a try before spending tens of thousands of dollars on cluster systems.

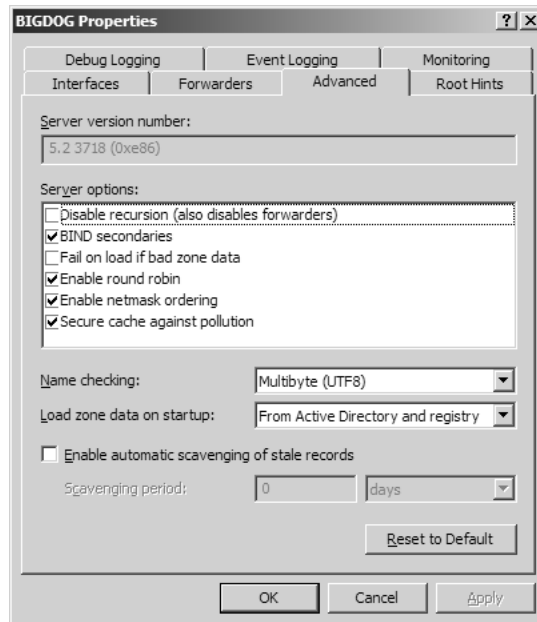

**NOTE** Note that although I used an example of four consecutive IP addresses, you need not use consecutive addresses for your round-robin groups. Also, another great way to load-balance on Web servers is with Network Load Balancing Clusters, which you read about in the previous chapter.

### Exercise: Configuring Round Robin

If you'd like, you can try it out with bigfirm.biz. First, check that the round-robin feature is enabled on your DNS server. It's enabled by default, but you can control it from your server's Advanced Properties page. To see that, right-click the server's icon (bigdog in our example) and choose Properties, then Advanced to see something like Figure 7.55.

**FIGURE 7.55**

A DNS server's Advanced Properties page

Note that one of the options is Enable Round Robin, and it's checked. As far as I know, you can only configure round robin at the server level, not the zone level—a DNS server that contained a lot of zones could not do round robin on one zone and not another. Click Cancel to remove the dialog box.

To see this in action, we'll add two more A records for the www host name for bigfirm.biz, giving them IP addresses 192.168.0.10 and 192.168.0.25. Remember that we already have a www.bigfirm.biz record at 192.68.0.5, so we'll end up with three possible answers for www.

Enter the A records for www at 192.168.0.10 and 192.168.0.25; when done, you should see all three www records in the bigfirm.biz folder in the DNS snap-in. Now try it out. Type **nslookup** and press Enter. Now type **www.bigfirm.biz** and press Enter. I get three addresses as an answer—192.168.0.25, then 192.168.0.10, and then 192.168.0.5. (You may get a different order; if so, don't worry about it.) Now try it again; type **www.bigfirm.biz** and press Enter. I then get the three addresses again, but in a different order this time—.5, then .25, and then .10. Do it once more and I get yet

another order—.10, then .5, and finally .25. (Again, you may see a different order; that's not important. What's important is that if you repeatedly query for `www.bigfirm.biz`, then you keep getting the three results, but in a different order.) Figure 7.56 shows a sample run that I got from my `bigfirm.biz` DNS server.

**FIGURE 7.56**

Round robin  
in action

```

C:\>nslookup
*** Can't find server name for address 192.168.0.2: Non-existent domain
Default Server:  Unknown
Address:  192.168.0.2

> www.bigfirm.biz
Server:  Unknown
Address:  192.168.0.2

Name:     www.bigfirm.biz
Addresses: 192.168.0.25, 192.168.0.10, 192.168.0.5

Addresses: 192.168.0.10, 192.168.0.5, 192.168.0.25

> =

```

### SIMPLE ROUTE OPTIMIZATION: SUBNET MASK ORDERING

If you've set up round-robin DNS, where you have several systems that have the same name but different IP addresses, then Server 2003-based DNS servers not only can do round robin for you, they can also ensure that clients get directed to the nearest server that matches their request.

Suppose I have 10 machines all named `server1.minasi.com` and 10 subnets on my network. Then suppose I have one of these machines on each subnet. Think about what happens when a computer on a particular subnet asks DNS to resolve `server1.minasi.com`. Simple round robin would just offer the 10 IP addresses in some random order. But clearly it'd make life easier on the routers if I could somehow tell DNS, "Listen—when someone asks for the IP address of `server1.minasi.com`, and if one of the `server1.minasi.com` systems is on the same subnet as that someone, then always offer the IP address of the *local* `server1.minasi.com` first." Server 2003's DNS server will do that—it's called *subnet mask ordering*. It is enabled by default. (You can turn it off in the Advanced tab of the DNS server's properties page, as you'll see if you look back to Figure 7.54.)

If you feel like seeing this in action, go to `bigfirm.biz` and delete the .10 and .25 entries for `www.bigfirm.biz`. Then create a `www.bigfirm.biz` entry in a different subnet, like 10.0.0.1. Then try the `nslookup` for `www.bigfirm.biz`. You'll still get two answers in return, but the 192.168.0.5 entry will always be the first one, because it's on the same subnet as the computer that you're sitting at—it's subnet mask ordering that makes that happen.

Go ahead and delete the .10 and .25 `www` records at this point, just to keep the zone simple.

### SOA RECORDS (START OF AUTHORITY)

Every domain has a *start of authority* record, abbreviated in zone files as an *SOA* record. It's the record that names the primary DNS server for the domain, provides an e-mail address for an administrator

for the domain, and specifies how long it's okay to cache its data. (I'll explain what a "primary" and a "secondary" DNS server are a bit later, but here's the short version: The primary DNS server for a zone contains the only read/write copy of the zone. Secondary servers—there can be as many as you like—contain read-only copies of the zone, so they can help.) It also alerts the outside world when any of the domain's records have changed through a serial number. In Figure 7.53, the [59] in the SOA record is the domain's serial number and indicates that since the domain was set up, there have been 52 changes—new records, deleted records, modified records. Secondary DNS servers can use this to see whether data on the primary server has changed, requiring them to go get updates from the primary DNS server.

### **Exercise: Examining an SOA Record**

You can see (and modify) an SOA record for `bigfirm.biz` by just double-clicking the record in the folder that says "(same as parent folder) Start of Authority (SOA) [1]..." to see a dialog box like Figure 7.57.

**FIGURE 7.57**

SOA record for  
`bigfirm.biz`

The screenshot shows the 'bigfirm.biz Properties' dialog box with the 'Start of Authority (SOA)' tab selected. The fields are as follows:

Field	Value	Buttons/Options
Serial number:	8	Increment
Primary server:	bigdog.bigfirm.biz.	Browse...
Responsible person:	hostmaster.bigfirm.biz.	Browse...
Refresh interval:	15 minutes	Dropdown arrow
Retry interval:	10 minutes	Dropdown arrow
Expires after:	1 days	Dropdown arrow
Minimum (default) TTL:	1 hours	Dropdown arrow
TTL for this record:	0 : 1 : 0 : 0	(DDDD:HH:MM:SS)

At the bottom are 'OK', 'Cancel', and 'Apply' buttons.

There's a whole *ton* of stuff in an SOA record, but it's not bad when taken one piece at a time.

First, there's the serial number. Note that in this case it's 8, which reflects the number of changes that I've made to the zone. If you want to increase it for some reason, then click the Increment button; just changing the number doesn't do anything.

Next, the primary DNS server is this machine, `bigdog.bigfirm.biz`. After that comes the Responsible Person, `hostmaster.bigfirm.biz`. What's that all about? I mentioned previously that the SOA record includes the e-mail address of the domain's administrator. And while `hostmaster.bigfirm.biz` doesn't look like any e-mail address that you've ever met, it's DNS's way of writing the more familiar-looking `hostmaster@bigfirm.biz`. For some historical reason you write the admin's e-mail address this way.

So if I wanted the SOA record to reflect my e-mail address, help@minasi.com, then I'd modify this to say help.minasi.com.

Notice something about the Primary Server field and the Responsible Person field—they're both written as fully qualified domain names. See the period at the end of the name? That's because all DNS records that aren't fully qualified get the domain's name added to them. Thus, if I specified the primary as bigdog.bigfirm.biz rather than bigdog.bigfirm.biz.—remember, that final period is the only difference—then the DNS server would think that I meant that the primary DNS server for bigfirm.biz should be called bigdog.bigfirm.biz.bigfirm.biz!

The remaining fields all describe important time intervals. The first two, Refresh Interval and Retry Interval, basically control how often secondary DNS servers return to this, the primary DNS server, for up-to-date information. As I've not covered secondaries yet, though, I'll return to these later.

Remember that when a DNS server gets information from another DNS server, the first one caches the information for some amount of time; if your DNS server looks up www.bigfirm.biz at 2 P.M. one day and you ask it for www.bigfirm.biz ten minutes later, then the DNS server's not about to go ask Bigfirm again where to find its Web site. But how long should your DNS server cache Bigfirm's information? However long Bigfirm tells it to. And here's where Bigfirm does that.

Minimum (Default) TTL advises other DNS servers how long to cache information received from this server. It's 60 minutes by default, so any DNS server that does a name resolution on bigfirm.biz and then needs the same name resolved 59 minutes later need not re-query one of the bigfirm.biz DNS servers. Sixty minutes is the Microsoft default, and personally I think it's a bit short—I'd set it somewhere between four hours and a day. The field is called Minimum TTL because every single record in a DNS zone file can have its own separate TTL. The vast majority of the time, however, you won't assign a specific TTL to a specific DNS record, so this "Minimum" TTL is probably more properly called a "Default" TTL. You can override that on any given record, and that's what the field at the bottom of the dialog does—you can use it to say "I don't care what the default TTL for this zone is, I want to set a different one *for just this SOA record*."

### NAME SERVER/NS RECORDS (DNS SERVERS)

Name server records (called NS records in a zone file) define the name servers in the domain. The two NS records in the minasi.com zone name the two DNS servers currently supporting the minasi.com DNS domain.

**NOTE** By the way, a single machine running DNS server software can act as a DNS server for as many zones as you like, within the limits of CPU power and memory space. You need not dedicate one server to one zone. Actually, you saw that in Figure 7.53; notice that this DNS server acts as a name server for several domains.

Notice that both records look like "(same as parent folder) Name Server *servername*." Notice that one of the servers' IP addresses (dun.win2ktest.com) isn't listed anywhere here. That's because it's a server on another domain. To find its IP address, you'd search DNS for its A records in the win2ktest.com zone.

### NS Records and Delegation

Second, notice the "(same as parent folder)"; what that means is that these are name servers for this domain. But you can also use the NS records to delegate authority to a subdomain, a zone. An NS record for an imaginary zone westcoast.minasi.com might look like (in zone file terms):

```
westcoast    NS    surfers.earthlink.net.
```

That record would say, “To resolve names for *somename.westcoast.minasi.com*, go to surfers .earthlink.net.”—notice again that the surfers address ends with a period and is an FQDN. Knowing how to create NS records that point to DNS servers for subdomain zones will come in handy later when you’re seeing how to cope with non-2000/2003-based DNS servers.

### **Exercise: Working with and Creating NS Records**

A look at bigfirm.biz will—or should, anyway, if you’ve been following along—show that record that says

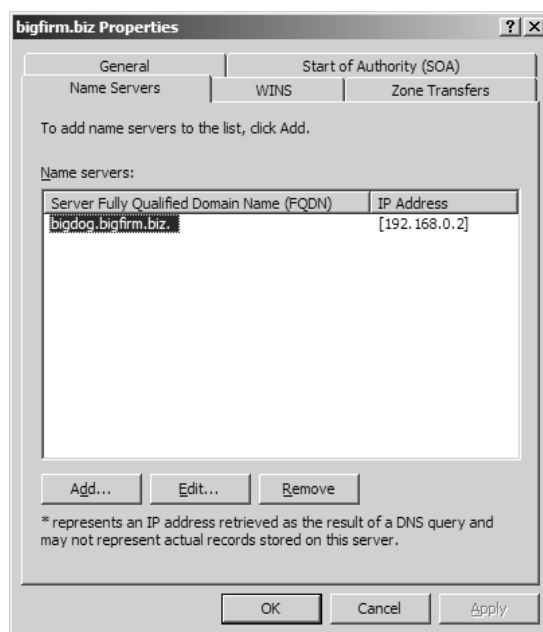

(same as parent folder) Name Server (NS) bigdog.bigfirm.biz.

But I’ve suggested that we’ll have two DNS servers for bigfirm.biz. In addition to bigdog, we’ll also have a system ns2.bigfirm.biz. You’ve already entered ns2.bigfirm.biz’s A record. Here’s how to add it to the list of name servers—another name for DNS servers, in this case—for bigfirm.biz.

You’d expect, or at least *I* expected, that you could just right-click the bigfirm.biz folder and choose New Name Server (NS) Record or something like that, but for some reason you can’t. Instead, right-click the bigfirm.biz folder and choose Properties and then click the Name Servers tab on the resulting property page to see something like Figure 7.58.

**FIGURE 7.58**

Name Servers tab  
for bigfirm.biz

NS records are pretty simple, much simpler than an SOA record—you just tell the record what DNS server to add an NS record for. We can add ns2.bigfirm.biz’s record by clicking Add to see a screen like Figure 7.59.

This dialog wants to know both the name and IP address of the new DNS server, but all you have to do is type the name into the Server Fully Qualified Domain Name (FQDN) field and click

Resolve, and the DNS server will go out and get its IP address for you. Note that this dialog box is smart enough that if you don't put a period on the end of the name—you type ns2.bigfirm.biz instead of ns2.bigfirm.biz.—it will add the period for you.

**FIGURE 7.59**

Adding  
ns2.bigfirm.biz's  
NS record

Click OK twice and you'll be back at the bigfirm.biz folder in the DNS snap-in. You should then see the new NS record.

### **CNAME RECORDS (ALIASES)**

Many times, you'll need a host to respond to more than one name. For example, my Web server has two NICs in it and each has an IP address. One NIC is connected to my intranet and has the name dun.win2ktest.com; the other is connected to the public Internet and is called cablenic.minasi.com.

#### **Using CNAME/Alias Records**

When folks from the outside world want to visit my Web site, I want them to address my Web server through the cablenic.minasi.com interface. (By the way, please don't look at that configuration and try to make a lot of sense out of it—there are no deep insights on How to Design the Optimal Web Server, trust me. It's just a matter of "I need to get some time to straighten this thing out." Shoe-maker's kids and all that.) So when someone punches `www.minasi.com` into a Web browser, I want that person to go to cablenic.minasi.com.

But how to make that happen?

Well, I could surrender and just rename cablenic.minasi.com. But now suppose this were also my ftp server that I wanted to name ftp.minasi.com? Basically here I'm saying that I want to take a particular IP address and give it multiple names. I do that with an Alias or CNAME record. A

CNAME record says something like, “If you need a machine to respond to `www` in this domain, then point to the machine at `webpc.minasi.com`.” Notice how a CNAME record looks:

```
www Alias(CNAME) cablenic.minasi.com.
```

Notice that the left portion only says `www`, not `www.minasi.com`. This is another example of how DNS handles fully qualified or non-fully qualified names. If you create a CNAME within a given domain, the CNAME must be for a name that ends with the domain’s name, hence `www` rather than `www.minasi.com`. In contrast, the machine that it’s being equated to, `cablenic.minasi.com`, need not be in the domain, and so its full name is entered in the DNS record, *including* the trailing period—leave off the period and it’ll just add the zone’s name and it’ll think that you mean to equate `www.minasi.com` to `cablenic.minasi.com.minasi.com`!

CNAME, by the way, stands for *canonical name*. I don’t know why they didn’t use Alias from the very beginning—it’s got the same number of letters—but for whatever reason, we call these CNAME records in the DNS business.

### **Only One CNAME to a Name, Please**

For some reason, you’re not allowed to have more than one of a given CNAME. For example, suppose I wanted to give the name `www.minasi.com` to both NICs on the server, that is, to both `dun.win2ktest.com` and `cablenic.minasi.com`. Can I create two CNAME `www` records in `minasi.com`?

You *can*, but it’s not a good idea, or at least so I’m told. I’ve never found the particular RFC that says not to have multiple CNAMEs with the same alias name, but several threads on the message boards for BIND, the most popular DNS server, suggest that a BIND server might not handle multiple `www` CNAMEs in the same zone. So, while you can force your 2003-based DNS server to accept multiple CNAMEs with the same name by directly editing the zone files, you could run into trouble if the person trying to visit your Web site was resolving your DNS names with a BIND-based DNS server. So to be safe, don’t do multiple CNAMEs with the same name.

Just to make this very clear:

- ◆ You *cannot* use CNAMEs to give more than one IP address the name `www`.
- ◆ You *can* use CNAMEs to give more than one name to a given IP address—I could use a CNAME to give the `www.minasi.com` *and* the `ftp.minasi.com` names to `cablenic.minasi.com`.
- ◆ There is no problem at all with multiple A records with the same name, as you saw when we did the `www.bigfirm.biz` round-robin exercise—there we created three different A records, all for `www.bigfirm.biz`. Adding three CNAMEs for `www` in `bigfirm.biz` would, again, not be kosher.

### **Exercise: Adding the ftp Name to Bigfirm’s Web Server**

I mentioned in my early description of Bigfirm that they’ve got a Web server with the host name `www.bigfirm.biz`, as you may recall. That system is also their ftp server. Now, they *could* tell the world to access their ftp server at `www.bigfirm.biz`, but they’d like to be able to tell people to go to `ftp.bigfirm.biz` and have that work. The answer here is to give `www.bigfirm.biz` a second name, `ftp.bigfirm.biz`, and a CNAME is just the answer.

Right-click the `bigfirm.biz` folder and choose New Alias (CNAME) to see a dialog box like Figure 7.60.

**FIGURE 7.60**Adding a new  
CNAME

You can see that I've filled in the new alias, ftp, as well as the host name that it'll be associated with. Note that I only filled in ftp, not ftp.bigfirm.biz. Click OK and you've got an alias. An `nslookup` of ftp.bigfirm.biz will look like

```
Name:      www.bigfirm.biz
Address:   192.168.0.5
Aliases:   ftp.bigfirm.biz
```

### **MX RECORDS (MAIL EXCHANGE)**

If I send mail to bill@acme.com, then I've told my e-mail program that I want the mail to go to someone named Bill and that Bill has an account on some server in the acme.com domain.

#### ***MX Records: Enabling Flexible Mail Addresses***

What I *haven't* told my e-mail program is where exactly to send the e-mail for Bill, what his mail server's name is. If it's not immediately obvious why this is important, consider: If you know that my domain is named minasi.com, how do you know where to find my Web or FTP server? There's an *informal* convention in the world that I'd call my Web server www.minasi.com and my FTP server ftp.minasi.com, but nothing *requiring* that. You can't simply tell your Web server, "Go check out the minasi.com Web site." But you *can* tell an e-mail program, "Send this mail to minasi.com." That's because DNS includes something called a *mail exchange* or *MX* record, which answers the question, "Which machine is the mail server for minasi.com?"

Look back to Figure 7.53 and you'll see that my domain has two MX records; these answer the "which server to send the e-mail to?" question. A mail server would read that information and understand that mail for someone@minasi.com should go to the machine named alpha.win2ktest.com—a machine in a completely different DNS domain.

### **MX and Mail Fault Tolerance**

Why wouldn't the distant mail server send mail to the server named in the other MX record, `dun.win2ktest.com`? Because of the number in square brackets—notice that the MX record for `alpha.win2ktest.com` is `[10]` and the number on the second NS record, the one for `cablenic.minasi.com`, is `[100]`.

My main e-mail server, alpha, is a Linux box that runs an e-mail server called `sendmail`. It's pretty reliable, but its NIC is connected to the less-reliable of my two ISPs. (Actually, it's not the ISP's fault. The problem is that the frame relay between them and me is run by Verizon, and they can't seem to keep it up. That's why the `www` CNAME was connected to the `cablenic` [the NIC connected to the cable company's Internet connection] rather than `dun` [the NIC connected to Verizon].)

When alpha's disconnected from the Internet, then I need a place for my incoming mail to go. My Web server has the simple SMTP service that comes with IIS, and of course that's not a full mail server. But it *is* enough to receive incoming mail and to hold onto it until the main mail server, alpha, comes back online. So I run the SMTP service on the Web server and add its name as my "use in the event that alpha's not working" e-mail server. But again, how do I tell outside mail servers to prefer alpha over cablenic?

Notice that the MX record for `alpha.win2ktest.com` has a "priority" number in brackets, `[10]`. In contrast, `cablenic.minasi.com`'s MX record has a priority number of `[100]`. With the priority number, you indicate to DNS which mail server you prefer—lower numbers are preferred over higher numbers. Giving cablenic a priority of 100 means that no one ever tries to deliver to it unless alpha's not responding. Then, when alpha's back up, cablenic hands it the mail.

I am told that if you specify two MX records of the same priority, then DNS will end up load-balancing the two mail servers, but I've never tried this.

### **Exercise: Adding an MX Record**

Bigfirm's only got one mail server, `postoffice.bigfirm.biz`. Let's tell the world to send any mail to `anyname@bigfirm.biz` to `postoffice.bigfirm.biz`.

Right-click the `bigfirm.biz` folder and choose New Mail Exchanger (MX) and you'll see a dialog like Figure 7.61.

**FIGURE 7.61**

Adding an MX record to `bigfirm.biz`

The screenshot shows a Windows-style dialog box titled "New Resource Record". It has a tab labeled "Mail Exchanger (MX)". Inside the dialog, there are several input fields and a text block:

- A text box for "Host or child domain:" which is currently empty.
- A text block explaining the default behavior: "By default, DNS uses the parent domain name when creating a Mail Exchange record. You can specify a host or child name, but in most deployments, the above field is left blank."
- A text box for "Fully qualified domain name (FQDN):" containing the text "bigfirm.biz".
- A text box for "Fully qualified domain name (FQDN) of mail server:" containing the text "postoffice.bigfirm.biz.", followed by a "Browse..." button.
- A text box for "Mail server priority:" containing the number "10".

At the bottom of the dialog are "OK" and "Cancel" buttons.

Notice that I didn't put anything in the Host or Child Domain field. That's because for many DNS records, "blank" means "fill in the name of this domain automatically." As this will be an MX record for bigfirm.biz and this is bigfirm.biz's zone file, just leave that field blank. In the Fully Qualified Domain Name (FQDN) of Mail Server field, I fill in postoffice's FQDN. The dialog box offers a priority of 10, which works just fine. Click OK to accept the new record.

### SRV RECORDS

The record types you've read about so far have been around for quite some time. But SRV records are new—they first appeared in RFC 2052 (a 1995 document) and were later revised in RFC 2782. They are, however, essential to the Active Directory. You simply cannot run an Active Directory without DNS servers that understand SRV records.

SRV records are fairly long; here's an example:

```
_kerberos._tcp.marksite._sites.dc._msdcs 600 SRV 0 100 88 dc1.win2kbugs.com.
```

SRV records let DNS become a sort of "directory of services" for a domain. For example, if I tell you that my domain's name is minasi.com, how would you know the name of the Web server for that domain? By convention, you'd guess—it's just a guess—that the name of the Web server for minasi.com is www.minasi.com. But what if I wanted to call my Web server something other than "www" and still have you able to find it? I can't, as our common convention for naming Web servers is inflexible. Similarly, how would you find my FTP server, if I had one? You'd guess that its name would be ftp.minasi.com. Fine, so long as I only have one FTP server and want to call that computer ftp.minasi.com, but troublesome otherwise.

If it's still not clear why this might be a problem, consider this real-world example: Suppose I go to Bigfirm's headquarters to apply for a job. How would I find the HR office in the Bigfirm building, presuming that's where I go to apply for a job? Well, if we assigned rooms in corporate buildings the way that we assign names for Web and FTP servers, then we'd have some kind of convention such as, "The HR office is always in room 120, no matter what company we're talking about—*every* company's HR office must be in room 120." Sound like it might cramp your style? It probably would, which is why we have a building directory on the first floor of most buildings.

### Anatomy of an SRV Record

Put simply, an SRV record lets you say, "If you're looking for *this* kind of server, it's over *there*." More specifically, SRV records let you identify a server or servers who

- ◆ Run a particular service.
- ◆ Run on either the TCP or UDP protocol.
- ◆ Live in a particular DNS domain.

Once retrieved, the SRV record tells you the name of the server or servers who meet those criteria, as well as telling you what TCP or UDP port to address them on to access that service. Additionally, because you can specify more than one server, you can also give different servers different priorities, as we could the MX record priorities.

### **Service, Protocol, and Domain Information**

Let's start examining SRV records with a really simplified SRV record:

```
_kerberos._tcp.bigfirm.biz. SRV dc1.bigfirm.biz.
```

This isn't a complete SRV record and wouldn't work, but it's a perfectly good starting point.

The left part has three pieces to it: a service, a protocol, and a domain. In this case, `_kerberos` is the service, `_tcp` is the protocol, and `bigfirm.biz` is the domain. This oversimplified SRV record, then, says, "If you're looking for a Kerberos server that you access via TCP (rather than UDP) that serves the `bigfirm.biz` DNS domain, then go to `dc1.bigfirm.biz`." Kerberos is a service that does authentication for Active Directory and other OSes as well. As you've already learned in Chapter 6, TCP is the connection-oriented way to establish communications over IP, and of course `bigfirm.biz` is just the name of our example domain. I guess they add the underscore to the front of the name to avoid accidental collisions with existing servers; calling the record `kerberos.tcp.bigfirm.biz` instead of `_kerberos._tcp.bigfirm.biz` is a bit more readable, but there's the small probability that some other system already has that name (really small).

What other services are there? There's a list of common services in the ASCII text file `\windows\system32\drivers\etc\services`, but you can use any service name that you like. Suppose I came up with a completely new kind of service called `engspa`, a service to which you could give a block of English text and that would return the equivalent translated Spanish text. As it's a simple question-and-answer system, I might implement it over UDP. I could then develop and offer `engspa` server software and people could put it on servers on the Internet. Then I'd develop `engspa` client software, maybe an add-in for Internet Explorer. You'd just grab some English text and paste it into the `engspa` window in IE. IE would then look around for an `engspa` server to translate the text for it...but how to find such a server? With an SRV record. Perhaps Bigfirm runs an `engspa` server on a computer called `polyglot.bigfirm.biz`. It might then advertise this with this (oversimplified) SRV record:

```
_engspa._udp.bigfirm.biz. SRV polyglot.bigfirm.biz.
```

Don't get the idea that there's any magic here; whoever writes the `engspa` client program has to write code into that program to teach the `engspa` client software to go ask for an SRV record named `_engspa._udp` in whatever domain it's working in. And *somebody* has to insert the SRV records for the `engspa` servers. But it's a nice standard way to announce services. Or here's another example. Remember, I pointed out that in order for people to find your Web servers you pretty much have to name them `www`? Well, if our Web browsers were smart enough to understand SRV records, then we could tell the world that Bigfirm's Web server was named `spider.bigfirm.biz` with an imaginary record looking something like

```
_http._tcp.bigfirm.biz. SRV spider.bigfirm.biz.
```

HTTP is the technical name of the Web service, and as far as I know all Web transfers are TCP, hence the `_http._tcp`. Again, this will not currently work, as Web client software—browsers—isn't programmed to look for SRV records. In an Active Directory you will only see four services:

- ◆ `_kerberos` is the authentication service.
- ◆ `_kpasswd` is a secure service for changing passwords.

- ◆ `_ldap` is the Lightweight Directory Access Protocol, the language that programs use to talk to the Active Directory.
- ◆ `_gc` is just LDAP, but Microsoft gives it another name because “gc” is the service that talks to a subset of domain controllers called Global Catalog servers. (You’ll meet GCs in the next chapter.)

You actually wouldn’t write even my oversimplified SRV records as I’ve been writing them—do you see why? I’ve been including the FQDNs of the names just to make them easier to read. But in the DNS world, we tend not to use FQDNs on the left side of DNS records. My Kerberos, engspa, and Web server examples would probably look more like these:

```
_kerberos._tcp SRV dc1.bigfirm.biz.
_engspa._udp SRV polyglot.bigfirm.biz.
_http._tcp SRV spider.bigfirm.biz.
```

The difference makes for shorter records, but they’re not as clear; nevertheless, that’s the standard.

### **Ports, Priorities, and TTLs**

I have been referring to my example SRV records as “oversimplified” because they don’t match actual in-the-real-world SRV records like this one:

```
_kerberos._tcp.marksite._sites.dc._msdcs 600 SRV 0 100 88 dc1.win2kbugs.com.
```

Let’s take it apart and see what we *do* know about it. First, what does `_kerberos._tcp.marksite._sites.dc._msdcs` tell us? Well, we see from `_kerberos` that it’s a Kerberos server—that is, a domain controller—and runs Kerberos over TCP. What’s the rest of the left part, `marksite._sites.dc._msdcs`? It’s a subdomain. This is a record in a DNS domain called `win2kbugs.com`, but an Active Directory domain named `win2kbugs.com` doesn’t register domain controllers as simply `_kerberos._tcp.win2kbugs.com`; instead, Microsoft designed AD to take your domain and make subdomains in it, and subdomains in that, and subdomains in that, and so on. `marksite._sites.dc._msdcs` means that when AD created `win2kbugs.com`, it also created a subdomain of `win2kbugs.com` called `_msdcs.win2kbugs.com`, and a subdomain inside that called `dc._msdcs.win2kbugs.com`, and a subdomain inside *that* called `_sites.dc._msdcs.win2kbugs.com`, and finally, a subdomain inside that called `marksite._sites.dc._msdcs.win2kbugs.com`. (Microsoft had their reasons, trust me. And don’t worry, these subdomains get built automatically when you create an AD, as you’ll see in the next chapter.)

So far, then, we know that there’s an SRV record for a Kerberos server using TCP in a subdomain of `win2kbugs.com`.

Next, there’s 600 SRV. The SRV part you know. The 600 is a record-specific TTL. Remember TTLs (time to live)? This says that if you look this record up, then you can cache it, but only for 600 seconds. In other words, once you know that this is a domain controller for `win2kbugs.com`, don’t count on it still being one in ten minutes—go back and check before you try to authenticate to it in the future.

Then there are two more numbers, 100 and 88. 88 is the port that the service runs on. A computer in an Active Directory asks, “Are there any Kerberos-over-TCP servers in `win2kbugs.com`? I’d like to log on.” DNS responds, saying, “Sure, we’ve got a server named `dc1.win2kbugs.com` that does that—it does it on port 88.” Sort of like walking into a shopping mall and asking the information

booth, “Are there any bookstores in this mall?” and getting the answer, “Sure, there’s one at store location 233.”

Finally, the 100 is a priority number and it works just like the MX record’s priority numbers. If I had a bunch of `_kerberos._tcp` SRV records for a given Active Directory domain, then that would be the domain’s way of saying that it has more than one Kerberos server, or, put differently, more than one server that can provide authentication or logon services—put one final way, more than one domain controller. (These phrases honestly do mean the same thing.) But which to use? Pretty much any one that you want, *so long as they have the same priority level*. Suppose DNS told you about five different domain controllers, three with priority 50 and two with priority 100. You would attempt to contact each of the priority 50 DCs before you even considered the priority 100 systems. By default, AD gives all DCs the same priority, 100. But you might want to monkey with the priorities to bias your systems towards or against a particular DC; this is how you’d do it. More on this next chapter.

To summarize, then, this SRV record:

```
_kerberos._tcp.marksite._sites.dc._msdcs 600 SRV 0 100 88 dc1.win2kbugs.com.
```

says, “There is a Kerberos server using TCP (that is, a domain controller) in the `marksite._sites.dc._msdcs` subdomain of `win2kbugs.com` at `dc1.win2kbugs.com`. It will respond to Kerberos requests when addressed via TCP port 88. You should use a priority weighting of 100 for this, which is to say that if you see similar records for other Kerberos servers with smaller priority numbers, then use them first, before this one. If you’re caching this record, please don’t cache it for more than 600 seconds.”

Don’t let SRV records scare you. There’s a lot of information there, but much of it is specific to the program using it. In the Active Directory world, we can completely ignore SRV records most of the time, as they’re handled automatically. But when we’re troubleshooting AD problems, then knowing SRVs will come in handy—you’ll see more on that in the next chapter.

## INTRODUCTION TO PTRs: REVERSE LOOKUP ZONES REVISITED

Those are the common record types you’ll find in a forward lookup zone. Now let’s consider reverse lookup zones. In general, they have a smaller variety of records: they have SOAs and NS records, as do all zones, and PTR or “pointer” records.

A *pointer record* works just like a host record—an A record—except that where you use an A record to look up the IP address associated with a given host name, a pointer record lets you look up a host name associated with a particular IP address. But before we worry too much about PTR records, let’s revisit the home of PTR records—that is, reverse lookup zones; that’ll provide me an excuse to cover PTR records.

### Do You Need a Reverse Lookup Zone at All?

In the perfect world, every computer would have at least two records about it in DNS: an A record to identify it by name, and a PTR record to identify it by IP address. In the real world, many systems do not have PTR records, and in fact you can probably run a network for years without either reverse lookup zones or PTR records with no worse side effects than those irritating “unable to find server” messages when you start `nslookup`.

Before you start worrying too much about this, I should explain that in some cases you not only needn’t set up a reverse lookup zone, you may actually be *unable* to. If you own the `bigfirm.biz` domain, then you clearly get to set up and manage the corresponding zone file because, again, you own it.

But reverse lookup zones aren't oriented toward DNS names; they're oriented toward ranges of IP addresses. Who owns those IP addresses? Well, that sorta depends. If you're like me, and have a small range of addresses, either a C network or a CIDR block, then it's not like you got that block straight from the IANA guys; the Big Internet Authorities don't handle IP allocations under a few tens of thousands at a clip. That means that as far as the Big Internet Authorities are concerned, *your ISP* owns your IP addresses, at least reverse DNS-wise.

Some ISPs insist on managing the reverse zones, so your ISP might say, "You've got DNS responsibility for bigfirm.biz, and you've got the addresses in such-and-such range of IP addresses, but we'll keep track of its reverse lookup zone for those IP addresses." You can ask yours if you can be authoritative for your network, but if they won't let you, it's not the end of the world.

As far as I can see, there are no mandatory reasons for running or controlling the reverse lookup zones for your IP addresses. I've seen four reasons to control a reverse lookup zone:

- ◆ Having a reverse lookup zone avoids the annoying "UnKnown" complaints from `nslookup`.
- ◆ If your internal network connects to the Internet by dialing up, then having a reverse lookup zone avoids a lot of unnecessary connections, perhaps saving you on phone charges.
- ◆ Some Internet servers will not communicate with you unless your forward and reverse lookups match.
- ◆ If it appears that one of your systems is attacking another system on the Internet, then it's polite to allow the attackee to look up your domain name and thereby find contact information so as to call or e-mail you and say, "Knock it off!"

Let's consider this separately.

### **A Reverse Lookup for `nslookup`**

Depending on how your network is set up, starting `nslookup` on bigdog.bigfirm.biz results in one of two kinds of responses. `nslookup`'s first output probably looks something like this if you've set it up as I've suggested:

```
C:\>nslookup
*** Can't find server name for address 192.168.0.2: Timed out
Default Server: UnKnown
Address: 192.168.0.2
>
```

That may even be preceded by some complaining about the server timing out. What's causing this annoying message? A quirk of `nslookup`. Remember that you're sitting at Bigdog and that Bigdog not only runs DNS *server* software, it also runs DNS *client* software. In fact, virtually every system that you run nowadays runs the DNS *client* software—without it, that system wouldn't know how to query DNS, and if you can't query DNS you can't get very far in an TCP/IP-based network, whether it's connected to the public Internet or not.

When you start `nslookup` on Bigdog, it asks the DNS client software on Bigdog, "Who's your preferred DNS server?" We've configured Bigdog to prefer itself for DNS queries and Bigdog's IP address is 192.168.0.2, so the DNS client software responds, "192.168.0.2." For reasons known only to `nslookup`'s designer, `nslookup` then says, "Well, let's go see what DNS name this server has,"

and of course the only way to do that is to do a reverse lookup on the zone named 0.168.192.in-addr.arpa. So `nslookup` asks the DNS server—that is, the one running on Bigdog—to look up the specific 2 PTR entry in the 0.168.192.in-addr.arpa zone—“2” because Bigdog’s IP address is 192.168.0.2.

This leads to a problem. There isn’t a server with a 0.168.192.in-addr.arpa zone. Remember, 192.168.x.x is a range of addresses set aside for private networking. There are, then, thousands, hundreds of thousands, maybe millions of small networks using 192.168.x.x addresses. You might have a system at 192.168.0.2 and I might have one with the same IP address, and we don’t conflict with each other because (1) we’re not on the same physical network, and (2) we’re using addresses that everyone agrees should not be routed over the Internet.

So when `nslookup` asks your DNS server who does reverse lookups for the 192.168.0.x range of IP addresses, then of course there’s no server to do that. But we can fix that—let’s create a reverse lookup zone for 192.168.0.x. It’ll only be visible from inside our network; outsiders won’t be able to use it to reverse-resolve entries in our reverse lookup zone, but who cares? They’re nonroutable addresses anyway so there wouldn’t be any point in them even trying to reverse-resolve our internal systems.

1. Open the DNS snap-in.
2. Right-click the Reverse Lookup Zones folder and choose New Zone.
3. That opens the New Zone Wizard; click Next, and, as before, choose Primary Zone and Next. You’ll see a wizard page like Figure 7.62.

**FIGURE 7.62**

Naming a reverse lookup zone

4. In the Network ID field, enter the network number for your subnet—192.168.0. Then click Next and again click Next.
5. In the Dynamic Update page, choose Allow Both Nonsecure and Secure Dynamic Updates, then Next and Finish.

### Creating a PTR Record

Here's a perfect opportunity to see how to create a PTR record. Let's create one for Bigdog. You'll now have a folder inside **Reverse Lookup Zones** labeled **192.168.0.x Subnet**; right-click it and choose **New Pointer (PTR)** to see a dialog like Figure 7.63.

**FIGURE 7.63**

Creating a new PTR record

Fill in the last quad of the IP address—**2**—and the fully qualified domain name of the host; just “bigdog” won’t do it here.

Now try `nslookup`; you’ll see a response of

```
Default Server: bigdog.bigfirm.biz
Address: 192.168.0.2
>
```

We now have the Bigdog heeling properly, so to speak. Before I leave this, though, let me make one point that we’ll return to a bit later. As I’ve suggested already, this DNS server now satisfies the need for a reverse zone, but it will only do that for systems that use this DNS server as their preferred DNS server. Tell a client to prefer some other DNS server and start up `nslookup`, and you’ll be back to the old complaints.

### Reducing the Mysterious Dial-Ups

Many people run a small network that only connects to the Internet via some kind of dial-up connection, either a simple modem or ISDN. If you’re in that company, then you have my sympathy; in the game of networking, modems are the dice. They’re unreliable and hard to troubleshoot, as I’m reminded every time I travel. In any case, if you connect your internal network to the Internet via some kind of dial-up, then you may find that your connect charges go through the roof when you first install Windows 2000 or later systems, either workstations or servers, on your network.

Here's what's going on: Windows 2000 Professional, 2000 Server, XP Pro, XP Home, and Server 2003 all include a dynamic DNS client. While we haven't talked about dynamic DNS much yet, I've mentioned the basic purpose of it: with DDNS, a system can insert its own records into DNS. For example, a mail server might insert its own MX records into DNS, or a domain controller might insert its own SRV records into DNS, or, more commonly, any system might insert its own A and PTR records into DNS.

That's where the problem comes in. You're running your network with some set of nonroutable addresses, like 192.168.x.x. A workstation or server wakes up, gets a set of IP addresses from DHCP or perhaps has a static address, and wants to register a PTR record. But where does it go? Who's the official receiver of dynamic PTR registrations for the 192.168.x.x IP range?

Well, as you read in the last section, there isn't one, as it's a private range. But the dynamic client on DNS tries to find the DNS server for PTR records in 192.168.x.x and register with it. And where does that search take it? Out to the Internet root servers. That's what's causing those mysterious dial-ups. A system starts up and wants to register, or perhaps a system renews a DHCP lease, which also triggers a reregistration. The system asks its DNS server who to go to with registrations for 192.168.x.x, and so the DNS server looks for that server.

The IANA has created a catch-all server for reverse registrations on the three ranges of nonroutable addresses. It doesn't accept dynamic registrations, but at least it's there, so DNS servers don't waste their time trying and retrying to find that authoritative DNS server for the reverse lookup zones of the nonroutable ranges. The IANA servers have an interesting set of names: blackhole-1.iana.org and blackhole-2.iana.org. An SOA record reveals that the *primary* DNS server is named prisoner.iana.org.

This freaks network administrators out who are trying to troubleshoot some network problem; they start looking at network logs and see references to prisoner.iana.org or blackhole-something-or-other.iana.org—sure sounds like a hacker site, doesn't it? Well, it isn't. Messages like that mean that your system's just trying to register their PTR records.

How can you kill off these pointless searches and stop the unwanted dial-ups? The same way that we made `nslookup` happy—just create that reverse zone and make it dynamic. It'll happily take your registrations, and your systems will stop looking for the prisoner in his black hole.

### ***Pleasing Servers That Match Forward and Reverse Lookups***

This is less of an issue than it once was, but back in the old days I was unable to access some news group (NNTP) servers or FTP servers unless my workstation's forward resolution matched its reverse resolution. When I'd try to access some FTP site, then unknown to me, it would see my incoming IP address, and it would do a reverse lookup on that address. The reverse lookup would tell the FTP server my computer's FQDN. The FTP server would then look up that FQDN in DNS to get an IP address. That IP address had to match my IP address, or the server assumed that I was an evildoer.

It wasn't a bad way to ensure that someone's actually who they say they are, but it doesn't work in today's world. If an ISP gives you a block of addresses, then the ISP either doesn't bother populating its reverse lookup zones, or fills them with generic names. For example, if I had IP address 200.100.100.5 and my ISP ran the reverse lookup zone for 200.100.100.x, then it might insert a PTR record for 5 called Host5.subnet200100100.myisp.net. Thus, if someone asks the Internet's DNS servers what the name of 200.100.100.5 is, it'll be told host5.subnet200100100.myisp.net. Now, that's not anything *like* what I named my system, so as far as I'm concerned the PC probably has a name like markspc.bigfirm.biz. The mismatch would cause the FTP, news, or whatever server

to reject me unless the ISP took the time to actually create forward lookup zones that match the FQDNs in the reverse lookup zones. Or alternatively, I suppose I could call my ISP up every time I rename a system and ask them to update my PTR record...yuck. Thankfully, this authentication approach is not very common anymore. Note that setting up a local in-addr.arpa zone would *not* solve this problem because the outside world would not know to ask your local DNS server about that reverse lookup zone, as your DNS server's not authoritative for that zone.

### **Helping Outsiders Find You**

In the late fall of 2001, the Nimda worm made its way around IIS-based Web servers around the world. The worm causes your IIS server to try to find and infect other IIS servers. You can patch your system against Nimda, and one would hope as you're reading this that *everyone* with an infected system would have found and fixed it.

A vain hope, sadly.

I can set up a new IIS server, wait a few days, and look in its logs. Believe it or not, in that time I'll see some idiot or, more likely, several idiots have tried to infect my Web server. What causes this? Someone sets up an NT 4 or 2000 server and both of those OSes install a Web server, whether you asked for it or not. The server gets infected, but the guy using it doesn't notice, because he never uses the Web function. Okay, my Web server's patched against Nimda and friends, but it's still irritating.

My Web log tells me only the IP address of the Web server, not its name or owner. How do I find the unwitting Webmaster, smack him upside the head, and say, "Willya *please* shut that thing off?" With a reverse lookup.

Unfortunately for reasons we've already seen, not everyone can or does set up reverse lookup zones. If you can, however, then it's a good way to help the outside world warn you that one of your systems is Doing Something Bad.

### **Fault Tolerance: Primary and Secondary DNS Servers**

Now that we've got *one* DNS server running, let's next consider how to make this DNS database highly available and fault-tolerant.

If a ton of people all decide at the same time to come surf [www.bigfirm.biz](http://www.bigfirm.biz), then that means that a ton of *DNS servers* will all be trying at the same time to resolve the address [www.bigfirm.biz](http://www.bigfirm.biz). But what if I only have one DNS server? That's asking for trouble. It'd be nice if I had more than one DNS server containing a copy of the [bigfirm.biz](http://www.bigfirm.biz) zone file; then those servers could share some of the burden of name resolution. (Of course, those extra DNS servers had better be listed in the DNS servers for the biz domain—if a DNS server isn't recognized as authoritative by being listed in its parent's DNS servers, then no one will ever know to even *try* to query the DNS server.)

But that might be a bit chaotic. Suppose I've got five DNS servers that all hold a copy of the [bigfirm.biz](http://www.bigfirm.biz) zone file. When I want to make a change to the zone file, perhaps to add or delete an A record, how do I do that? Must I make the identical change to each of the five copies of the zone file by hand? That doesn't sound like much fun.

Fortunately, I needn't do that. DNS has a built-in system for managing updates to a zone's file. Here's how it works. Each domain has one and only one "primary" DNS server. That's the one that you make changes and updates to the zone file on. And when you set up a DNS server for a particular domain, you must tell the DNS server whether it is the primary DNS server for that domain. As I

suggested a few pages back, you designate which DNS server is authoritative for a given zone by naming that DNS server in the SOA record for the zone. You can have only one primary DNS server for a given zone.

**NOTE** *A zone's primary DNS server is the only one that can accept additions, deletions, or changes to DNS records for that zone.*

### **SECONDARY DNS SERVERS HOLD READ-ONLY ZONE COPIES**

You can have as many *secondary* DNS servers for a zone as you like, however. When you set up a zone on a DNS server, you tell the DNS server whether it should act as the primary DNS server or secondary DNS server for the zone. If it's to be a secondary DNS server, then you must tell the DNS server that is the primary DNS server for that zone, so that the secondary knows where to go to get the "official" copy of the zone files.

**NOTE** *Note that any DNS server can act as the primary server for more than one zone. In fact, a DNS server can simultaneously act as the primary server for several zones while at the same time also acting as a secondary server for several zones. DNS servers can hold any number of zones. So it's never meaningful to talk simply of a "primary DNS server"; rather, a DNS server can only be primary or secondary for a particular DNS domain or zone.*

### **HOW PRIMARY AND SECONDARY DNS SERVERS SYNCHRONIZE**

As the zone files change, you need some kind of mechanism to update the zone files on the secondaries on a regular basis or, to use another popular phrase, to *replicate* the zone files. Here are the mechanics of how DNS servers stay in sync.

Recall that you make any changes to a zone on the primary DNS server for that zone; if you were to make a change to a zone on a secondary server for that zone, then the change would be lost. So how do those changes on the primary get synchronized to the secondaries?

When the primary learns something new, it does *not* contact the secondaries; rather, it's normally the job of the secondaries to periodically ask the primary if there are any changes. Five things cause a replication:

**When you start up a secondary server for a zone** If you restart the DNS service on a DNS server that happens to be a secondary for a given zone, then the DNS server contacts the primary for that zone to get the latest zone data.

**When you force a zone transfer** If your DNS server is secondary for a zone, you can force it to get a new copy of the zone from the primary by right-clicking the folder for the zone and choosing Transfer from Master to simply update the changes, or Reload from Master to completely wipe the local copy of the zone clean and reload it from the primary DNS server for that zone.

**When the zone data expires** Remember when I showed you an SOA record and told you that I'd explain three of the numbers (refresh interval, retry interval, and expires after) when we got to secondaries? Here's the time. The refresh interval tells a zone's secondary DNS servers to ask the primary every 15 minutes, "May I see your SOA record?" The secondary asks about the primary's SOA record because it will then use the *serial number* on the primary to determine whether something has changed—see, that serial number came in handy! Every time the primary stores a new change, it increments the serial number. If that number hasn't changed since the last time the secondary talked to the primary, the secondary doesn't have any replicating to worry about.

So for example, let's say that the secondary has updated its zone from the primary at 10:00 A.M., learning among other things that the latest serial number for the zone is 237. At 10:01 A.M., you add a new host A record at the primary. The primary stores that new A record and increments the serial number to 238. The secondary, of course, knows nothing of this.

But 15 minutes after the last synchronization, the secondary asks the primary for the SOA record. When the primary responds, the secondary notices that the serial number is now larger than it was the last time it asked, so something must have changed. The secondary requests an update on the zone records, and now it's in sync. Fifteen minutes later, it requests the SOA record again and, if the serial number hasn't changed, does not request an update. The secondary thus polls the primary every 15 minutes, whether things have changed or not.

But what if the primary doesn't respond? In that case, the Retry Interval option in the SOA record instructs the secondaries how often to try to communicate with the primary. It's every 10 minutes by default. If the primary's unavailable for a long time, then the Expires After value in the SOA record tells the secondaries that if they are unable to communicate with the primary DNS server for some time—one day by default—then they should assume the information that they have is too far out-of-date and discard it. In other words, when a secondary cannot access the primary for more than one day, then the secondary basically stops answering name resolution queries.

**When the primary tells the secondary, “Come get my zone data”** It's called *notifying*, and you'll see a bit later how to tell the primary DNS server to tell any or all of the secondaries to come get the latest zone data. It's relatively new in the DNS world, having only appeared in RFC 1996.

Secondary DNS servers are just machines that hold a backup copy of the primary DNS server's database. They can also satisfy DNS name resolution queries when asked. They cannot accept changes to the zone files. When the primary DNS server will be down for some time, you can promote any secondary to be the primary DNS server for a domain. In general, however, that's something that an administrator's got to initiate—secondary DNS servers will not promote themselves.

#### **EXERCISE: SETTING UP A SECONDARY DNS SERVER FOR BIGFIRM.BIZ**

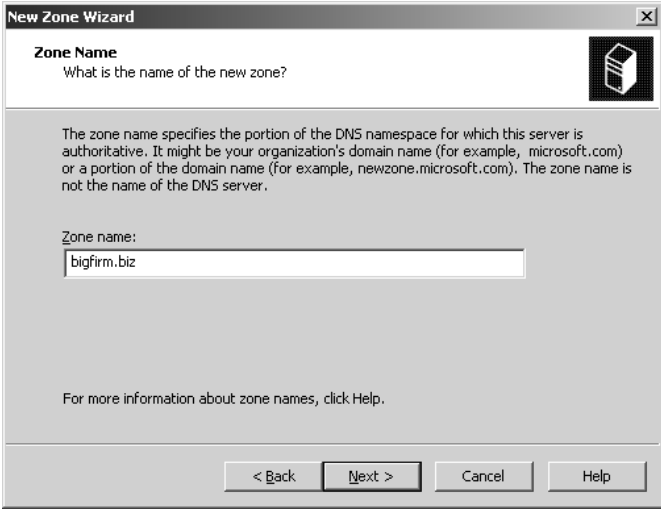

This seems like a perfect time to create our second DNS server, ns2.bigfirm.biz. If you want to follow along, you'll need a second computer running Server 2003. Install the DNS server on it as you did on Bigdog. Point ns2.bigfirm.biz at itself for a preferred DNS server. Be sure to give ns2 the IP address 192.168.0.3, the computer name ns2, and DNS suffix bigfirm.biz. Once you've got DNS running on ns2, open the DNS snap-in, right-click the Forward Lookup Zones, and choose New Zone, which as before, starts up the New Zone Wizard. Click Next to arrive at the first page, where you specify that you want a primary, secondary, or stub zone. Choose a Secondary and click Next. You'll then see a page like Figure 7.64.

Here, I've filled in bigfirm.biz. Notice that this dialog is different from the one shown when creating a primary, as the server doesn't ask you what to call the zone file. A DNS secondary just uses zone files with the same name as the ones that the primary uses. Click Next to see where to tell the server where to find the primary DNS server for this zone, as you see in Figure 7.65.

**FIGURE 7.64**

Enter domain name for secondary DNS server

**New Zone Wizard**

**Zone Name**  
What is the name of the new zone?

The zone name specifies the portion of the DNS namespace for which this server is authoritative. It might be your organization's domain name (for example, microsoft.com) or a portion of the domain name (for example, newzone.microsoft.com). The zone name is not the name of the DNS server.

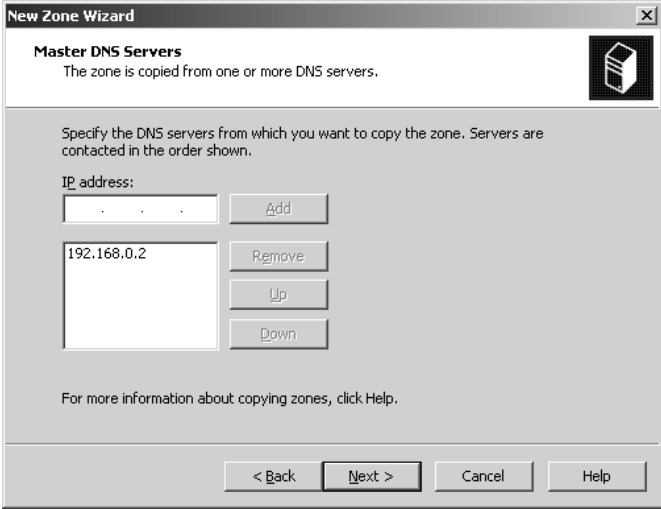

Zone name:  
bigfirm.biz

For more information about zone names, click Help.

< Back   Next >   Cancel   Help

**FIGURE 7.65**

Specify the zone's primary ("master")

**New Zone Wizard**

**Master DNS Servers**  
The zone is copied from one or more DNS servers.

Specify the DNS servers from which you want to copy the zone. Servers are contacted in the order shown.

IP address:  
   Add  
 192.168.0.2   Remove  
   Up  
   Down

For more information about copying zones, click Help.

< Back   Next >   Cancel   Help

As you've already read, DNS uses a single primary server for a zone. The secondaries then copy the zone and treat the zone as read-only—you should make any changes to the zone on the primary, not any of the secondaries. Fill in the primary's IP address, add it, and click Next, then Finish to create the zone.

At this point, I usually find that the DNS snap-in complains that the zone didn't transfer correctly, and all the pressing of F5 that I can do doesn't change that error message. Just close the DNS snap-in and then reopen it at ns2.bigfirm.biz, and you'll find the zone completely copied at ns2.

While you're there, try right-clicking the bigfirm.biz zone folder and you'll see Transfer from Master, a command to force a secondary to synchronize its zone information with the primary. This synchronization happens automatically every 15 minutes by default, but the Transfer from Master command is the way to force a replication whenever needed.

### REPLICATING ZONES: FULL VERSUS INCREMENTAL TRANSFERS

Until recently, DNS servers replicated data to their secondaries in a fairly primitive way.

The secondary servers in a domain periodically contacted the primary DNS server and copied its database to theirs. The *whole* database. So if a zone file contained 4000 lines of information and only one line changed, the secondary servers got the whole file when they requested an update.

RFC 1995 changed that, allowing for “incremental zone transfers.” Put simply, RFC 1995—compliant DNS servers would know how to transfer just the few records that have changed, rather than resending the whole zone file. Server 2003’s DNS server is RFC 1995—compliant, and will do incremental zone transfers whenever communicating between Windows 2000 or 2003—based DNS servers. If a Windows 2000 or 2003 DNS server detects that it’s talking to a DNS server running on something other than a 2K or 2003—based DNS server, however, then it will do complete zone transfers rather than incremental zone transfers.

You cannot to my knowledge configure 2000 or 2003—based DNS servers to always do full zone transfers to other 2000/2003 systems. But you can configure a 2000 or 2003—based DNS server to do incremental zone transfers to non-2000/2003 DNS servers.

1. Open the DNS snap-in (Start/Administrative Tools/DNS).
2. Right-click the icon representing the server and click Properties.
3. Click the Advanced tab on the resulting properties page.
4. On the Advanced tab, uncheck the box labeled BIND Secondaries. Nonintuitive as this sounds, you must uncheck the box to have 2003’s DNS do incremental zone transfers.
5. Click OK or Apply, and the server will do incremental zone transfers to all other DNS servers. Close the snap-in.

If you like, try making ns2 a secondary DNS server for the reverse lookup zone 0.168.192.in-addr.arpa as well.

If you read about full transfers versus incremental transfers, you may stumble across an odd bit of terminology. When taking Microsoft’s Windows 2000 certification exams, I ran across several DNS questions that referred to AXFR versus IXFR operations. I had no idea what they were talking about at first, but it quickly dawned on me that this idea of full versus incremental transfers was *another opportunity for an obscure acronym!* As you’ve probably guessed by now, AXFR just means “do a full zone transfer when updating a secondary,” and IXFR means “do an incremental zone transfer when updating a secondary.” The two phrases are apparently the internal commands that DNS servers use. In any case, don’t blame Microsoft entirely for this—AXFR and IXFR are liberally used terms in DNS-related RFCs.

### CONFIGURING ZONE TRANSFERS AND NOTIFICATION

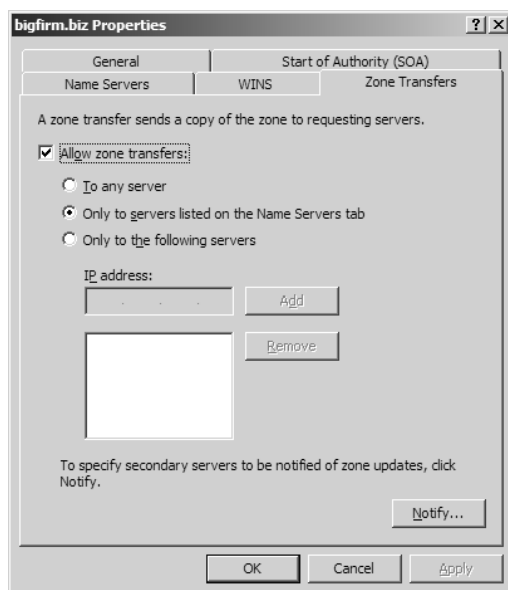

For a secondary DNS server to operate, it has to copy the information in the primary DNS server’s zone files to its own zone files—to ensure that its database of names and IP addresses is up-to-date. Copying zone information from one server to another is called *zone transfers*, as you’ve already read. Why control this? Security. You might not want just *anyone* being able to make themselves into secondary DNS servers on one of your zones. You tell a DNS server whether or not to allow zone transfers, and if so to whom, from the Zone Transfers tab. You can get to that in the DNS snap-in by right-clicking the zone’s folder and choosing Properties, then click the Zone Transfers tab to see something like Figure 7.66.

By default, this DNS server will transfer the contents of its zone files to any server that asks. But knowing the names of your system’s machines can help bad guys compromise security on your network,

so Server 2003's DNS gives you the option to disallow transfers altogether, to name a set of acceptable DNS servers to limit transfers to, or to just transfer to the other name servers listed on the Name Servers page—a quite logical option. If you've got a group of people in your organization who set network security policy, then check with them before leaving zone transfers open to just anyone.

**FIGURE 7.66**

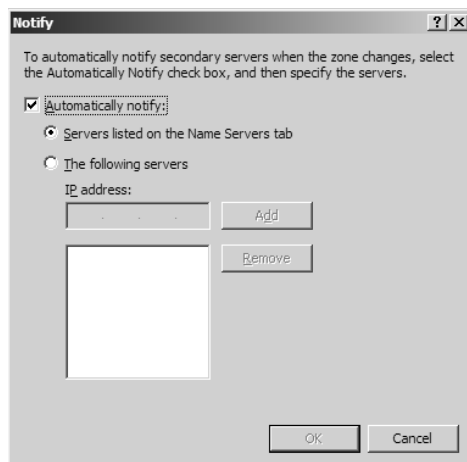

Controlling zone transfers

Recall that secondaries get updated by the primary in one of four ways: when the secondary DNS server gets restarted, when the operator forces the secondary to do it, when the secondary checks the latest serial number every 15 minutes (by default), or when the primary taps the secondary on the shoulder and says, “I’ve got zone changes, you should come get them.” That last idea is called “notification” and it’s configured from the Zone Transfers page by clicking the Notify button. You then see a dialog like the one in Figure 7.67.

**FIGURE 7.67**

Setting up the primary to “push” zone changes to secondaries

You'll see that these settings—which are the defaults for Server 2003—tell the primary to notify the secondaries whenever there's a change. These notifications, which are just UDP datagrams, aren't mandatory commands to do an update; they're just suggestions.

#### AN ALTERNATIVE ZONE REPLICATION METHOD: ACTIVE DIRECTORY–INTEGRATED ZONES

Microsoft's DNS server can do all of the things that I've described so far; it follows the RFCs, the rules of the road for the Internet. But it can do more as well, offering a non-RFC mode that lets you create a zone that is neither a standard primary nor secondary zone, but instead an *Active Directory–integrated zone*.

Active Directory–integrated zones offer two features:

- ◆ They eliminate the notion of primary and secondary DNS servers, making all DNS servers into primary DNS servers.
- ◆ They secure dynamic DNS by keeping unwanted outsiders from registering dynamic DNS records. Only machines that are members of an associated Active Directory domain can dynamically register records with an AD-integrated zone.

Why is the first notion—doing away with primary versus secondary DNS servers—interesting? Because of dynamic DNS. You've already read several times in this book that AD really relies upon DNS; I've said that AD relies upon DNS in that machines in an AD find domain controllers with DNS. That's important because DCs are the subset of servers that perform the essential function of authenticating machines and users to an Active Directory domain. But that's only one of the things that AD needs from DNS; AD not only needs to find out information about a DC's whereabouts, it also needs to be able to *store* information about where domain controllers exist. The technology that lets a DC register its whereabouts with DNS is dynamic DNS—the ability for a system to store SRV, A, or other records on a DNS server.

Microsoft's DNS server supports dynamic DNS for this very reason, as Microsoft's thinking was that if you want to set up an AD and your current DNS server doesn't support dynamic DNS, then you'd at least have the option to replace that DNS server with one that could do dynamic DNS—Microsoft's. But now imagine that you have 10,000 machines in a domain served by one primary DNS server and 30 secondary DNS servers. Every morning people turn their computers on and those computers want to go reregister their A records with a DNS server...but which one? Well, in a standard primary/secondary system, there's only one DNS server in a zone that can accept changes, remember? The primary. That would suggest that the primary might be pretty busy, so it'd be nice to share its load. Standard by-the-RFC dynamic DNS doesn't support that; AD-integrated zones do.

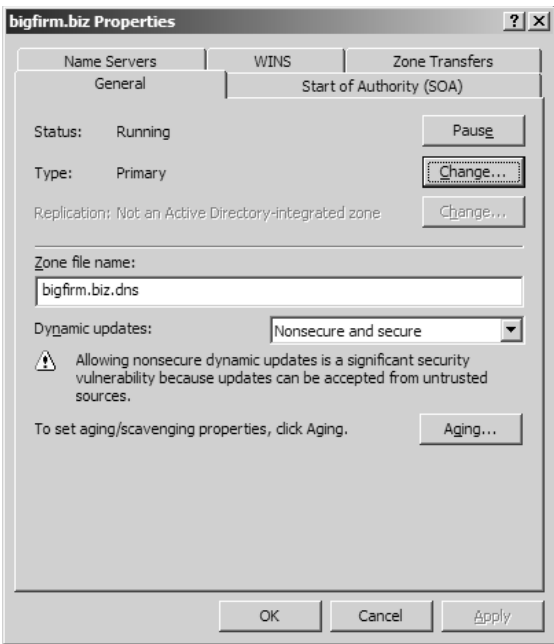

If your zone is supported by Server 2003–based DNS servers and you have an Active Directory working, then you can choose to store your zone data not in ASCII files but instead in the Active Directory itself. Once you do that, there are no primaries and secondaries; instead, any DNS server can accept dynamic registrations.

There's just one catch: in an AD-integrated zone, your DNS servers must also be domain controllers. Yes, you can still have DNS servers for a zone that are *not* DCs, but they can only be old-style secondary DNS servers, and so cannot take registrations.

To tell your DNS server to store the zone information in the AD—that is, to create an AD-integrated zone—open the DNS snap-in and find the folder for the zone that you want to make an AD-integrated zone. Right-click the folder, choose Properties, and click the General tab. You'll see a page like the one in Figure 7.68.

**FIGURE 7.68**

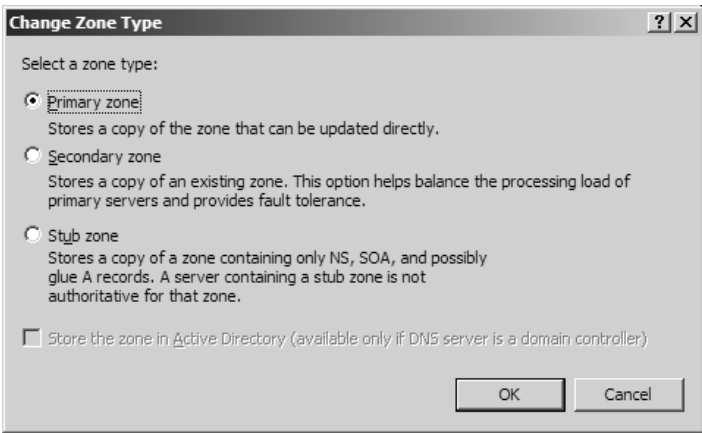

Properties for the bigfirm.biz zone

Notice the label Type: Primary and the nearby Change button. Click the Change button to see the dialog in Figure 7.69.

**FIGURE 7.69**

Zone type options

You could use this dialog to promote a secondary DNS server to the primary, if you had a standard single-primary, many-secondaries zone and the primary died. Or you could choose to store your zone information in the Active Directory with the grayed option, Store the Zone in Active Directory (Available Only if DNS Server Is a Domain Controller). It's grayed in Figure 7.69 because we haven't created an AD yet.

Summarizing, then, making a zone AD-integrated means that any DNS server in the zone can accept registrations, and you can restrict registrations to domain members. But AD-integrated also means that only domain controllers can be DNS servers. (Although other systems can act as secondaries still—they just can't accept registrations.) I find that I like AD-integrated zones for Active Directory work, but we'll take this up again when we look at dynamic updates in greater detail.

## Delegating: Creating Subdomains in DNS

Now bigfirm.biz is running well. But suppose we wanted to delegate control of some of Bigfirm to another group within the organization, as you see in Figure 7.70?

**FIGURE 7.70**

Expanded  
bigfirm.biz  
DNS structure

In that figure, I've added three systems: ns1.ecoast.bigfirm.biz (192.168.0.6); svr1.ecoast.bigfirm.biz (192.168.0.7), a file server of some kind; and svr2.ecoast.bigfirm.biz (192.168.0.8). Notice that all of the names have gotten longer—they're all *something.ecoast.bigfirm.biz*—and that means that we'll need another DNS server. For whatever reason, the bigfirm.biz IT management decided to let the ecoast.bigfirm.biz folks administer their own DNS, and so wants to give them a new subdomain, ecoast.bigfirm.biz. There are three parts to setting up a new subdomain that someone else's DNS server keeps track of:

- ◆ Tell the upper-level domain that there will be a lower-level domain under another system's control.
- ◆ Tell the upper-level domain's DNS server where to find a DNS server for the new lower-level domain.
- ◆ Set up the new lower-level domain's DNS server.

In DNS-ese, we'd call this *delegating control of a zone*. (And if you find yourself nodding off, then let me plead with you to pay attention here—many of you will use this to make the Active Directory fit into an existing Microsoft-hostile DNS infrastructure!) Briefly, do it this way:

1. Right-click the upper-level domain (bigfirm.biz) in the DNS snap-in and choose New Delegation.
2. That starts a wizard that basically wants to know just three things: what the subdomain will be called and what are the name and IP address of its first authoritative DNS server. Tell it that the new delegated domain is named ecoast (it adds the bigfirm.biz all by itself), that the name server for ecoast.bigfirm.biz is called ns1.ecoast.bigfirm.biz, and that its IP address is 192.168.0.6.
3. Go to the new DNS server for the new ecoast.bigfirm.biz subdomain (that server is ns1.ecoast.bigfirm.biz, recall) and set up the new ecoast.bigfirm.biz subdomain in the exact same way that you've already created other DNS domains.

Here's a look at a step-by-step example of how to do it in bigfirm.biz.

#### TELL BIGFIRM.BIZ TO DELEGATE ECOAST.BIGFIRM.BIZ

There are actually a few steps under the hood to telling bigfirm.biz that it needn't worry about name resolution for anything whose name ends with ecoast.bigfirm.biz. In the days before the DNS snap-in you'd have had to do those steps one at a time. The DNS Delegation Wizard, however, handles them all for you. I right-click the **bigfirm.biz** folder and choose New Delegation, which starts up a wizard. Click Next past its title screen and you'll see a screen like Figure 7.71.

**FIGURE 7.71**

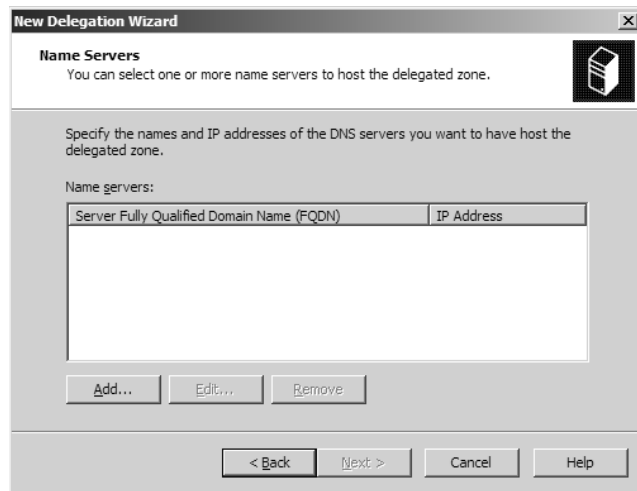

Naming the subdomain to delegate to

Here, I fill in the name of the subdomain ecoast, not the whole ecoast.bigfirm.biz domain. Again, it's just the new part of the domain name, ecoast rather than ecoast.bigfirm.biz. I then click Next and see something like Figure 7.72.

**FIGURE 7.72**

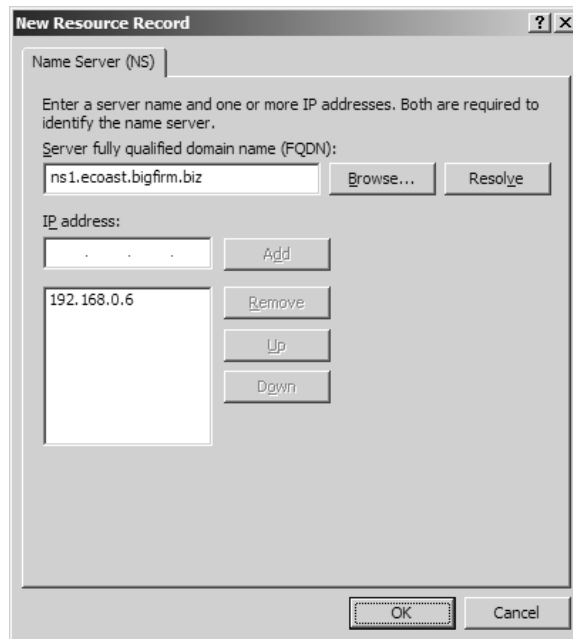

What DNS server to delegate to

This panel wants to know the name and IP address of the DNS server (or servers) for the new sub-domain. I can enter a name and IP address by clicking Add, which shows the dialog box in Figure 7.73.

**FIGURE 7.73**

Specifying the DNS server

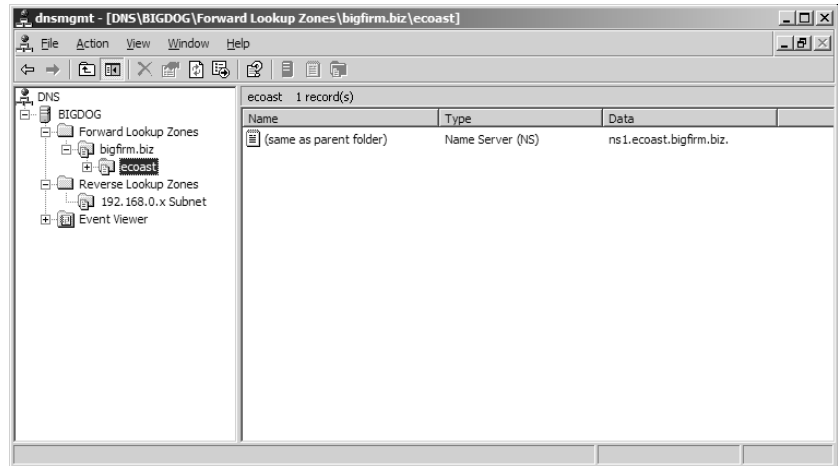

You've got to fill in *both* IP address and name to satisfy this dialog box, because clicking the Resolve button will fail—it can't look up ns1.ecoast.bigfirm.biz until there's an ecoast.bigfirm.biz zone to look it up in! Click OK and Next, and the final screen is a confirmation. Click Finish, and the delegation is done. The snap-in now looks like Figure 7.74.

**FIGURE 7.74**

DNS snap-in with delegated domain

It doesn't look very different on a black and white page, but instead of the usual light yellow that most folders show, the **ecoast** folder is gray, indicating it's a delegated domain. At this point, the work's done on this server; time to go work at ns1.ecoast.bigfirm.biz.

#### CREATING THE LOWER-LEVEL DOMAIN, ECOAST.BIGFIRM.BIZ

Working from ns1.ecoast.bigfirm.biz, run its DNS snap-in, right-click its **Forward Lookup Zones** folder and choose **New Zone**. From this point on, it ought to look familiar. You create a subdomain with exactly the same wizard you used to create the domain.

In fact, if you think about it, it makes perfect sense. If you get a domain name from Network Solutions with a name such as bigfirm.biz, then Network Solutions has already gone to its domain named simply com and delegated control of a subdomain of com—that is, bigfirm.biz. We don't think about that much because it's not anything we worry about normally. But the second part of the process, creating the zone, we *do* think about, as that's usually our job as network engineer types.

#### STUB ZONES

You may have noticed that Server 2003 lets you create three kinds of zones—primary, secondary, and stub zones. But what's a stub zone, and what good is it? Now's the time to explain it.

A stub zone is something like a reduced-size secondary zone. Like a secondary, it's just a copy of the primary's information, and you can't make changes to a zone at a stub zone. But it's unlike a secondary in that it only contains name server information for its zone.

For example, suppose I were to put a DNS server on a server and then create a new stub zone for bigfirm.biz. A look in the zone file would show just three kinds of records:

- ◆ The SOA record for bigfirm.biz
- ◆ The NS records naming the DNS servers for bigfirm.biz
- ◆ The A records identifying the IP addresses of the DNS servers listed for bigfirm.biz (these are called *glue records*, as you'll learn later)

That's it, no other bigfirm.biz records would be there. What good are these zones? It often makes sense to create something called a "split-brain DNS" design on your network. With split-brain DNS,

you'll create a set of zones that are only visible inside your network. To make it easy for the DNS servers in your network to find these invisible-to-all-but-your-insiders zones, you put stub zones for each of the zones on each of your internal DNS servers. I'll take this up later in greater detail, when we consider split-brain DNS.

## Peeking at the Zone Files

Before I leave our simple zone, let's take a look beyond the GUI and see how the DNS data is stored for a delegation. So long as you do not choose to create an Active Directory–integrated zone, then Server 2003's DNS server stores your DNS records in the same format as a BIND DNS server would—in a simple ASCII file called a *zone file*. The Server 2003 DNS server stores these zone files in the `\windows\system32\dns` folder; look there, and you'll see a file named `bigfirm.biz.dns`.

Why would you bother doing this? Troubleshooting or recovery. Sometimes it's just easier to stop the DNS service and then directly examine the zone files. (You must stop the DNS service, because if you modify a zone file without first stopping the DNS service, then your changes will be lost.) We'll see a bit more about recovery a bit later in the chapter.

Returning to the `bigfirm.biz.dns` file, after a bit of editing to rearrange the records (which doesn't affect DNS's behavior at all) and remove some comments, mine looks like this:

```
@ IN SOA bigdog.bigfirm.biz. mark.bigfirm.biz. (
    25          ; serial number
    900         ; refresh
    600         ; retry
    86400       ; expire
    3600       ) ; default TTL

@          NS      bigdog.bigfirm.biz.
@          NS      ns2.bigfirm.biz.
@          MX      10 postoffice.bigfirm.biz.
ftp        CNAME   www.bigfirm.biz.
bigdog     A       192.168.0.2
ns2        A       192.168.0.3
postoffice A       192.168.0.4
router     A       192.168.0.1
www        A       192.168.0.5
ecoast     NS      ns1.ecoast.bigfirm.biz.
ns1.ecoast A       192.168.0.6
```

This zone file contains SOA, NS, A, CNAME, and MX records. Let's see what they say. As you've seen so far:

- ◆ The A records relate host names to IP addresses.
- ◆ The NS records identify name servers for particular zones.
- ◆ The MX records identify mail servers for particular machines or zones.
- ◆ The SOA record describes the characteristics of the zone and who to contact if there's a problem with the zone.
- ◆ The CNAME record lets you add an extra recognized name to an IP address.

Most records have three pieces of information on them: the object being described, the record type, and the descriptive information. For example, consider a record like this:

```
postoffice A 192.168.0.4
```

This would mean, “The host named postoffice in this domain has IP address 192.168.0.4.” Notice that the leftmost part of the text says postoffice rather than postoffice.bigfirm.biz. Within zone files, descriptive labels in general are assumed to be only host names, and zone names are appended automatically. If you *don’t* want that to happen, put a period at the end of the name, as in:

```
postoffice. A 192.168.0.4
```

Notice the period after postoffice. That would assign the IP address to a host whose fully qualified domain name was simply postoffice, with no .com or the like after it. (You probably wouldn’t ever want this.)

I’ve mentioned TTL, or time to live, information. None of the previous records have TTL information, but if you want to put a TTL on a record, then just put the number of seconds that it’s good for. So, for example, to tell the world that postoffice.bigfirm.biz has the IP address 192.168.0.4, but to check back with us on that information every day, we might have this A record:

```
postoffice 86400 A 192.168.0.4
```

### SOA RECORD IN ZONE FILE FORMAT

The first record is the SOA record:

```
@ IN SOA bigdog.bigfirm.biz. mark.bigfirm.biz. (
```

It’s basically saying, “This the start of authority record for bigfirm.biz.”

Wait a minute—I don’t see “bigfirm.biz” anywhere in that line. Where’d I get that this is the SOA for bigfirm.biz? The answer is the @ sign. It’s got a magic meaning inside zone files completely *different* from the magic meaning that it has in e-mail addresses. Instead of separating an e-mail name from a user’s domain, the @ here is shorthand for “this zone.” So, because this is the bigfirm.biz zone, @ is just a shorthand way of saying bigfirm.biz. If you wanted to, you could write the SOA record as this:

```
bigfirm.biz. IN SOA bigdog.bigfirm.biz. ...
```

*This* is why you can’t type the e-mail address of the responsible person for the zone with an @. If you did, DNS would just expand the @ to bigfirm.biz, leading to a pretty funny-looking e-mail address.

The IN is a holdover from the early days of DNS—it stands for *Internet* and refers to the fact that at one point it appeared that there would be other namespaces that DNS would worry about. Strictly speaking, every one of these records needs the IN part—I’ve worked with older DNS servers that wouldn’t function without it—but it appears that the Server 2003 DNS server doesn’t need it. You might have to edit zone records to insert an IN before the record type—for example, all of the As might have to become IN As—if you wanted to put a Server 2003 DNS zone file on an older DNS server.

Following the @ IN SOA is bigdog.bigfirm.biz.—that’s the DNS name of the primary DNS server for this zone.

**NOTE** Notice—that’s the primary DNS server, which is not necessarily the authoritative DNS server. How can you tell by looking at this zone file which server is authoritative? You can’t. You find out which DNS server is authoritative, recall, by looking in the zone files of the parent domain to find out how the parent delegates name resolution responsibility for the child.

Following that is the e-mail address of the technical contact for the domain, the e-mail address of the person to mail to if there’s a problem with the domain. Then there are the five numbers that the SOA record uses to describe the domain data, as explained earlier.

### A RECORDS IN ZONE FILE FORMAT

As with most zones, the bulk of the records are A records:

```
bigdog      A      192.168.0.2
ns2         A      192.168.0.3
postoffice  A      192.168.0.4
router1     A      192.168.0.1
www         A      192.168.0.5
ns1.ecoast  A      192.168.0.6
```

There are just two points to make about these records. First, notice that all of the names do not end in periods, so they’re relative to the zone name. In other words, `www` is short for `www.bigfirm.biz`. Second, notice that you *can* have periods in the middle of a name. Even though `ns1.ecoast.bigfirm.biz` is not, strictly speaking, in the `bigfirm.biz` zone—it should be in the separate `ecoast.bigfirm.biz` zone—you can still include its A record by labeling that record `ns1.ecoast` and, as DNS just tacks on the domain name by default, it ends up being clear (to the DNS server, anyway) that this is an A record for `ns1.ecoast.bigfirm.biz`. (Remember that record—I’ll have more to say about it in a minute.)

### NS RECORDS IN ZONE FILE FORMAT AND “GLUE” RECORDS

Next are two NS records, as follows:

```
@ NS bigdog.bigfirm.biz.
@ NS ns2.bigfirm.biz.
```

These records say that the name servers for this zone, `bigfirm.biz`, are `bigdog.bigfirm.biz` and `ns2.bigfirm.biz`. Again, this works because `@` gets automatically translated by the DNS server to “this zone” or, in this case, `bigfirm.biz`. They could have just as well been written like so:

```
bigfirm.biz NS bigdog.bigfirm.biz.
bigfirm.biz NS ns2.bigfirm.biz.
```

There’s another NS record farther down:

```
ecoast      NS      ns1.ecoast.bigfirm.biz.
```

Now, *this* one has a different job than identifying the DNS servers for `bigfirm.biz`. Can you figure out what it does? It’s an NS record, so its job is to identify a DNS server for a zone. But it doesn’t refer to `@` or `bigfirm.biz.`, it refers to `ecoast`, and notice that there’s no period at the end of it. That means that we’re supposed to add the zone name, `bigfirm.biz`, to get its full name. Expanded, then, the DNS server reads this record like so:

```
ecoast.bigfirm.biz. NS ns1.ecoast.bigfirm.biz.
```

This is the delegation record for the ecoast subdomain. *This* is the record that essentially “creates” the ecoast.bigfirm.biz zone. If you were to look in the (huge) zone file that serves the com domain, then you’d see a similar record for your “dot-com” domain (assuming you have one). This is half of what the wizard that performed the domain delegation did. The *other* half of what the New Delegation Wizard did was to add an A record for ns1.ecoast.bigfirm.biz that could be written in one of two ways:

```
ns1.ecoast.bigfirm.biz.    A    192.168.0.6
```

or

```
ns1.ecoast    A    192.168.0.6
```

Notice that the first example includes a fully qualified name, as it ends with a period. That A record (however you enter it) for NS1 is called a “glue” record. Let’s see why.

Suppose you want to resolve a name in the subdomain ecoast.bigfirm.biz. How does your DNS server do it? Well, it wants to find the DNS server for ecoast.bigfirm.biz so that it can query that DNS server about whatever name it’s trying to resolve. As you’ve seen, you find the DNS server for ecoast.bigfirm.biz in the DNS server for bigfirm.biz. Specifically, your DNS server asks the bigfirm.biz DNS server for any NS records that are relevant to ecoast.bigfirm.biz. And, as you can see, the DNS server would return the answer, “You can find a DNS server for ecoast.bigfirm.biz at the machine named ns1.ecoast.bigfirm.biz.”

If that were *all* that the bigfirm.biz DNS server said, then it wouldn’t be very useful. So to look up a name on ecoast.bigfirm.biz, I ask a machine named ns1.ecoast.bigfirm.biz? Okay, then I guess I need to find the IP address of that machine named ns1.ecoast.bigfirm.biz; I wonder who I’d ask about that? Well, let’s see, ns1.ecoast.bigfirm.biz is part of the ecoast.bigfirm.biz domain, so the DNS server I’ll query to find the IP address of ns1.ecoast.bigfirm.biz would be...umm...ns1.ecoast.bigfirm.biz. So, in other words, the only way to get the phone number for Mel’s Grocery is to call Information, but before I can call Information I must know the phone number for Information, and the place to call to find all numbers (including Information’s) is Information.

To avoid this chicken-and-egg situation, DNS zones often contain A records for hosts that aren’t part of that zone. In some senses, you might say that they’re out of place—but without them, we’d never be able to find the IP address of ns1.ecoast.bigfirm.biz. So adding this seemingly out-of-place A record solves the problem. Such an A record is called a *glue record*.

### CNAME RECORDS IN ZONE FILE FORMAT

Next, you see a CNAME record:

```
ftp            CNAME    www.bigfirm.biz.
```

This CNAME equates ftp.bigfirm.biz to a machine named www.bigfirm.biz. The result is that anyone seeking to resolve ftp.bigfirm.biz gets returned the IP address of www.bigfirm.biz.

### MX RECORDS IN ZONE FILE FORMAT

Lastly, let’s consider the MX record, which looks like

```
@            MX 10    postoffice.bigfirm.biz.
```

Notice how it's laid out: again, starting with an @ to indicate it refers to the entire domain, then the record type **MX**, then the preference value, and finally the name of the mail server. I could have more than one, but this zone only has one.

### DIRECTLY MANIPULATING ZONES FILES: AN EXAMPLE

I'll return to looking at the ASCII files that drive a standard DNS server (and a Server 2003 DNS server, provided that you don't make your zones AD-integrated) a bit later, but before leaving the topic for now, let me offer some step-by-step advice on working directly in a zone file.

Suppose you wanted to add a host name entry—an A record—for a machine named `test.bigfirm.biz`, at address `192.168.0.10`. You could do it via the GUI, but here's how to add the entry to the zone files directly. Basically, you stop the DNS service, modify the zone file, then start it up again:

1. In the DNS snap-in, right-click the icon representing the DNS server and choose All Tasks/Stop. This stops the DNS service on that server.
2. Look in `\winnt\system32\dns` to find the zone file named `bigfirm.biz.dns`. Edit it with Notepad.
3. Add **test A 192.168.0.10** to the end of `bigfirm.biz.dns`, and as you type it, you need only remember to start the line with **test**, then leave at least one space, then the capital A, then at least one space, then the IP address.
4. Increase the numeric value in the Serial Number entry of the SOA record by one so that the other servers (such as `ns2`, if you built it, or for that matter any other DNS server out there looking to this one to resolve `bigfirm.biz`) know there's new data in the zone.
5. Save the file.
6. Return to the DNS snap-in, right-click the server, and choose All Tasks/Start.

Once the DNS server has started again, take a look in the `bigfirm.biz` zone. You'll see that `test`'s entry is visible. Once again, why would you modify the ASCII file instead of just clicking? Well, you might not—but you *might* decide to make large-scale changes to the zone via some program or macro that you wrote, a program that reads and massages the ASCII zone file. You'd follow basically the same approach in that case—stop the DNS service, run the program that modifies the zone file, then start the DNS service.

### Dynamic DNS (DDNS)

Well, I've been dropping hints about it for the past 40 pages or so—so let's talk about *dynamic DNS*, or DDNS to the acronym-oriented.

For years, WINS has been a pain in the rear for many reasons. But it was better than DNS in one important way: Its database was automatic and dynamic. What I mean is that you almost never had to tell a WINS server about a machine out on the network. Instead, the machines would tell WINS about themselves automatically; whenever they booted up or renewed their DHCP leases, they'd go back and reregister themselves with WINS. The result? WINS automatically kept a database of machines on the network.

Now DNS, in contrast, wasn't automatic. You had to punch in A records for every one of your machines by hand, either by editing a zone file or by clicking in a GUI. It would have been pretty nice if DNS servers could collect information about the names and addresses of the machines on the network in a similar way to WINS.

Well, now DNS can, with DDNS. RFC 2136 describes a process whereby DNS clients—the workstations and servers that rely upon DNS for name resolution—can register themselves with DNS automatically, telling DNS to create an A (or any other type) record for them, without requiring any work on an administrator's part.

### SEEING DDNS WORK

Want to see it in action? You can, if you've been following along and built the bigdog.bigfirm.biz machine. Just put Windows 2000 Pro, Server, XP, or Server 2003 on a computer. Call that computer MYPC. Give it a static IP address of 192.168.0.20, subnet mask 255.255.255.0, don't fill in the default gateway, and set the DNS server to 192.168.0.2—that is, bigdog. Finally, set the DNS suffix to bigfirm.biz and reboot the computer.

Once MYPC has rebooted, go over to bigdog, start the DNS snap-in, and open the bigfirm.biz forward lookup zone. You will see an A record for MYPC with an IP address of 192.168.0.20—an automatically created A record.

Next, stop the DNS service so that the zone data gets flushed out to the zone files, and take a look at `\windows\system32\dns\bigfirm.biz.dns`. You'll see an A record for MYPC that looks like this:

```
mypc 1200 A 192.168.0.20
```

Notice the 1200—remember what that is? It's a time to live value for the A record. 1200 seconds is 20 minutes. So when MYPC registered with the DNS server, it basically said, "I'm mypc.bigfirm.biz and I'm at 192.168.0.20, but if anyone asks about me, tell them that I might be a different address in 20 minutes—so don't cache the data for any longer than that."

**NOTE** You can change that value if you care to by creating a `REG_DWORD` value entry called `DefaultRegistrationTTL` in `HKEY_LOCAL_MACHINE\SYSTEM\CurrentControlSet\Services\Tcpip\Parameters`. Fill the value entry with the length in seconds that you'd like the TTL set to. I can't think of a reason why you'd mess with it, but I include this for the curious. Please note that this is not how often your system reregisters with DDNS—there really isn't a Registry entry to affect that, as you'll see later in this chapter.

If you look at the reverse lookup zone for 0.168.192.in-addr.arpa, then you may see a PTR record for 192.168.0.20, as the computer normally automatically registers both the forward and reverse entries. (I say "may" because XP and Server 2003 seem not to automatically register PTRs if their IP addresses are in a nonroutable range. That's not anything that I've been able to get verified, but it makes some sense, as it'd cut down on those unnecessary dial-ups to talk to prisoner.iana.org.)

The registrations might not have worked if you didn't set up 0.168.192.in-addr.arpa or the bigfirm.biz zone willing to accept dynamic entries—remember that zones aren't dynamic by default. You can easily check that both zones accept dynamic updates. In the DNS snap-in, right-click the folder representing your bigfirm.biz zone, then choose Properties and click the General tab. Then choose Nonsecure and Secure under Allow Dynamic Updates.

### WHAT TRIGGERS DDNS REGISTRATIONS?

If you forgot to make the zones dynamic until after MYPC booted, how can you force MYPC to re-try registering? Well, clearly you could turn MYPC on and off, but who wants to do that? Instead, open a command line at MYPC and type this:

```
ipconfig /registerdns
```

Then check the zones—you should now see the updates.

How do the registrations work? Well, remember that DDNS registrations are *initiated by the client*. The DNS server does not ask the client to register; instead, the client requests the registration of the server. Five events cause a client to register or, more likely, to *rregister*:

- ◆ The computer has been rebooted and the TCP/IP software has just started.
- ◆ You've changed the IP address on a system with a static IP address.
- ◆ Your computer gets its IP address from DHCP and the computer has just renewed its DHCP lease.
- ◆ You type **ipconfig /registerdns**.
- ◆ 24 hours has passed since the last time the system registered with DDNS.

You can change that 24-hour period to another one with a Registry change to HKEY\_LOCAL\_MACHINE\SYSTEM\CurrentControlSet\Services\Tcpip\Parameters: add a new value entry DefaultRegistrationRefreshInterval of type REG\_DWORD. You can then specify how often to reregister in seconds. The default is 86,400, the number of seconds in a day.

#### DDNS REGISTRATIONS IN MORE DETAIL

My simple example with one workstation—MYPC—and just one DNS server—bigdog—obscured some of the complexity of a DDNS registration. Here is more specifically how a registration happens.

##### **On a System with a Static IP Address**

1. First, the client computer asks its local DNS server to retrieve the SOA record for the client computer's DNS suffix. So, for example, because MYPC sees that its DNS suffix is bigfirm.biz, it asks its local DNS server (which happens to be bigdog) to go find the SOA record for bigfirm.biz.
2. The local DNS server queries its DNS hierarchy for the answer to the client's question. In the case of bigdog, it already *knew* the answer, as bigdog contained the zone files. But if MYPC had been hooked up to a different DNS server, that DNS server could still have queried other DNS servers to get the SOA record for bigfirm.biz, and returned that information to MYPC.
3. Inside the SOA is, you may recall, the name of the DNS server that is primary for the bigfirm.biz zone. That's why MYPC wanted the SOA record: It has to register (or reregister) with the DNS server that acts as the primary DNS server for the bigfirm.biz zone, because recall that only the primary DNS server can change a zone. Even if a secondary DNS server for bigfirm.biz chose to accept MYPC's registration, it wouldn't be any good because that secondary DNS server wouldn't replicate MYPC's A record to other DNS servers, and they wouldn't listen if it tried anyway. The registration must be done at the primary (unless you build an Active Directory–integrated zone).
4. Now that MYPC knows the name of the primary DNS server for bigfirm.biz, it contacts that DNS server and sends its registration requests: "Please create an A record for mypc.bigfirm.biz at 192.168.0.20."
5. But it's not done yet—now it needs to register a PTR record with the reverse zone. So it asks for the SOA record for the reverse zone and then uses that SOA record to identify the primary server for the reverse zone. Once it knows the primary server for the reverse zone, it asks the reverse zone's primary server to register it.

### **On a System That Uses DHCP**

That's how MYPC worked, as it has a static IP address. But if MYPC had gotten its IP address from DHCP, then things would work just a bit differently.

When a system gets its address from DHCP, then the system only registers its *forward* record—the A record—rather than the PTR record. The DHCP server handles registering the reverse zone's PTR record. Furthermore, you may, if you like, tell the DHCP server to handle *all* registrations, both forward and reverse. Look back to Figure 7.20 in the section on DHCP and you see the DNS tab on a DHCP scope's properties. It's not the default, but you can choose a radio button labeled Always Update DNS and, if you do, then the clients don't do registrations, the DHCP server does.

Remember that I said that DDNS registrations are initiated by the client. But what about if the client *isn't* running Windows 2000? A Windows 98, Windows Me, or NT 4 system wouldn't know how to register itself in DNS, nor would it know that it even had to. Recall that also back near Figure 7.20, I explained—and it seems a good time to say again—that the Server 2003 DHCP server is smart enough to detect systems that don't know to register themselves with DNS. In that case, the DHCP server will register both the forward and reverse entries for those systems. (Unless you tell it not to; that's an option.)

### **MUST MY SYSTEM REREGISTER?**

Anyone with a good knowledge of how WINS works will probably assume, as I did, that you *must* reregister with DDNS on a regular basis, or the DDNS server will simply “forget” your system's dynamically registered records.

### **By Default, 2003's DNS Server Does Not Clean Out Old Records**

Actually, though, that's not true. At least, not by default.

In fact, if you leave the DNS server defaults in place, your workstation really need only register once. Once it has told the DNS server to create an A record and a PTR record (and whatever other records it may need created), then those records stay in the zone file indefinitely.

### **Scavenging: Cleaning Out the Old**

That may sound a tad inelegant. I mean, dynamic DNS is supposed to be *dynamic*, right? So if one day I shut down the machine named pc152.bigfirm.biz and never start it up again, then I really shouldn't have to go root around in the bigfirm.biz zone file and delete its records. Can't the system do this kind of housekeeping itself?

Yes, it can. The process is called *scavenging*. Scavenging is a process whereby a DNS server periodically (you can configure how often, as you'll see) checks its dynamically created records to see how long it's been since they were registered (or reregistered). Then, if the scavenger finds records that haven't been registered or reregistered in a long time (and you can configure how long “a long time” is), it deletes them from the zone file.

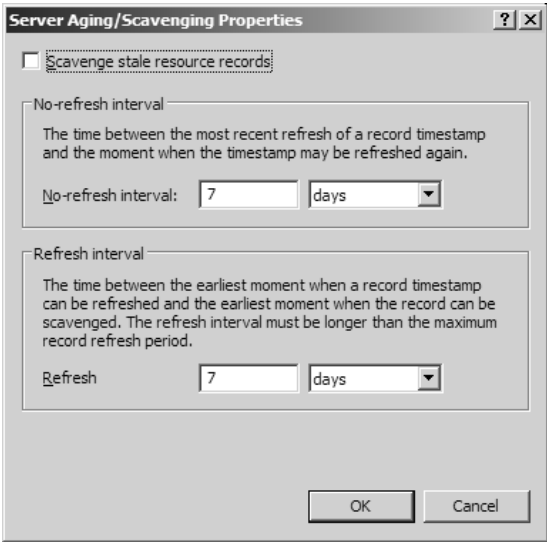

### **Controlling Scavenging: Just Three Numbers**

To see how to set up scavenging, right-click the DNS server's icon in the DNS snap-in and choose Set Aging/Scavenging for All Zones and you'll get a dialog box like Figure 7.75.

Check the box labeled Scavenge Stale Resource Records and click OK twice (you'll see another dialog box asking about AD-integrated zones; again, just click OK to go with the defaults) to enable scavenging. But what about those two time values, the No-Refresh Interval and the Refresh Interval? Well, there are

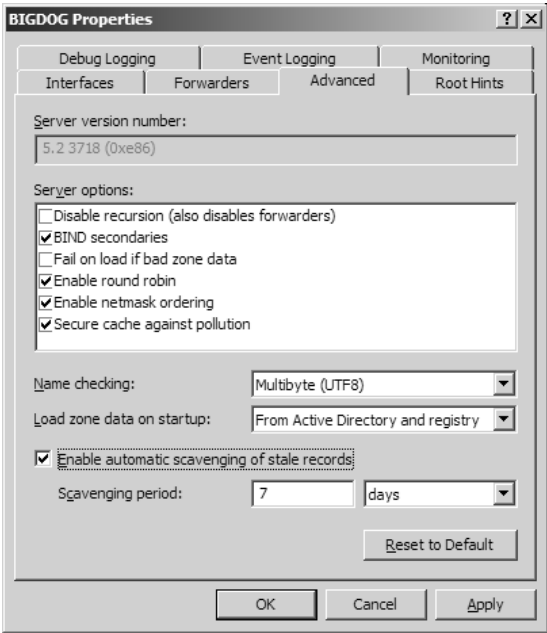

three numbers relevant to how scavenging works; here, you see two of them—and I’ll explain them in a minute, but if you’re in a real rush, then here’s the short version: just use the defaults, they’re fine.

**FIGURE 7.75**  
Setting scavenging parameters

But you’re not done setting up scavenging. Right-click the server again, choose Properties, and click the Advanced tab. You’ll see something like Figure 7.76. Check Enable Automatic Scavenging of Stale Records to kick off the scavenger on a regular basis.

**FIGURE 7.76**  
How often to scavenge?

**The No-Refresh Interval** Now let's consider those three numbers.

Look back to Figure 7.75 and you'll see the first value, something called the No-Refresh Interval. It creates a period of time wherein your computer *cannot* reregister itself in DNS. So, for example, if the no-refresh interval were one day and your computer had reregistered at 9:00 A.M. on Tuesday morning, then any attempts to reregister itself before 9:00 A.M. Wednesday morning would simply be ignored by the DDNS server.

Why'd Microsoft bother with something like this? Mostly because you have the option, as I've mentioned (and will discuss later in some detail) to store your zones not in a traditional zone file, but instead in the Active Directory, a so-called "Active Directory—integrated zone." Any time that your system reregisters, that creates a change in the AD, and any change in the AD must be replicated to every other AD controller in the enterprise. Replication traffic can clog your WAN links and slow down the DCs, so I guess the idea with the no-refresh interval is to reduce the burden imposed on the AD by overzealously reregistering systems.

If you're experimenting and want to force an immediate reregistration within the no-refresh interval, just open the zone in the DNS snap-in and use the GUI to delete the A record for the system that you want to register. Then go to the system that you want to reregister and type `ipconfig/registerdns` at a command line.

**The Refresh and Scavenging Intervals** Figure 7.75 also includes a field called the Refresh Interval. But that's not a very descriptive name. A better name would be The Remainder of the Immunity from Scavenging Period. It's an interval that says to the scavenging routine, "If this record's age is less than the sum of its no-refresh and refresh intervals, then don't even *think* of scavenging it."

For example, suppose I've got a no-refresh interval of one day and a refresh interval of two days. And let's suppose that the scavenging routine runs every day. (You set the scavenging interval shown in Figure 7.76.) Your system registers at 9:00 A.M. Tuesday morning. As you read before, that means that the DDNS server would be deaf to any attempts by your system to reregister. Let's say that the scavenging routine runs every evening. It sees that the no-refresh plus the refresh intervals equals three days. The scavenger then sees that your workstation's A record is less than a day old. That age is less than three days, so the scavenger leaves the record alone.

Let's suppose that you're on vacation for the week. So 9:00 A.M. Wednesday morning is when your DDNS server would accept a reregistration for your system, but your system's not on, so it doesn't try to reregister. Wednesday evening, the scavenger sees that your workstation's A record is about a day and a half old—still too young to scavenge. The same thing happens Thursday night, when the scavenger sees a two-and-a-half-day-old record. But on Friday night, your workstation's A record is three-and-a-half days old, so the scavenger munches it.

Simplified, think of it this way. Add the No-refresh and the Refresh intervals together. That's how long you want a record to stay in a dynamic DNS zone.

**Choosing a Good No-Refresh and Refresh Interval** There really isn't any relationship between the scavenging interval and the no-refresh/refresh intervals. But you should take a minute to ensure that you don't set the no-refresh/refresh intervals too small. The sum of those two should be larger than the frequency of reregistration.

Here's an exaggerated (and impossible) example of what I mean. Suppose your system reregisters with DDNS only once every 30 days. But then suppose you set a no-refresh interval of six days and

a refresh interval of seven days, and a scavenging interval of one day. Let's follow the process through from Jan. 1:

1. On Jan. 1, your system registers with DDNS.
2. The DDNS server will not accept another registration from your system until Jan. 7, but that's no problem—your system doesn't intend to reregister until Jan. 31.
3. Every day until Jan. 14, the scavenger runs and sees that your system's A record is less than 13 days (6 plus 7) old, and so leaves it alone.
4. Around Jan. 14, however, the scavenger runs, finds the record older than 13 days, and deletes it.

Remember that this is a client-driven registration system, so there's no method for the DDNS server to give the client a heads-up that it's time to reregister.

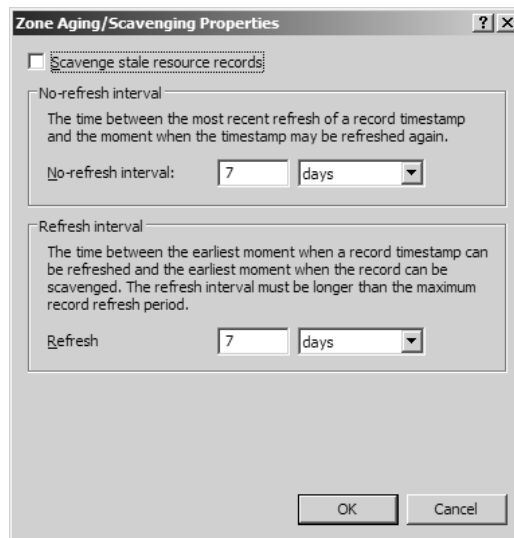

So, clearly you should set the sum of your no-refresh and refresh intervals so that they always exceed the maximum possible interval between subsequent reregistrations. But what's the maximum possible interval between reregistrations? Recall the things that trigger a reregistration: They happen every 24 hours (if the system stays up), upon a DHCP lease renewal, or when you turn your computer on. So the longest you'd probably ever go between reregistrations would be as long as you ever have your computer off—seven days, perhaps, unless you're in the habit of taking two-week vacations.

### Setting Scavenging for One Zone

Figure 7.75 showed you how to set the scavenging values for all zones. To set a different set of refresh and no-refresh intervals for just one zone, then you'll need to right-click the zone and then choose Properties. Click the General tab and you'll see an Aging button; click it and you'll get a dialog box that looks like Figure 7.77.

**FIGURE 7.77**

Scavenging settings for a particular zone

Notice that it's identical to Figure 7.75. The defaults of seven days apiece are probably just fine. Notice the information field at the bottom of the dialog box—that says when scavenging could next

occur. If you look in the zone file at a dynamic record after you've turned on scavenging, you might see an entry like this:

```
ca [AGE:3505395] 96 A 192.168.0.21
```

You should recognize the `ca 96 A 192.168.0.21` part—that's just an A record for a host named `ca.bigfirm.biz` at address `192.168.0.21` with a TTL of 96 seconds. The `[AGE:3505395]` is the “birthday” of this record, the hour in which it was created. As near as I can tell, this is a value measured in hours since January 1, 1600, or thereabouts, and don't bother with decimals—it seems that scavenging works in units of hours or larger.

**WARNING** Note something about that `[AGE:]` entry—it's not a standard part of a DNS record. Therefore, if you turn on scavenging, you'll still have zone files, but they won't be portable to non-Microsoft-based DNS servers anymore, at least not without some work—you'd have to edit the zone files to remove the `[AGE:]` items before trying to transplant a 2000 or 2003 zone file onto another kind of DNS server.

In sum, then, to enable scavenging you must remember to:

- ◆ Set the no-refresh and refresh intervals for the server as a whole, as in Figure 7.75.
- ◆ Turn on scavenging, as in Figure 7.76.
- ◆ If you want to set different intervals for each zone, then adjust their specific refresh properties.

### Viewing When a Record Will “Go Stale”

If you want, you can find out when a particular record will go stale, although not directly. Start up the DNS snap-in and choose View/Advanced. Then right-click any record and choose Properties; you'll then see something like Figure 7.78.

**FIGURE 7.78**

Viewing a record's properties with View/Advanced enabled

The screenshot shows the 'ns2 Properties' dialog box. It has a title bar with a question mark and a close button. The 'Host (A)' tab is selected. The 'Host (uses parent domain if left blank):' field contains 'ns2'. The 'Fully qualified domain name (FQDN):' field contains 'ns2.bigfirm.biz'. The 'IP address:' field contains '192.168.0.3'. There are two checkboxes: 'Update associated pointer (PTR) record' (unchecked) and 'Delete this record when it becomes stale' (checked). The 'Record time stamp:' field shows '12/16/2002 1:00:00 PM'. At the bottom, the 'Time to live (TTL):' field shows '0 :0 :20 :0' with '(DDDD:HH:MM:SS)' to its right. There are 'OK', 'Cancel', and 'Apply' buttons at the bottom.

Here, I took the ns2 system and deleted its record in the zone on bigdog, after turning on scavenging on bigfirm.biz. Then I went over to the ns2 system and typed `ipconfig/registerdns` to make ns2 reregister itself dynamically with bigdog. The date that you see of 12/16/2002 at 1:00 P.M. isn't telling me that this record goes stale at that time; instead, it's telling me that this record *was created*—registered—at that date. To find out when it'll go stale, I'd have to first add the no-refresh plus the refresh intervals. Suppose the no-refresh interval is two days, and the refresh interval is three days. That'd tell me that the earliest time that this record can go stale is five days later at 1 P.M. on Dec. 21, 2002. But, of course, that's not the *only* information that I need. Recall that stale records only get deleted when the scavenging routine runs, so I'd need to know when the scavenging routine runs to determine exactly when this record will disappear.

### Viewing Scavenging Logs

Windows 2000 Server and Server 2003-based DNS servers report what happened in every scavenging cycle in the Event Viewer in the System log. Just look for a DNS event with event ID 2501.

### WINS REGISTRATION VERSUS DDNS REGISTRATION

Now that you've seen how DDNS registration works, you might have committed a bit of mental shorthand (I know *I* did when I first learned this) along the lines of "DDNS for Winsock is equivalent to WINS for NetBIOS—and so many of the same issues apply." That's *partially* right; but there's one significant difference between WINS and dynamic DNS, and that difference will affect how you decide how many DNS servers you need, and where to place them.

As you've seen, every TCP/IP-enabled computer gets a "primary WINS server" and a "preferred DNS server." At first blush, it looks like a system's primary WINS server and its preferred DNS server do basically the same thing, and in some senses they do: Your preferred DNS server is the DNS server that resolves DNS names for you, and your primary WINS server is the WINS server that resolves NetBIOS names for you. But here's the difference: Your system needs to register with both the WINS and DNS databases. Your system registers its NetBIOS name with its primary WINS server, but it *doesn't* register its DNS name with its *preferred* DNS server; instead, it registers its DNS name with the *primary* DNS server for its zone.

As you've previously read, every WINS server has two very different tasks. First, it resolves NetBIOS names from its database. Second, it collects names to populate that database. Clearly a WINS server that serves one-fifth of the organization would only receive registrations from one-fifth of the organization, and therefore would be ignorant of the other four-fifths—and so any time that one of the WINS clients asked that WINS server to resolve a machine name in the organization, there'd be an 80-percent chance that the WINS server wouldn't know the name. That's silly, so, as you've read, any enterprise that uses more than one WINS server must set that WINS server up to share its database with the other WINS servers and to accept databases from other WINS servers and to merge those other databases with its own so that it (and every other WINS server) has a consistent, enterprise-wide database of machine names, hence the Microsoft "14 WINS servers worldwide" rule of thumb. That's a shame from the name resolution side—it'd be really great to be able to somehow scatter dozens of WINS servers all over the place to resolve names. But that'd be a nightmare if all of those dozens or hundreds of WINS servers each contained a little database that needed to be merged with all of the other databases—that's just asking for database corruption. Wouldn't it be cool if you could just create a kind of "low-octane WINS server" incapable of accepting registrations,

a kind of “resolving-only” WINS server? You’d give it a copy of the WINS database somehow and it could focus only on resolving names. With tons of them around, each one could serve just a small number of clients, with the result that all of those clients would receive very snappy response on their name resolution requests.

Well, sadly, you can’t do that with WINS, which brings me to the major point about how WINS and DDNS are different.

Should you limit yourself to 14 servers total with DNS? Absolutely not. In WINS, the machine that you register with *must* be the one that you use to resolve names. With DNS, the machine that resolves names is your preferred DNS server. You register with a different computer—the primary DNS server for your zone. The result is terrific—you can place any number of DNS servers in your organization whose only job is to resolve names and therefore help your network respond to clients more swiftly.

### **DDNS SECURITY IS WEAK, IF YOU CARE**

One thing that troubles some people about vanilla, by-the-RFC DDNS servers is that they will accept a registration from anyone. So, for example, if bigfirm.biz’s DNS server were “live” on the Internet, then anyone anywhere could just set their Windows 2000, XP, or Server 2003 computer’s domain suffix to bigfirm.biz and type **ipconfig /registerdns**. This would work even if that machine’s local DNS server didn’t do DDNS. Remember, all that your preferred DNS server must do is be able to retrieve the SOA record for bigfirm.biz—and any DNS server can do that.

Should the bigfirm.biz people care that people are registering on their domain? So what if the machine at 62.11.99.3 registers itself as poindexter.bigfirm.biz? A Microsoft person told me that it might matter. For example, he explained, consider the 128-bit downloadable versions of Internet Explorer. In the past, you weren’t supposed to be able to download them if you weren’t in the United States or Canada. Microsoft’s Web site determined whether you were in the United States or Canada by looking at your domain. If bigfirm.biz’s record in the Network Solutions database showed a U.S. address, then the download was okayed, so someone from outside the United States or Canada could sneak in that way.

Presumably, a hacker could first register with bigfirm.biz, then try to hack some system. If the system administrator of the attacked system noticed that he was being hacked by someone at bigfirm.biz, that might make for a bit of a hassle for the bigfirm.biz administrator. Particularly if the hacker was trying to crack an NSA or CIA site.

Not every brand of DDNS server software is wide open. There are now RFCs on secure dynamic DNS registration, although when last I checked, Microsoft’s dynamic DNS software can’t interoperate with it. You can, as I’ve suggested, secure a Microsoft DNS zone by making it AD-integrated; I’ll cover that soon.

### **Making Windows 2000/XP Computers Not Do Dynamic Registration**

Windows 2000 and later Microsoft operating systems automatically attempt to register their host names and IP addresses with the primary DNS server of the DNS domain that they belong to, as you’ve seen. But that can cause some problems in places that haven’t adopted the Active Directory or that use static DNS servers for some reason.

I had a client that used Unix-based BIND servers and that hadn’t made their DNS zone dynamic. (There wasn’t any reason to, as they hadn’t rolled out an AD yet.) The PC guys rolled out a few hundred Windows 2000 Professional systems.

The BIND guys—a different group—noticed.

All of a sudden, the DNS server logs were chock-full of warnings and errors about all of these computers trying to register with their static DNS zones. That worried the BIND guys, so they tracked it down to all of these new PCs. What to do? Well, the BIND folks could have just ignored the messages. But that *does* seem a bit inelegant. So rather than lowering the river, why not just raise the bridge? In other words, how could they get the 2000 or, for that matter, XP or Server 2003 boxes to stop bugging the DNS servers?

You can tell a Windows 2000/XP/Server 2003 computer to forgo registering altogether either from the GUI or with a Registry hack. The Registry hack is in `HKEY_LOCAL_MACHINE\SYSTEM\CurrentControlSet\Services\Tcpip\Parameters`. Add a new value entry, `DisableDynamicUpdate`—it's a `REG_DWORD` entry—and set it to 1 and reboot the computer. That'll keep the computer from attempting a dynamic update whenever the computer has a static address or got it from DHCP. Or here's a (long) command line to do it:

```
reg add hklm\system\currentcontrolset\services\tcpip\parameters /v
DisableDynamicUpdate /t REG_DWORD /d 1 /f
```

That's all one line. You can even do it on a remote system by prefixing the Registry key's name with the system's name. For example, to reach across the network and make this change to Bigdog, you'd type

```
reg add \\bigdog\hklm\system\currentcontrolset\services\tcpip\parameters /v
DisableDynamicUpdate /t REG_DWORD /d 1 /f
```

You can tell the computer not to try to update DNS in the GUI, as well; it's in the Advanced TCP/IP Settings property page, on the DNS tab. Uncheck the Register This Connection's Addresses in DNS box.

But what if you want to distribute this setting to bazillions of machines? The best solution is probably a custom policy; either a system policy would work (if you've got Windows 2000/XP workstations on an NT 4 domain) or a group policy (if you're running the AD). Custom policies are a big topic, though, so I won't go through the step by steps here—see Chapter 9 on how to create a custom system policy. Microsoft has a Knowledge Base article that explains how to build a group policy to tell a workstation to stop trying to register with their DNS servers at 294832.

## Active Directory—Integrated Zones

You've read that DNS zones come in three flavors: primary, secondary, and stub zones. But 2000 and 2003's DNS offer you a third type of zone called an *Active Directory—integrated* zone. As I see it, AD-integrated zones offer two main benefits: multimaster zone replication and a DDNS registration process that is both load-balanced and secured. But they've got a drawback as well: They stray from the RFCs for DNS a bit—but *just* a bit—and you've got to make your domain controllers into DNS servers. Let's see how to make a zone an AD-integrated zone, then look into the pluses and minuses in some detail.

### CREATING AN AD-INTEGRATED ZONE

Go to any primary zone on a Microsoft DNS server and right-click it, then choose Properties. The resulting properties page looks like the one back on Figure 7.59. To convert between a primary and

an AD-integrated zone, click the Change button and you'll see a dialog box like the one back in Figure 7.69.

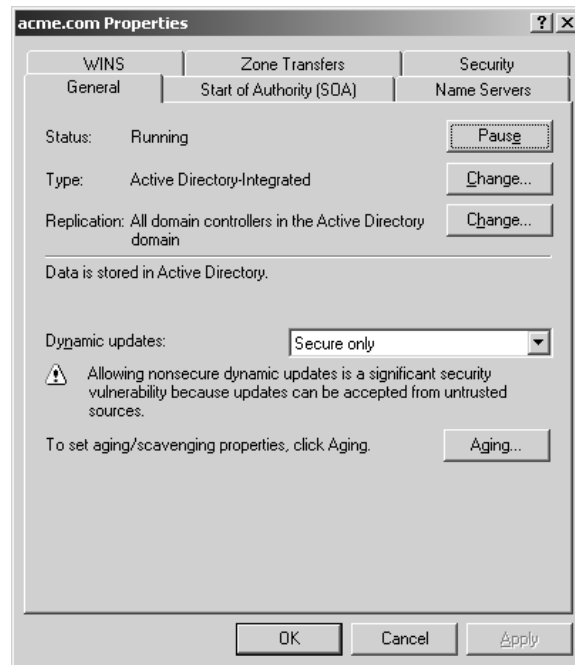

As I noted earlier, if you've been following along in the *bigfirm.biz* example, your Store the Zone in Active Directory (Available Only if DNS Server Is a Domain Controller) option will be grayed out. That's because you can only host an AD-integrated zone on an Active Directory domain controller, and the DNS server that we created for *bigfirm.biz*—*bigdog*—isn't a DC. (Recall that in fact we haven't created any domains at all yet.)

It may not be immediately obvious from Figure 7.69, but you've got a lot of flexibility if you want to experiment with an AD-integrated zone versus a standard primary zone. Just a mouse click or two converts a zone from primary to AD-integrated or vice versa—going AD-integrated isn't a one-way trip.

Once you make a zone an AD-integrated zone, then a visit back to the General tab of the properties page for that zone (right-click the zone in the DNS snap-in and choose Properties) will look like Figure 7.79.

**FIGURE 7.79**

Properties of an AD-integrated zone

Notice that the Dynamic Updates drop-down no longer says Secure and Nonsecure but instead shows Secure Only, an option that only appears once you're AD-integrated. (Notice also that this is not a property page for *bigfirm.biz*, as again we've not created its AD domains yet—that's in the next chapter.)

## MULTIMASTER ZONE REPLICATION

You've already read that under standard DDNS, only one computer can accept registrations in a given zone—the computer that happens to be the primary DNS server for that zone. That means that a

worldwide company might think twice about using DDNS (and therefore the Active Directory), because no matter where a 2000/XP-based workstation or server was situated, it would have to find and communicate with that *one* computer in the world every time that it wanted to reregister. And recall that Windows 2000 and later-based computers want to reregister whenever they renew their DHCP lease, reboot, every 24 hours, or when you type **ipconfig /registerdns**. So if your worldwide enterprise has an office in Khartoum with 200 machines and a primary DNS server in New York, then every single time the computers in Khartoum want to reregister, they've got to do it live-on-the-WAN to New York. That might be impractical.

With an AD-integrated zone, you can have as many primary DDNS servers as you like. Any one of these DDNS servers can accept DDNS registrations. They then replicate this information among themselves. So you could have a domain controller in Khartoum that not only handles logons for the users, but also handles machine registrations. Then, instead of requiring every system to talk to New York one at a time, the Khartoum DC just chatters with the closest DC now and then, perhaps a machine in Cairo, and tells the Cairo DC about the new DDNS registrations. Cairo's DC might forward that to the Paris DC, which sends it to the New York DC, and so eventually every DNS server knows about the Khartoum DDNS registrations.

Is it a lot of work to tell Khartoum how to find Cairo and then telling Cairo how to find Paris and so on? Not really, but here's the important point: As you'll see in the next chapter, you have to set this up to have a worldwide Active Directory domain anyway. The DCs share this information as part of their normal DC-to-DC chatter. So once you've set up the DCs to be able to send normal domain information back and forth, then you don't have to do anything at all to enable them to send DDNS registration information back and forth.

Once you've converted a zone to an Active Directory-integrated zone, you can install the DNS server service on any other DC for that domain. You enable that DNS server to assist in name resolution and registration for the domain by just creating a new forward zone, as you've seen, just as if you were creating a secondary zone for an existing domain—but instead of choosing Secondary Zone, you choose Active Directory-Integrated Zone. From that point on, everything's automatic. The AD-integrated DNS servers will then automatically tell some machines to register with one DDNS server, others with a different DDNS server, and so on.

### **NEW TO 2003: CONTROLLING DNS SERVER REPLICATION**

As you've read, AD-integrated zones store the zone information—the DNS records—not in an ASCII file but as data in the Active Directory. In general, the kind of data in AD is account information: if you have a user account on the domain then your account information is part of the AD. When domain controllers talk to domain controllers, they are mainly updating each other on account information—"We have a new user account for someone named darla82, it's got a password of 'swordfish,'" that sort of thing. Domain controllers are basically database servers that hold onto the database of domain information.

But keeping more than one or two database servers up to date on a database, whether it's user account information or a stamp collection, is a nontrivial issue. So when Microsoft designed the programs to allow a server to be a domain controller, they had to do a lot of work on the programs that DCs use to keep each other up to date—the "replication engine," so to speak, of Windows 2000 and Server 2003, and they did a pretty decent job at it. What's interesting about that is that there are plenty of uses for a piece of software that allows a bunch of distributed database servers to remain in

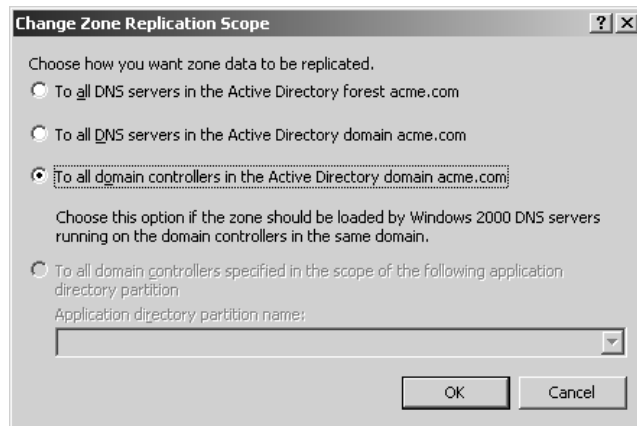

sync automatically without needing a lot of management by network administrators. Uses that have nothing to do with keeping track of accounts and passwords. (Microsoft even offers a version of the Active Directory database engine that *doesn't* keep track of accounts, passwords and the like—it's just a distributed database engine that developers can put any kind of data on without the need of an Active Directory. It's called ADAM, Active Directory Application Mode.)

It was this flexibility that led Microsoft to offer AD-integrated zones. The idea was, as you've already read, to add the DNS zone information to the other account information being passed around among DCs. But only DCs get the AD database information, which is what leads to what is (as you'll read in a page or two), in my opinion, AD-integrated zones' biggest weakness—to wit, AD-integrated zones force you to put DNS only on your domain controllers.

But to some people, putting the DNS info on the AD database presented another problem. All DCs in a domain get the same database information, as you've seen, so all DCs get the DNS info. But what if you have a DC that is *not* a DNS server? As it's a DC, it gets the DNS info, even though it's not going to use that info. Some people felt that this was a waste of network resources and wanted to fine-tune AD's replication of DNS zones. They got their wish in Server 2003, as Figure 7.80 shows.

**FIGURE 7.80**

Controlling how  
AD replicates  
DNS info

In a Windows 2000–based Active Directory, an AD-integrated zone's DNS info was only replicated to DCs in that zone's domain—in other words, the bigfirm.biz DNS info would only get copied to the domain controllers in the bigfirm.biz AD domain. As you'll learn in the next chapter, organizations can create groups of domains and cause them to automatically trust one another with security information, and those groups of domains are called *forests*. But under Windows 2000, only bigfirm.biz's DCs got the DNS information—not the other domains in whatever forest bigfirm.biz was a member of. (This screen shot refers to acme.com rather than bigfirm because we haven't created a bigfirm domain yet and I didn't want you to wonder how to duplicate that screen shot with the machine that we've been doing exercises on—you can't. It's not possible to make a zone AD-integrated until you have an Active Directory, and we don't yet.)

With a Server 2003–based DNS server, you can control how primary DNS servers keep their secondaries up to date. As you see in Figure 7.80, you have three replication options.

The second and default option, “To all domain controllers in the Active Directory domain acme.com,” works identically to 2000's DNS server, replicating DNS information to all DCs in

acme.com, whether those DCs are DNS servers or not—that’s the selected option. This option does *not*, however, replicate the DNS information to other DNS servers in acme.com’s forest; that made AD-integrated zones a bit harder to work with in Windows 2000.

That’s why Server 2003’s DNS server includes the first option, To All DNS Servers in the Active Directory Forest acme.com. Any Server 2003–based DNS server that is a member of any domain in the same forest as acme.com will automatically get acme.com’s zone.

The third option, To All Domain Controllers in the Active Directory Domain acme.com, is the interesting one if you want to cut down the Active Directory chatter about DNS, as it only replicates the acme.com zone info to machines that are both DCs and DNS servers in acme.com.

Of the three options, the one that shares the DNS info with the most systems in your forest is the first one, To All DNS Servers in the Active Directory Forest *domainname*, so if you find that DCs for different domains can’t find each other once you start building domains, then try that setting. Alternatively, you can solve that problem with something called *conditional forwarding* or *stub zones*. We’ve discussed these a bit, but we’ll cover this in detail in just a few pages when I explain something called *split-brain DNS*.

### SECURE DDNS REGISTRATION

I’ve got several domains running in my network, but I have one main Active Directory domain in my network, named win2ktest.com. It needs, as you know by now, a dynamic DNS zone to support the Active Directory, and besides I liked the whole idea of DDNS, so I set up win2ktest.com as a DDNS zone early on, back in the Windows 2000 Beta 3 days. I made it a standard primary zone rather than an AD-integrated zone.

Then the first edition of my earlier book *Mastering Windows 2000 Server* came out.

Because I sometimes take screen shots from an actual running network—mine—my examples tend to show dialog boxes from the DDNS server that hosts win2ktest.com. Unfortunately, some readers don’t understand that win2ktest.com is only an example domain name, rather than the one that they should use, so they create domains named win2ktest.com on their test networks. Unfortunately, if those readers are sitting at machines with routable IP addresses attached to the public Internet, then their Windows 2000 machines will attempt to find the primary DDNS server for win2ktest.com and then try to register themselves with that machine’s zone files.

In other words, with *my* DNS server’s.

I didn’t imagine that this would be a big problem when 2000 Server book’s first edition came out. But I happened to look in the win2ktest.com zone files about four weeks after the book came out and found that *1000* machines had registered with win2ktest.com from around the world—yikes! Clearly I needed to do *something* to keep the *rest* of the world from registering with my domain, but what? The simplest answer was to convert my zone from a simple primary zone to an AD-integrated zone and then to enable Only Secure Updates on that zone. (That’s two steps—just converting the zone to an AD-integrated zone doesn’t set dynamic updates to Secure Only. You have to go to Properties for that zone and drop down the Dynamic Updates list box to select Secure Only.)

The value of doing that was this: Machines can only register DNS records with an AD-integrated zone on a DDNS server by first *logging in to the AD domain*. So any random Windows 2000, XP, or 2003 machine on the other side of the world that happens to have a DNS suffix of win2ktest.com can’t register itself with my DDNS server unless it has a machine account on the win2ktest.com domain.

And for those new to Microsoft networking, there is indeed such a thing as a machine account, nonintuitive as it might seem! When you first attach a machine to an NT or an AD domain, you must have at least some administrative powers, as you're asking the domain to create an account much like a user logon account. Unlikely as it seems, every time that you turn your Server 2003, XP, Windows 2000, or NT-based computer on, it goes out to its domain and *logs in*. That's how AD-integrated zones keep my zone from growing beyond the size of my computer's hard disk!

As time has gone on, it has become clear that converting the zone to an AD-integrated one was a good idea. Once I briefly converted the win2ktest.com zone back to a standard primary zone to get a screen shot *just for 30 seconds* and, when I changed it back, I noticed that *two* machines had registered on the temporarily opened win2ktest.com zone! So if you see a message like this in your Event Viewer, then you'll know that your system tried to register with my DDNS server and was rebuffed:

The system failed to register network adapter with settings:

```
Adapter Name: {994A8620-8987-4D4A-ABA9-507122C08F28}
Host Name: dodo
Adapter-specific Domain Suffix: win2ktest.com
DNS server list:
    206.246.253.111
Sent update to server: 206.246.253.111
IP Address(es):
    210.20.10.4
```

The reason it could not register was because the DNS server refused the dynamic update request. This could happen for the following reasons: (a) current DNS update policies do not allow this computer to update the DNS domain name configured for this adapter, or (b) the authoritative DNS server for this DNS domain name does not support the DNS dynamic update protocol.

To register a DNS host (A) resource record using the specific DNS domain name for this adapter, contact your DNS server or network systems administrator.

### POTENTIAL AD-INTEGRATED PROBLEMS

So is Active Directory integration the answer for you? Probably. The whole idea of basing my DNS infrastructure on a nonstandard Microsoft implementation troubled me at first, but the more I think about it, the less troublesome it seems. Let's consider the issues.

First of all, does using AD-integrated zones force you to use only Microsoft DNS servers? Not at all. You can use other DNS servers as secondary servers on an AD-integrated zone. Those secondary servers receive zone transfers from the AD-integrated servers, as before. Yes, it *is* true that the AD-integrated servers must all be Microsoft Windows 2000 or Server 2003 DDNS servers, but what's the harm in that? If we were to stay with a standard BIND-type DNS implementation, then we'd be restricted to just one primary DNS server. In effect, all AD integration does is to expand the number of possible "primary" DNS servers. I have tested a Linux box running BIND as a secondary DNS server on an Active Directory-integrated zone and experienced no trouble whatsoever.

Second, once you “go Microsoft,” is there no going back? Not at all. A few mouse clicks converts an AD-integrated zone back to a standard primary zone. Once you convert a zone back to standard primary and shut down the DDNS server, then you’ll have a standard ASCII zone file that you can place on a non-Microsoft DNS server, instantly “migrating” your DNS hosting from a Windows 2000 or Server 2003 box to some other DNS system.

No, if I have a complaint with AD-integrated zones, it’s this one: The only machines that can be AD-integrated servers are Active Directory domain controllers. That worries me because I’ve always thought it a bad idea to put the name registration services on the same computer that does the logons. Remember that whenever you reboot your computer, it tries to reregister with DDNS. When do most people boot their computers? First thing in the morning. But what else do people do first thing in the morning? Log in to the domain. Early in the day, then, is when the domain controllers are busiest, logging people in. It seems to me that the busiest time of the day for a DDNS server is *also* first thing in the morning. Why take two functions that are both busiest at the same time and put them on the same machine? It seems somewhat unwise. But consider the alternative: If you use only a single primary DDNS server, then you’ve set up your enterprise so that if that one machine goes down, DDNS registrations don’t happen. (But, on the other hand, don’t forget that if you haven’t turned on scavenging, then it’s not going to be a big deal.)

What’s the right answer, then? I can’t say that I have the 100-percent best answer, but on balance I’d say that using AD-integrated zones makes the most sense in a predominantly 2000, XP, and/or 2003-based shop.

## DNS Resolution in Detail

Now that you’ve seen how to set up a Server 2003-based DDNS server, let’s look at how DNS works from the *client’s* point of view. And in the process, I’ll get a chance to discuss several important concepts I haven’t covered yet.

Let’s say you’re sitting at a Windows 2000, XP, or Server 2003 machine attached to the Internet. You start up Internet Explorer or Netscape and point it to my Web site, [www.minasi.com](http://www.minasi.com). Your browser hasn’t a clue that [www.minasi.com](http://www.minasi.com) is the DNS name of the machine with IP address 68.15.149.117, so it needs something to do that name resolution for you—a local DNS server. I’ll assume you’re sitting at work while doing this, and that your firm has at least one local DNS server, which needn’t be a Microsoft-based DNS server; any type of DNS server will do the trick here. Here are the specific steps that your workstation and the local DNS server perform to turn [www.minasi.com](http://www.minasi.com) into 68.15.149.117.

We’re going to do a few exercises along the way, so if you like, get ready for them. Make sure that you’re (1) sitting at [bigdog.bigfirm.biz](http://bigdog.bigfirm.biz) and (2) that system is connected to the public Internet—that you can ping some IP address out on the Internet. You don’t *have* to do these exercises, so don’t worry if you don’t have a computer handy.

### STEP 1: CHECK HOSTS

As has been the case with Microsoft DNS clients from the beginning, your workstation will first look in `\windows\system32\drivers\etc` for an ASCII file named `hosts`. If the DNS name that it’s looking for is there, then your workstation will use that IP address and not look any further. The `hosts` file only stores A records, but the “what IP address does [www.minasi.com](http://www.minasi.com) have?” question is an A record lookup, so that’d be relevant here.

**Exercise: Messing with hosts**

Just to prove that hosts always beats anything else, try this.

1. Open up the hosts file: click Start/Run and fill in `notepad %systemroot%\system32\drivers\etc\hosts`, then press Enter.
2. Add a line to the bottom of the hosts file that looks like this:  
`136.1.240.21 www.minasi.com`  
 Be sure to press Enter at the end of that line. Save the file, but don't close Notepad.
3. Now start up Internet Explorer and point your browser to `www.minasi.com`.

Where did you end up? As I wrote this, 136.1.240.21 was the IP address of one of Ford Motor Company's Web servers. They might have changed it by the time you read this, but if not, pointing IE to my Web site sends you instead to Ford's. The power of hosts!

Before we leave, please go *delete that line from hosts and save hosts!* (Thanks; I'd miss you guys if you couldn't visit my Web site.)

**STEP 2: CHECK THE DNS CLIENT CACHE**

On a Windows 9x or NT 3.x or 4 computer, the next thing that your workstation would do to resolve `www.minasi.com` would be to ask the local DNS server, "What's the IP address for `www.minasi.com`?" But the DNS client software on Windows 2000 and later Microsoft OSes—that is, the built-in software that knows how to ask DNS servers to resolve names—has an extra new feature: It caches the results of name resolution requests.

**Viewing the DNS Client Cache**

Here's how DNS caching works. Suppose you pointed your browser to `www.minasi.com` first thing in the morning; that causes your workstation to go ask the local DNS server to search the public DNS namespace for the IP address of `www.minasi.com`. But then suppose you returned to `www.minasi.com` 20 minutes later; in *that* case, your workstation wouldn't *have* to ask a DNS server for the IP address of `www.minasi.com` because the Windows 2000/XP/2003 DNS client software remembers the answers to old name resolution requests. Want to see what DNS names your workstation currently knows? Open up a command line and type this:

```
ipconfig /displaydns
```

You'll see a list of names and addresses, as well as the TTL in seconds. Like a DNS server, the Windows 2000/XP/2003 DNS client will only cache information for as long as the TTL specifies. Thus, if your system asks my DNS server to resolve `www.minasi.com`, then my system says, "Its IP address is 68.15.149.117 and its TTL is 3600 seconds," so for the next hour your system wouldn't bother to try to re-resolve `www.minasi.com`, choosing instead to assume that the address hadn't changed.

Adding caching on the DNS client was a good move on Microsoft's part precisely because, as you may recall, Active Directory uses DNS the way NT used WINS, as the basic workhorse naming system. There are probably servers in your network that your workstation communicates with all the time; relieving the local DNS servers of having to resolve and re-resolve the names lightens the burden on those servers and reduces network chatter.

**Remembering Resolution Failures: “Negative” Caching**

Once in a while, however, you’ll want the DNS client to *forget* what it’s learned. For example, suppose you’d built the simple `bigfirm.biz` DNS system, but misspelled `bigdog` as the machine, accidentally miskeying it as `bgidog` or something like that. You then sit down at some other machine and type **ping bigdog.bigfirm.biz**, and your system tells you that there’s no machine by that name. You realize the error and go over to `BGIDOG`, rename it to `bigdog` and reboot it. You go over to your workstation and try another **ping bigdog.bigfirm.biz**, but it *still* tells you that there’s no such system. Huh? You *fixed* the silly thing—*now* what’s wrong? What’s wrong is called *negative caching*. The DNS client not only caches the *successes*, it also caches the *failures*, remembering any failed name resolution attempts for five minutes. So if you wait a few minutes more, **ping bigdog.bigfirm.biz** will work. But who wants to wait? You can alternatively tell your system to forget all of its cached entries with this command:

```
ipconfig /flushdns
```

So remember: When you’re doing network troubleshooting, flush your DNS cache regularly so you don’t get errors arising out of previously failed DNS resolutions that *shouldn’t* fail anymore but that do anyway for some mysterious reason. Negative caching is the reason, so flush that cache after re-trying any failed command! And if you decide that five minutes is too long or too short a period to remember failed name resolutions, you can change that. Just look in the Registry in `HKEY_LOCAL_MACHINE\SYSTEM\CurrentControlSet\Services\Dnscache\Parameters` to find the value entry named `NegativeCacheTime`. It’s a value in seconds.

But if you’ve never tried to resolve `www.minasi.com` before from this workstation, then clearly the IP address for my Web site won’t be in your cache. So in that case it would be time to check with the local DNS server.

**Exercise: Working with the DNS Cache**

Let’s try out the DNS cache. Make sure if you added the bogus entry in the hosts file for `www.minasi.com` that you took it out. While sitting at a Windows 2000, XP, or Server 2003 system, start Internet Explorer and view `www.minasi.com`. Close IE and open a command prompt. Type **ipconfig /displaydns** and you’ll see something like this:

```
C:\>ipconfig /displaydns
```

```
Windows IP Configuration
```

```
www.minasi.com
-----
Record Name . . . . . : www.minasi.com
Record Type . . . . . : 5
Time To Live . . . . . : 375
Data Length . . . . . : 4
Section . . . . . : Answer
CNAME Record . . . . . : cablenic.minasi.com
...[more output follows]
```

Note the Time To Live—just 375 more seconds, and I’ll have to look it up again!

Next, try flushing the cache with **ipconfig /flushdns**. Then try another **ipconfig /displaydns**; you’ll see that your cache only contains entries for the loopback, `127.0.0.1`.

### STEP 3: THE PREFERRED DNS SERVER LOOKS IN ITS CACHE

If the local DNS cache didn't have the answer, then your workstation must ask for the help of a DNS server. When configured, every computer running TCP/IP gets the IP address for a *preferred DNS server*. That's the server that the workstation should first go to when it needs a name resolved. You can include a second choice DNS server, which the TCP/IP software will query to resolve a name *only* if the preferred DNS server doesn't respond at all. (You can also offer a third, fourth, fifth, sixth, seventh, and eighth choice server.)

### DNS Queries Go to Port 53

The client—your workstation—queries the DNS server on port 53. (In the network traces that I've done, the queries seem to all run on *UDP* port 53, but there might be a TCP-based implementation.) The workstation also supplies a port number for the DNS server to respond on; as is usually the case with TCP or UDP communications, the port for server-to-client responses isn't a "well-known" port; it's basically just a random value—in effect, the client says, "Well, I've *got* to address DNS queries on port 53. What port should the DNS server use to talk back to me? How about 1066? Yeah, that sounds good, 1066—Battle of Hastings and all that. Hey, listen, DNS server, can you resolve *www.minasi.com* for me and send me back the answer on port 1066 here at my IP address, 210.10.20.11? Thanks."

### DNS Servers Also Have Cache

Like the Windows 2000-and-later DNS client, the Server 2003 DNS server caches entries for places that it's already visited. In fact, that's been true for as long as I can remember for DNS servers of *all* kinds, Microsoft and otherwise. So if someone has asked your DNS server to look up *www.minasi.com* in the past hour—the TTL that I set on my *www.minasi.com* record—then that DNS server need not query any other servers to resolve *www.minasi.com*. Instead, it just looks into its cache and finds the answer.

You can see what your DNS server has in its cache by enabling the Advanced View (in the DNS snap-in, click View and look at Advanced; if it's not checked, then click Advanced) and you'll see a folder in the snap-in labeled **Cached Lookups**. Open it and you'll see all of the places that DNS has cached. You can clear the cache, should you want to—perhaps for troubleshooting purposes—by right-clicking the **Cached Lookups** folder and choosing **Clear Cache**. Typing **ipconfig /flushdns** while sitting at the DNS server will not clear the cache; instead, it would only clear the *DNS client cache* on that particular computer.

### Definition: A Caching-Only DNS Server

Before leaving this section, it's worth briefly defining a term: *caching-only* DNS server. I've just explained that a DNS server that contained a zone for some domain would look in that zone first, rather than searching the Internet. But I haven't explicitly pointed out yet that you might well be running DNS servers *that contain no zones at all*—in fact, the majority of DNS servers are zoneless. What's the point of a zoneless DNS server? Simple: It focuses solely on searching other DNS servers to resolve name resolution questions. The fact that the server caches the answers to DNS queries that it has received previously leads to the name of this kind of DNS server—a "caching-only" server.

If it's not clear why a caching-only DNS server can be useful, consider Figure 7.81.

**FIGURE 7.81**Simple SOHO  
Internet connection

In Figure 7.81, you see a typical small office/home office (SOHO) connection between a small LAN and the Internet. The SOHO setup has a persistent 56K frame relay connection between it and the Internet. Does 56K sound unreasonably slow? It's not—first of all, if you want more than one IP address, then your ISP typically doesn't connect to you via cable modem or DSL, and, second, the vast majority of the world doesn't have the option for DSL or cable modem.

So here's the question: What DNS server should we use as the preferred DNS server for the workstations in the small office? The ISP runs a DNS server and is perfectly happy for us to point all of our workstations to that DNS server as their preferred DNS server. The ISP then worries about keeping the thing up and running, and we needn't buy a DNS server.

Alternatively, however, we could set up a DNS server locally. It wouldn't have to be a dedicated machine, and as you've seen we could just add the DNS server function to an existing Server 2003 (or Linux or Novell or you-name-it) server. That server would know how to search the other DNS servers on the Internet, and we'd configure all of the workstations to use that local DNS server as their preferred DNS server. Which is the better answer?

I think most network architects would go with the latter approach—set up a local DNS server. To see why, ask this: What's the bottleneck in this network? It's a common one for many networks, namely, the connection to the Internet. The fact that a DNS server caches the responses to name queries keeps us from burning up that WAN link. For example, suppose four people in the company decide to visit Microsoft's Web site. In the case where we use the ISP's DNS server, that's four DNS queries that go over the WAN link. But with a local DNS server, then the local DNS server queries other DNS servers on the Internet once to find the IP address of Microsoft's Web site. The local DNS server can resolve the subsequent three queries from its own cache, meaning that those three queries stay on the fast local network. So it can make good sense to set up a local DNS server on your site, even if it *doesn't* hold any zones.

Let's return to following our system in resolving `www.minasi.com`...

#### STEP 4: THE PREFERRED DNS SERVER LOOKS IN ITS ZONES

But what if the DNS server *hasn't* been asked to resolve `www.minasi.com` recently? Is it time to go out to other DNS servers on the Internet? Maybe, but maybe not. It depends on whether this DNS server contains any zones...and if it does, then there's the possibility of *split-brain DNS*—possibly one of the two or three most important concepts in this chapter. (So if you were nodding off or starting

to skim, then KNOCK IT OFF—some important stuff's coming! Or at least *I* think so, anyway, so I ask that you humor me.

### **Local Zones Take Priority**

If you were sitting on a workstation computer in my local network, then it's likely that the preferred DNS server for that computer would be the same DNS server that acts as the primary DNS server for minasi.com. In that case, the workstation's primary DNS server would be the perfect machine to ask the question, "What's the IP address for www.minasi.com?"

When queried, DNS servers look in their local zones—whether primary or secondary—before querying other servers on the Internet (or, if your DNS hierarchy isn't connected to the public DNS system, other servers in your private DNS hierarchy).

### **IMPORTANT DIGRESSION: INTRODUCING SPLIT-BRAIN DNS**

You're going to learn a bit later in this chapter that sometimes you quite deliberately want to present one set of DNS names to your private internal intranet and quite a different set of names to the external Internet—I think of it as "keeping two sets of books" DNS-wise. Some people call it "split-brain DNS." I don't want to hit you with all of those details right now, but I *do* want to get you ready by highlighting the basic reason split-brain is possible: when a DNS server attempts to resolve an address, it first looks in its local zone files. If it finds a zone file whose name matches the zone that it's looking for, then the server will look no further than that zone file, even if there's a zone by the same name out on the public Internet. In short, local zone files take precedence over anything on the Internet.

At first glance, it makes perfect sense to say that if your local DNS server also happens to be the authoritative DNS server for minasi.com, then when you ask that server to resolve www.minasi.com, the DNS server gets the answer from its local zones rather than querying other servers on the Internet. After all, if your local DNS server is the only authoritative DNS server for minasi.com, there wouldn't be much point to looking elsewhere on some other DNS server to resolve a minasi.com name...there aren't any others.

### **Virtually All Active Directories Need Split-Brain**

But what happens if your local DNS server has a minasi.com zone, but isn't the *authoritative* DNS server for minasi.com? Is your DNS server smart enough to say, "Hmmm, I'm not the authoritative server for minasi.com...this zone must be bogus, I'll ignore it?" Nope. But that's good, as it lets us fool a DNS server into thinking that it's authoritative for any zone that we like. *That* is absolutely essential and, as I said a few paragraphs back, is the way that split-brain DNS is going to work. But this isn't some obscure trick; no, it's a major tool in a DNS admin's tool belt. I'm not exaggerating when I say that *over 90 percent of the Active Directories out there use or will use split-brain DNS*; if anything, that's an underestimate. So this is a must-understand skill.

People use split-brain DNS for Active Directory security. To see why, let's review what you've seen so far about DNS and Active Directory.

- ◆ Machines in a domain must find domain controllers, so there has to be a list of DCs installed on every machine (which is impractical) or a group of servers standing by to answer the question, "Which machines are DCs for this domain?"

- ◆ Microsoft designed Active Directory to use DNS as its DC locator service, matching DNS zone names to AD domain names. Thus, an AD named bigfirm.biz needs a corresponding DNS zone named bigfirm.biz.
- ◆ More specifically, machines in a domain look for Kerberos (authentication) and LDAP (query) services by asking DNS for SRV records.

That's another way of saying that anyone who can look in the DNS zone that corresponds to your Active Directory domain can see the names and addresses of your domain controllers—which is something of a security breach. I mean, it's not a *terrible* breach of security, as it's not like you store the passwords in your DNS zone or anything like that. But DCs are pretty powerful servers, and there's no sense in announcing their location to all and making life easier for the weasels. But there's one more thing to consider about AD/DNS security:

- ◆ For all this to work, someone or something has to insert a bunch of SRV records into that DNS zone. Microsoft decided to use dynamic DNS to allow DCs to insert—"register"—their own SRV records.

In this context, dynamic presents *another* potential security risk in addition to the ones that I enumerated a few pages back. Suppose someone figures out how to build a piece of software that mimics a domain controller. Once installed in a network, this bogus DC fools machines into trying to log onto it by giving the faux DC the account names and passwords of the machine and its user. (Such a piece of software does not exist, as far as I know, nor would it be very easy to write, so don't lose too much sleep over it.) In order for this imaginary DC to do damage, machines on the domain would have to somehow find the bogus DC, and how do machines find DCs in Active Directory? Through DNS records. So one way to secure an AD domain would be to set up its DNS servers so that the outside world cannot see them, and thus would have no chance to register false SRV records for malicious would-be DCs.

For many organizations, then, the right way to set up DNS for Active Directory is to have a non-dynamic DNS zone that the outside world sees that contains only the names of the Web and mail servers for that firm, and a separate, internal dynamic DNS zone that serves your AD clients.

Let's try it out with our working bigfirm.biz DNS server. If you don't have one working, don't worry, you can read along.

### **An Example Exercise: Faking dell.com**

Suppose you wanted to visit Dell and buy a computer from them over the Web. You'd start out by pointing your browser to [www.dell.com](http://www.dell.com), and your preferred DNS server would search the Internet's other DNS servers to get the IP address of Dell's Web site. So far, so good—nothing that I said in the preceding sentence should run counter to your real-life experience.

Try this experiment.

1. While sitting at Bigdog, start `nslookup`. Type **www.dell.com** and press Enter. `nslookup` will respond with an IP address, or probably several IP addresses. Type **exit** to exit `nslookup`.
2. Next, open up the DNS snap-in at Bigdog and create a new forward lookup zone named `dell.com`. Add an A record for `www` and give it the IP address `68.15.149.117`.
3. Now return to the command prompt. Type **ipconfig /flushdns** and press Enter. Then start up `nslookup`. Again, try to resolve `www.dell.com` and you'll get just one IP address—`68.15.149.117`.

4. Start up Internet Explorer and surf to `www.de11.com`. You won't end up at Dell, you'll end up at my Web site.
5. Now that you've seen that it works, do yourself a favor; open up the DNS snap-in and delete the `de11.com` folder now, while you still remember to do it. It could be awfully frustrating to try to visit Dell for tech support sometime in the next day or two, only to find yourself trapped in my site!

Let's review what you did. By putting a new primary zone called `dell.com` on one of your local DNS servers, you caused anyone who uses that particular DNS server as their preferred DNS server to be unable to get to the real Dell. You didn't crash Dell's worldwide empire—*everyone else on the Internet can still find Dell without a problem*. Sure, you've got a bogus `dell.com` zone, but it doesn't affect anyone else, because there would be no reason for anyone to visit your DNS server to resolve `www.dell.com`. The only people who *would* use that DNS server to resolve `www.dell.com` would be those people who happen to use that DNS server as their preferred DNS server.

#### **Another Example: Internal versus External `bigfirm.biz` Zones**

As you sat at the Bigdog server to do the Dell example, something might have occurred to some of you. Bigdog is the primary DNS server for `bigfirm.biz`, as you know. But did you ever try sitting at another computer, opening up Internet Explorer and surfing to `www.bigfirm.biz`, just to see what would happen? If you did, then you know that “`www.bigfirm.biz`” takes you to `www.minasi.com`, my Web site. But it wasn't marketing that led me to do that. You see, in earlier books I used examples like `acme.com` and `browsers.com` for my DNS zones. As I said earlier, it dawned on me one day that people misconfiguring my examples could cause hundreds or thousands of systems to try to register with the `acme.com` or `browsers.com` DNS servers. Not nice. So I registered `bigfirm.biz` so that any resulting problems would be mine.

But here's the important point: there is currently an Internet domain that is properly registered with the naming authorities called `bigfirm.biz`. But our examples have, by working with a local zone named `bigfirm.biz`, completely bypassed that properly registered DNS domain.

In other words, *we've been doing split-brain DNS from the very beginning!*

Here's another use for split-brain. You could run a dynamic DNS service in a company that perhaps doesn't want to put a DDNS server on the public Internet. For example, imagine that Bigfirm already *has* an externally hosted zone called `bigfirm.biz`, and you want to create an Active Directory internally called `bigfirm.biz`. The external `bigfirm.biz` zone is probably run by some ISP on a static DNS server—they're not about to make their zone dynamic just to make you happy. Sure, you *could* take charge of—that is, become authoritative for—your zone, but it's not necessary.

Suppose you set up a DNS server—a dynamic one—of your own, with a `bigfirm.biz` zone on your intranet. As long as all of your workstations used that DNS server as their preferred DNS server, then any time that a workstation or server asks that DNS server to resolve a `bigfirm.biz` name, the DNS server will notice that it *holds* a zone file for `bigfirm.biz`. It will then say to itself, “Heck, I don't have to go out on the Internet to resolve this name—I'm ‘the guy’ for this zone! I have the answers!” Systems could then register names for `bigfirm.biz` with this DNS server and your AD would work like a charm. *That's* the basics of how I recommend that you set up your DNS server. But we'll cover this in more detail later in this chapter; for now, let's get back to seeing how resolution occurs.

**STEP 5: THE PREFERRED DNS SERVER FINDS AND QUERIES MY DNS SERVER**

Well, presuming that the local DNS server can't resolve the query from its local cache or zone files, what next? As you read earlier in this chapter, your local DNS server will next try to locate a DNS server that is authoritative for minasi.com and then go query *that* server. But how to find that authoritative server? Recall from the discussion earlier in this chapter that

- ◆ your local DNS server wants to find the zone for the com domain because that will contain the record pointing to the DNS server for minasi.com,
- ◆ but before your DNS server can query the com server, it needs to know the DNS server for com,
- ◆ and the way it gets *that* is by querying the root servers,
- ◆ and the way it knows how to find the root servers is that your DNS server comes prepackaged knowing the names and addresses of the 13 root servers.

Once your DNS server obtains the IP address of the minasi.com domain's DNS servers, then your DNS server will go ask one of the minasi.com DNS servers to resolve www.minasi.com, and report the value back to your computer.

At least, that's what I told you a few sections back—that's basically right, but I left out some details. Now I'll fill them in.

**Talking to the Root**

Let's back up a minute and consider what the client asked of the server. The DNS client software running on your workstation said to your local DNS server, "Please resolve the name www.minasi.com." But it said more than that: More completely, it said, "Please search for the answer, even if you have to talk to a bunch of DNS servers." And your local DNS server will do that, doggedly following the trail of other DNS servers until it gets the answer or discovers that no answer is possible.

In contrast, let's consider what happens when your local DNS server queries a root server. I've been saying up to now that your local DNS server asks the root for the address of the com DNS server so that it can ask the com server the address of the minasi.com DNS server, but that's not exactly true. Actually, your DNS server asks the root server, "What's the IP address of www.minasi.com?"

Now, the root server *could* choose to go root around (no pun intended) and get that answer for my DNS server. But it doesn't want to do any more work than is necessary—hey, it's pretty busy, just 13 root servers for the entire DNS hierarchy of Planet Earth means 13 pretty overworked computers—so instead of answering the question, the root server says, in effect, "I could find that answer for you, but I'm not going to. But here's what I'll do instead—I'll give you the name and address of the *next* DNS server that you should ask the question of." Your DNS server then re-asks the question, "What's the IP address for www.minasi.com?" of the DNS server that the root server referred it to. That subsequent server might be designed to go get the complete answer for your DNS server, or it might just be set up to work like the root servers, saying, "I won't give you the answer, but here's the next guy to try." For example, here's what the conversation might look like when your DNS server tries to find www.minasi.com:

1. Your DNS server asks a root server, "What's the IP address of www.minasi.com?"
2. The root server probably answers, "Don't ask me, ask one of these servers," and lists the names and addresses of the DNS servers for the com domain.

3. Your DNS server picks one of those names and says to the DNS server for the com domain, “What’s the IP address of www.minasi.com?”
4. The com DNS server answers, “Don’t ask me, ask either the DNS server at 206.246.253.111 or the one at 206.246.253.112.” (Those are the IP addresses of my two DNS servers and, yes, one of them is the same computer as the Web server.)
5. Your DNS server asks my DNS server, “What’s the IP address for www.minasi.com?”
6. My DNS server responds, “www.minasi.com is at 206.246.253.111.”

**Definition: Recursive versus Iterative Queries**

So you’ve seen that your DNS server will go to great lengths to answer a query. Mine works that way, too, and so will most DNS servers with which you’ll ever work. But those root servers and the DNS servers for the com domain and other top-level domains don’t do that. That’s because DNS recognizes two kinds of queries: recursive and iterative.

A *recursive* query is the kind that you make against your local DNS server. You tell it to keep asking the questions until it gets an answer.

An *iterative* query is what the root servers do. When asked to resolve a name, they’ll only resolve the name if they have the information right there in their zone files. If not, they just pass along the name of the next DNS server—or servers, usually—in the chain.

Down at the programming level, it’s possible for a DNS server to specify when querying whether it wants a recursive or iterative answer. But that won’t matter if the server has been configured to only answer recursively.

**Controlling Recursive and Iterative Behavior**

By default, the Server 2003 DNS server answers queries recursively, searching as long as is necessary. But you can modify that behavior. In the DNS snap-in, right-click the icon representing the DNS server, click Properties and then the Advanced tab, and you’ll see a page like you did back in Figure 7.55, Advanced DNS Properties.

By checking the box labeled Disable Recursion, you cause the DNS server to respond in an iterative (“I don’t have that answer, but if you ask *this* guy he could probably help you”) rather than a recursive (“I looked all over and here’s your answer”) manner.

Summarizing, then, these are the major steps that happen when your Windows 2000, XP, or Server 2003 system—let’s generically call it the *client*—needs a DNS name resolved:

1. First, the system looks as well as steps 4–7 in the local file named *hosts*.
2. If that doesn’t help, it looks in the DNS client’s local cache.
3. If the local cache can’t help, it then contacts the client’s preferred DNS server, asking it to resolve the name.
4. The preferred DNS server looks in its cache and then its zones to answer the query.
5. If it can’t answer, then the preferred DNS server looks for the DNS server that *can* answer the query, the DNS server (or, usually, servers) that is authoritative for the domain in question. It does that by asking the root servers, which direct it to the next level of DNS servers, finally getting the IP addresses of the authoritative DNS servers.

6. The preferred DNS server then directly queries the authoritative DNS server, getting the IP address of the target system.
7. Finally, the preferred DNS server returns the answer to the client.

## DNS Forwarding

We've got one more basic DNS concept to cover, and it's an important one: forwarding. DNS forwarding includes three topics:

- ◆ Centralized caching of DNS records
- ◆ Securing internal DNS servers from exposure to outside attack
- ◆ Knitting together a system of DNS servers doing split-brain DNS

### Centralizing DNS Caches with Forwarding

As time goes on, the percentage of computers in your network that can be full-fledged Active Directory clients and servers and the share of applications in your network that are Active Directory-compliant will grow. That's important because once your network consists entirely of AD-compliant pieces, then DNS becomes the main name resolver, and WINS fades away. When that happens, you'll want fast-responding DNS servers.

Now, thankfully, Microsoft put a DNS cache on every workstation, so you might hope that most of those name resolutions will be resolved by the workstation itself, out of its DNS cache. Despite that, though, there will be an awful lot of name resolutions in your network that can't be handled by the 2000, XP, or 2003 DNS client's cache, and so network designers will constantly face this inescapable truth: Networks that resolve names slowly will be perceived as slow networks.

Fast name resolution isn't the only thing that you'll need for a fast network, but you can't have a fast network without it. So how do you plan to provide fast name resolution?

On the face of it, the answer would seem to be DNS servers, and lots of them. If you have lots of DNS servers sprinkled around your network and a low DNS client-to-server ratio, then client machines will see fast response, won't they? Well, yes, except for one consideration: caching on the DNS servers.

#### THE "MANY DNS SERVERS" SCENARIO

Imagine that we're designing the DNS architecture for Megabucks Corporation, a firm with 2000 employees on a single large campus. Megabucks is attached to the Internet via a few T1 lines that are always busy transmitting and receiving e-mail, Web traffic, and streaming multimedia. Every unnecessary access to the Internet creates congestion on those lines.

We figure that one DNS server for every 100 employees seems like a good ratio (I just made that up, please don't take it as an actual rule of thumb—I don't think it'd be possible to come up with a rule of thumb for DNS servers that would be simple and useful, sadly), so we set up 20 DNS servers that we'll call ns01.megabucks.com through ns20.megabucks.com. Let's watch them work.

First thing in the morning, people show up and start working. One employee, Mary, sits at a workstation whose preferred DNS server is NS01. She points her browser to [www.cnn.com](http://www.cnn.com) to get the headlines, and so her workstation asks NS01 to resolve [www.cnn.com](http://www.cnn.com). NS01 hasn't been asked for [www.cnn.com](http://www.cnn.com) yet today, so it's got to go out on the Internet to get the answer. When other people whose workstations subsequently go to [www.cnn.com](http://www.cnn.com), NS01 has the name already resolved and so can respond to their name resolution requests instantly.

But now Bill sits at his workstation, starting off his day with the headlines at [www.cnn.com](http://www.cnn.com). *His* workstation, however, uses ns02.megabucks.com as its DNS server. NS02 hasn't been asked for [www.cnn.com](http://www.cnn.com)'s IP address yet, so it has to go out to the Internet to answer that query. Similarly, NS03, NS04, and so on—each of the 20 DNS servers—each have to separately learn the IP address of [www.cnn.com](http://www.cnn.com). (That's presuming that they have to learn it at all—for example, NS17 might only serve a bunch of people who might only use their computers to do work rather than the high-tech equivalent of reading the paper in the office.) In other words, if our servers could somehow get together on what they know in their caches, then we could reduce by up to 20-fold the amount of WAN bandwidth that the DNS servers suck up.

### THE “ONE BIG DNS SERVER” SCENARIO

Or we could take a different tack. Instead of installing DNS on a bunch of machines, some of which might also be serving in other roles, we go spend some of the company's money for a monster eight-CPU system with several gigabytes of RAM. Then we point *every* workstation in the plant to this system. The benefit? One server means one cache. After Mary causes the server to resolve [www.cnn.com](http://www.cnn.com), then Bill's subsequent resolution request can be answered instantaneously.

If *this* scenario makes you a bit queasy, then it should. Although one big cache would be nice, putting all of my eggs in one basket has always made me wish for a titanium basket. Is there a way to both unify the cache and get the benefits of scattering DNS servers all over the place?

### DNS FORWARDERS: THE BEST OF BOTH WORLDS

We *can* centralize the cache and yet keep our 20 DNS servers. The trick is called *forwarding*. Figure 7.82 shows how it works.

**FIGURE 7.82**

A DNS forwarder

You've read how a DNS server normally resolves a name—it looks in its cache and its zones, and then starts looking out on the Internet for the authoritative DNS server. With forwarding, you add an intermediate step. At Megabucks, you'd set up a 21st machine as a DNS server and then tell the 20 other DNS servers to use that 21st machine as a *forwarder*. Then they'd resolve a name in this way:

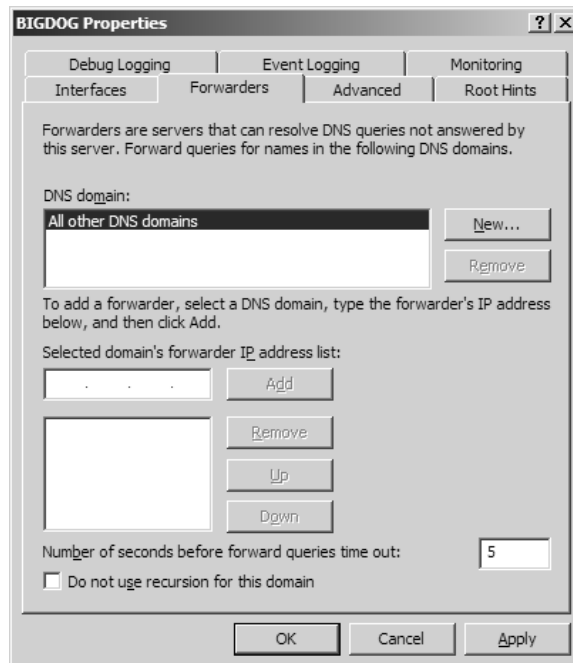

1. As before, look in the local cache and zones.
2. If the local cache and zones don't have the answer, then don't go out on the Internet. Instead, query the forwarder.

3. If the forwarder has the answer in its local cache or zones, then it can answer the question. If not, then the forwarder searches the DNS servers on the Internet, as you've already learned.
4. Once the forwarder has the answer, it sends that back to the querying DNS server.
5. *But* if the forwarder doesn't respond in a reasonable amount of time, then the querying DNS server just gives up on the forwarder and searches the DNS servers on the Internet itself.

Now, at first blush, it might look like we've just made things slower by adding a new step in the resolution process—querying and then waiting for the forwarder. But consider how the forwarder communicates with the local DNS servers—through the company LAN. That LAN's likely to be 100 megabits per second or faster—almost certainly in any case faster than the WAN link to the Internet. The value of the forwarder at Megabucks is this: Mary and Bill still have separate DNS servers, but their DNS servers don't ever have to communicate on the Internet. Because Mary first looked up `www.cnn.com`, that caused her DNS server (NS01) to try to resolve the name. It asked the forwarder, who also didn't know the IP address for `www.cnn.com`. So the forwarder went out over the WAN link to the Internet to find out `www.cnn.com`'s IP address, and told Mary's DNS server. Minutes later, when Bill's DNS server (NS02) needed to resolve `www.cnn.com`, it asked the forwarder to go look it up—and the forwarder responded instantly over the company's LAN because the forwarder already had the answer in its cache. The result? Now `www.cnn.com` is in the caches of NS01, NS02, and the forwarder—but it only went out on the Internet once.

Telling a Server 2003 DNS server to use a forwarder is simple. Just open the DNS snap-in and right-click the icon representing the DNS server, choose Properties, then click the Forwarders tab on the properties page. You'll see a screen like Figure 7.83.

**FIGURE 7.83**  
Configuring a  
DNS forwarder

If you're a Windows 2000 DNS veteran, then you'll immediately notice that 2003's DNS does forwarding a lot differently than 2000's DNS did—and the UI's not immediately obvious. To tell a 2003 DNS server to forward any queries that it can't resolve out of its own zones to another DNS server, click All Other DNS Domains under DNS Domain. Then look below that to the field labeled Selected Domain's Forwarder IP Address List, where you can punch in an IP address—the DNS server will now forward to the DNS server at that IP address.

Note the field in the lower right part of the Forwarders tab labeled Number of Seconds before Forward Queries Time Out and its default value, five seconds. This is the “reasonable amount of time” that I referred to when describing how a forwarder works a page or two back.

Does the forwarder need to be a particularly powerful machine? Not really; answering a query out of the cache isn't that stressful for a system. But you'd do well to give the forwarder a *lot* of RAM. The more RAM, the more items it can cache without having to page them out to disk.

### DO FORWARDERS PRESENT A SINGLE POINT OF FAILURE?

A bit earlier I suggested that the “one big DNS server” scenario might make you a bit nervous, as it was a case of putting all of your eggs in one basket. But isn't having a bunch of intranet DNS servers relying on a single forwarder just the same thing—isn't that one forwarder a new single point of failure? Not necessarily.

First, remember that when you specify a forwarder for a DNS server you also specify a timeout value. If the forwarder doesn't respond within that time, the DNS server simply bypasses the forwarder and resolves the name on the public DNS hierarchy all by itself.

Second, take another look at Figure 7.83 and you'll see that you can specify more than one forwarder. Having more than one forwarder has a down-side in that you no longer have one system that all queries funnel through, and so you don't have the one big master cache; instead, you'd have a group of forwarders, and each forwarder would have a pretty wide variety of things in its cache, but not as large a cache as if there were just one forwarder.

Adding more than one forwarder does mean that you'll end up having to repeat some DNS queries over the public Internet, and so name resolution will be a trifle slower than it would be with one forwarder. But on balance, I'd be willing to accept that in return for the benefit of fault tolerance on forwarding—if one forwarder fails, we're not without any forwarders. That will become even more important as we *slave* our internal DNS servers to external forwarders to secure those internal DNS servers, as we'll do in a few pages.

### EXERCISE: SETTING UP A FORWARDER

We'll try out forwarding with this exercise. If you've been following along with the exercises in this chapter, then you'll have two systems set up as DNS servers:

- ◆ bigdog.bigfirm.biz, a Server 2003 DNS server with IP address 192.168.0.2 as well as the ability to route to the public Internet and a local bigfirm.biz zone.
- ◆ ns2.bigfirm.biz, a Server 2003 DNS server with IP address 192.168.0.3 and, again, the ability to route to the public Internet. No zones necessary on this server for this exercise.

In this exercise, we'll try telling Bigdog to forward all of its DNS queries out over ns2 and also see what happens when we adjust the timeout values. Ensure that Bigdog's IP address is 192.168.0.2 and ns2's IP address is 192.168.0.3. (If they're *not* those values, then the exercise will work fine—just

substitute your system's IP addresses as appropriate.) And ensure that both systems can ping the public Internet. Tell Bigdog to forward through ns2 like so:

1. At Bigdog, open the DNS snap-in.
2. Right-click the icon representing the server—forwarding is a characteristic of a server, not a zone. Choose Properties.
3. In the Bigdog DNS properties, click the Forwarders tab.
4. Under Selected Domain's Forwarder IP Address List, enter **192.168.0.3** and click Add.
5. In the field labeled Number of Seconds before Forward Queries Time Out, fill in 60.
6. Click Apply.

Don't close the DNS snap-in; we'll be adjusting it again. Now open a command prompt at Bigdog. Clear the DNS cache with an `ipconfig /flushdns` command, then start `nslookup`. As Bigdog will end up asking its questions to ns2, which will in turn have to go search the Internet, then make sure `nslookup` is a bit more patient: type **set timeout=30** and press Enter to tell it to wait at least a half minute before emitting its irritating "DNS request timed out" error. Then try resolving an address on the public Internet, like `www.nasa.gov`. You should get the normal response, as a forwarded query looks no different from a direct one. Exit `nslookup` with the `exit` command.

How do you know that the forwarding actually worked, other than taking my word for it? Let's use a little split-brain to prove the point.

1. At Bigdog, clear the DNS client cache with `ipconfig /flushdns`. As Bigdog also runs a DNS server, clear the DNS server's cache by opening the DNS snap-in. Right-click the server icon for Bigdog and choose Clear Cache.
2. Over at ns2, create a forward primary zone, `nasa.gov`. It doesn't matter how you set its dynamic DNS properties. In the zone, add a new host record, `www`, and give it the IP address `10.10.10.10`.
3. Clear the cache on Ns2.
4. Back at Bigdog, open a command prompt, start `nslookup`, and set the timeout to 30 seconds again. Then try the `www.nasa.gov` query. You should get the answer "10.10.10.10" rather than the actual value.

Clearly the NASA Web server isn't at IP address `10.10.10.10`, so we've demonstrated that Bigdog does indeed get its DNS info from ns2.

Let's do one more thing just to be sure that forwarding works as I've described it. We've made Bigdog dependent on ns2 for DNS queries; what happens if ns2 fails? We'll stop the DNS service on Ns2 and try that NASA query again.

1. Go to ns2 and open the DNS snap-in. Stop ns2's DNS service by right-clicking its server icon, then choose All Tasks/Stop.
2. Go to Bigdog and open its DNS snap-in. Clear Bigdog's server cache—right-click the server icon and choose Clear Cache.
3. We don't want to have to wait a long time for Bigdog to figure out that ns2 isn't going to answer it, so let's drop the timeout value. Right-click the Bigdog server icon, choose Properties and the Forwarders tab. Change 60 back to the default of 5 and click Apply.

4. Open a command prompt and clear the DNS client cache with `ipconfig /flushdns`. Then start `nslookup` and this time, set the timeout to 30 seconds as you did before.
5. Tell `nslookup` to look up `www.nasa.gov`. You'll get the actual IP address of NASA's Web server this time.

In this case, Bigdog is still forwarding through `ns2`, but `ns2` didn't respond, so after a timeout, we saw that Bigdog will bypass its forwarder.

## Uprooting a DNS Server: When Forwarders Are Grayed Out

Before moving on to security and caching, it's time for a short digression. If you've just set up your DNS server and are following along with the book, then you might have seen something disconcerting—the controls on the Forwarders tab are grayed out. Click the Root Hints tab, and you see the same thing. What happened? You've got a false root. (Let me note that I've only seen this on Windows 2000–based DNS servers, where it showed up often; I've only *heard* of them on 2003 DNS servers, but I'm including this for the sake of completeness.)

What's happening here is that your DNS server thinks that it is *the* only DNS server in the world, that it is the root of the public DNS hierarchy. How'd it happen? In most cases, the Configure a DNS Server Wizard mistakenly decided that your DNS server was on an intranet completely disconnected from the public Internet. In that case, the 13 root servers aren't available. But a DNS hierarchy needs a root...so your server's elected to be a “private” root. Root servers can't use forwarders (although they can use conditional forwarding), and—here's the really annoying part—they can't search DNS servers on the public Internet, because they don't even know that public Internet *exists*.

Installing a private root on a DNS server tells it that there *isn't* any other DNS server around to which to refer questions. So if your DNS server doesn't have a zone that it can look something up in, then it just assumes that no one knows the answer.

Anyway, that's what went wrong. How to undo it? Here are three ways to reintroduce your DNS server to the rest of the world. All three share the same basic approach: they delete the root domain from your DNS server. I'm explaining all three approaches so that I can also offer some insight into how to do a bit of under-the-hood work on DNS.

First, there's the command-line approach. This needs a command called `DNSCMD.EXE`, which doesn't automatically install with Server 2003 but *is* included in the Server Tools add-on, which you can find on the Server 2003 CD in the `\SUPPORT\TOOLS` folder. Once `DNSCMD` is installed, you can de-root your DNS server with one command:

```
dnscmd /ZoneDelete .
```

Note the spacing—first `dnscmd`, then a space, then the option `/ZoneDelete`, then another space, then “.”, the name of the zone to delete. I notice in `dnscmd`'s Help that there's an option `/dsdel` that you must run to delete the zone if it's Active Directory–integrated, but I'm not quite sure how you'd end up with an AD-integrated root domain, at least not without a lot of work! Uppercase and lowercase seem not to matter. Once you execute the command, I recommend restarting the DNS service. Then open up the DNS snap-in and try to examine the Forwarders or Root Hints tabs on the server's properties page—you'll see that they're no longer grayed out.

You can also de-root a DNS server from the DNS snap-in. Open up the **Forward Lookup Zones** folder and you'll see a folder whose name is simply “.”; as you now know, that's the root domain. Right-click that folder and choose **Properties**. In the properties page, check that the zone type is

Primary rather than Active Directory—integrated; if it *is* AD-integrated, just click the Change button next to the type and convert it to a standard primary zone. Close the properties page.

In the **Forward Lookup Zones** folder, right-click the root zone and click Delete. Close the DNS snap-in, restart the DNS Server service, and re-open the DNS snap-in. You'll see that Forwarders and Root Hints tabs are no longer grayed out.

Finally, for those who enjoy a bit of Registry tweaking, here's a third uprooting procedure. As far as I know, this only works on a standard primary zone. First, stop the DNS Server service, either from the GUI or from the command line with this:

```
net stop "DNS Server"
```

Then edit the Registry to altogether remove the key at `HKEY_LOCAL_MACHINE\SYSTEM\CurrentControlSet\Services\DNS\Zones\.` and, again, notice that final period—that was part of the key, not the end of the sentence. Restart the DNS service, and you're back in the public DNS hierarchy.

Of course, now and then you might actually *want* a DNS server with a private root; I'll tell you how to set one up a bit later in this chapter.

## Securing Internal DNS Servers with Forwarding/Slaving

While forwarders are useful as a way to centralize cache, as I've just described, I think most people do forwarding less to speed up name resolutions than to secure DNS servers that are inside their firewalls. They do that by adjusting their internal DNS servers so that they don't *forward* to another DNS server, they *slave* to it. Slaving is a slight modification of the forwarding algorithm that forces the internal DNS server to depend *entirely* on the forwarder.

So how's it useful?

Well, imagine this scenario. You have a bunch of DNS servers inside your network. You're concerned about them being attacked if they make their presence known to the outside world but you don't want to have go through the time and expense of "hardening" them all against attack. So you create *one* hardened DNS server and put it outside the firewall. Then you set up the internal DNS servers to forward through the one external DNS server.

This makes your internal systems safer because of a characteristic of most firewalls—the "stateful inspection" characteristic that we discussed in the previous chapter. Systems outside the firewall cannot communicate with the DNS servers inside the firewall, *unless* the systems outside the firewall are answering queries made by the internal DNS servers. That's the value of the one hardened server outside the firewall: the internal systems ask it to do their queries, and it passes back the answers. The external system *is* outside the firewall but can still communicate with the systems inside the firewall because the external system is answering their questions. As the external system is the only one that queries other DNS servers on the Internet, the internal guys are safe, right?

Almost, but not quite. Remember how a DNS server uses a forwarder? It passes queries along to the forwarder and waits for the forwarder to search the Internet's DNS servers to resolve those queries. But remember that it only waits *so* long; if the forwarder doesn't respond in a particular period of time (a configurable period, but it's five seconds by default on Server 2003 DNS servers), then the internal DNS server just takes the bull by the horns and searches the Internet itself.

*That's* the troublesome part. If a server from behind a firewall initiates a conversation with a DNS server on the public Internet, then that server is essentially asking a question and waiting for an

answer. To allow the server on the public Internet to answer the query of the system behind the firewall, address translating routers must temporarily leave a link in place, an open port on the firewall leading back to the internal DNS server. Why exactly is that bad? Over the years the bad guys have sometimes found weaknesses in DNS server software, and they then write virus software to exploit it. That virus software masquerades as a DNS server, and when a server running buggy DNS server software asks the fake DNS server a question, the fake DNS server infects the unsuspecting DNS server. That's why you've got that one hardened system outside the firewall; you're careful to put all of the latest patches and antivirus software on it, so the bad guys' attacks just bounce off it.

So here's the problem: you have that external hardened system that you want to do all of your queries. You tell all of your internal DNS servers to forward through that external server. *But* if the external DNS server doesn't respond quickly enough, then the internal servers start querying DNS servers on the public Internet on their own. What to do?

The fix is simple. Just modify your internal DNS servers' behavior when they send queries to the forwarder. Tell your internal DNS servers, "If the external forwarder doesn't respond to your query, too bad—just consider the attempt failed." This is called *slaving* the internal DNS server to the forwarder. To see how to do that, look at the tab on a DNS server's properties page that controls forwarding (look back to Figure 7.83). Just check the box labeled Do Not Use Recursion for This Domain, and you've slaved the server. Slaving a DNS server to another DNS server is, then, nothing more than a restricted form of forwarding a DNS server to another DNS server.

If you *do* slave internal DNS servers to external forwarders, then make sure that it's external forwarders, plural. If all of your internal DNS servers were slaved to one external DNS server and that external DNS server went down, then you wouldn't be able to resolve any names on the public Internet.

#### EXERCISE: SLAVING BIGDOG TO NS2

This is a quick exercise. We've already got Bigdog forwarding through ns2, and in the last exercise we stopped the DNS server service on ns2. You saw that if we ask Bigdog to resolve `www.nasa.gov`, Bigdog would wait a while for ns2 to respond and finally, when it didn't, Bigdog could just resolve the name itself by querying DNS servers on the public Internet.

Now let's configure Bigdog to be slaved to Ns2.

1. On Bigdog, open the DNS snap-in.
2. Right-click the Bigdog server icon, choose Properties and the Forwarders tab.
3. In the Forwarders tab, check the box that says Do Not Use Recursion for This Domain.
4. Click OK to close the properties page.
5. Right-click the server icon and choose Clear Cache.
6. Close the DNS snap-in.
7. Now clear the client DNS cache and try to resolve `www.nasa.gov`. Open a command prompt, type `ipconfig /flushdns`, and then `nslookup`.
8. Once the `nslookup` ">" prompt appears, type `www.nasa.gov` and press Enter.

You should get a message from `nslookup` saying that the request timed out, demonstrating that Bigdog is slaved to ns2.

## Conditional Forwarding: Another Split-Brain Tool

We've already talked a bit about split-brain DNS, a method for fooling clients of a particular DNS server into thinking that the server is authoritative for a given zone. Remember how that worked: first, you put a zone on a DNS server for a given DNS domain—one that DNS server is *not* authoritative for. Any machines who look to that DNS server for name resolution then get false information whenever they query that domain.

So let's suppose that for some odd reason I decided that I wanted all of the 50 systems in my intranet to have the DNS suffix `microsoft.com`. I might accomplish that by pointing all of my 50 systems to a DNS server that I've set up at `100.1.1.5`, and putting a `microsoft.com` zone on that DNS server. I'd also set up my local DHCP server to give systems the DNS suffix `microsoft.com` by default, and if I enabled dynamic updates on that DNS server at `10.1.1.5` and set up all 50 systems so that they used `10.1.1.5` as their preferred DNS server, then I'd have accomplished the dubiously useful goal of having my own little micro-Redmond on my site. (Remember, there would be a cost here—any attempt to access a Web server in Microsoft's site would fail, as my one DNS server would think that it was authoritative for the `microsoft.com` domain and therefore would never look to see if there was an actual site by that name.)

So far, this looks like the split-brain DNS examples that I've offered in the past. But now consider this. A friend down the road runs a small company of his own, with about 60 systems and, again, one DNS server. He decides to go with Active Directory and for some reason thinks it would be just a hoot to call his Active Directory `novell.com`, so he needs a dynamic DNS zone by that name. As the domain name is already taken, he too adopts a split-brain approach, putting a dynamic `novell.com` zone on his one DNS server. His users can, like mine, use DNS to find their internal domain controllers in their Active Directory named `novell.com`, and they can surf the public Internet, except if they want to see something on the actual Novell Web site, send someone at Novell a piece of e-mail, or whatever. (Again, I have no idea why you'd do that, I'm just providing a simple example here.)

Time goes on and my friend and I decided to embark on some joint ventures. We're not going to merge the companies or anything like that, but we *do* need to access some of each other's resources. I might give his folks some limited access to our intranet Web server's content, share an e-mail server or something like that. That's where the problem arises.

His Web server is named `www.novell.com`. Whenever my folks punch that into IE's address field, then they go to the real Novell Web site. His split-brain system fools the machines who depend on his DNS server, but only them. Hmmmm...so what if I just point all of my systems to his DNS server? Well, that would let my systems find his Web server, but then they'd lose the ability to find *my* servers, as asking any `microsoft.com` question of my friend's DNS server would get an answer about the *real* `microsoft.com`! It seems that I'm in trouble either way. Or I could convince my DNS server to do split-brain for my friend's `novell.com` zone by making my DNS server a secondary server for `novell.com` and point to his DNS server as the "master" for `novell.com`...but we might not be *that* good friends, and he might be leery about shipping his internal zone to one of my servers.

There's another answer: conditional DNS forwarding. Here, I tell my DNS server, "If you ever need to resolve a name in the `novell.com` zone, then don't go looking all over the Internet—ask *that* server," pointing to my friend's DNS server. I could, if I wanted, have conditional forwarding commands for as many other DNS zones as I liked.

Server 2003's DNS server software lets you set up conditional forwarding for as many zones as you like. Just open the server's properties page and click Forwarders as you've done before, to see a

screen like the one back in Figure 7.83. Then set up conditional forwarding this way:

1. Click the New button in the upper right part of the page. You'll then see a dialog box like Figure 7.84.

**FIGURE 7.84**

Adding a conditional forwarding setting

2. There, I've filled in novell.com by way of example. Click OK, and your Forwarders page will look like Figure 7.85.

**FIGURE 7.85**

Forwarders showing a conditional forwarding

3. To specify the IP address of the server to ask whenever looking for novell.com information, fill the server's IP address into the Selected Domain's Forwarder IP Address List field and click Add.

Although it's not obvious, this page keeps separate lists of forwarders. So, for example, if this DNS server normally forwards to a server at 10.0.0.2, but forwards novell.com questions to a different server at 10.20.1.10, then you would only see the 10.20.1.10 IP address if you clicked novell.com; clicking All other DNS domains would then show a server address of 10.0.0.2.

**EXERCISE: WORKING WITH CONDITIONAL FORWARDING**

In this exercise, we'll tell Bigdog to forward to ns2, but *only* when looking for records in nasa.gov. We'll prove that Bigdog only forwards to ns2 when looking for nasa.gov information by creating two zones on ns2—a nasa.gov and an ibm.com zone. You'll see that resolving nasa.gov information reflects the zone on Bigdog, but resolving ibm.com information does *not* reflect the ibm.com zone on ns2.

1. First, remove any forwarding that we've set up on Bigdog. At Bigdog, open the DNS snap-in and right-click Bigdog's server icon, then choose Properties and click the Forwarders tab. Click any IP addresses under Selected Domain's Forwarder IP Address List and then click the Remove button so that when you're done, the only entry under DNS Domain is All Other DNS Servers and there are no IP addresses under that.
2. Now tell Bigdog to forward to ns2, but only for nasa.gov questions. Working still in the Forwarders tab, click New.
3. In the New Forwarder dialog that appears, fill in **nasa.gov** and click OK.
4. Back in the Forwarders page, ensure that the nasa.gov line in the DNS Domain list is highlighted. In Selected Domain's Forwarder IP Address List, fill in **192.168.0.3** and click Add.
5. Increase the Number of Seconds before Forward Queries Time Out to 15. Leave Do Not Use Recursion for This Domain unchecked.
6. Click OK. Clear Bigdog's cache.
7. Now go to ns2. Open its DNS snap-in.
8. Create a primary forward zone called nasa.gov and another called ibm.com.
9. In the nasa.gov zone, create a host (A) record for www with IP address 10.0.0.1.
10. In the ibm.com zone, create a host (A) record for www with IP address 10.200.10.1.
11. Clear ns2's server cache.
12. Return to Bigdog and open a command line, then type **ipconfig /flushdns** to remove any client cache information. Then start **nslookup**.
13. Type **www.nasa.gov** to query DNS for NASA's Web server. You should get "10.0.0.1" as an answer.
14. Type **www.ibm.com** to query for IBM's Web server. You should get a number of IP addresses in answer—and none of them will be 10.200.10.1.

**COMPARING CONDITIONAL FORWARDING, STUB ZONES, AND SECONDARY ZONES**

In my simple microsoft.com/novell.com example where two intranets have split-brain DNS but need to be able to resolve each other's names, I touched on the fact that conditional forwarding is not the only answer; let's take minute here and explore that in a bit more detail.

As I've said, split-brain DNS is not unusual at all and is in fact the norm for name services in most intranets. That gives rise to a problem: assuming that you've done split-brain on your intranet, how do people *outside* the intranet—clients, corporate partners, or even employees telecommuting—resolve names of systems inside your intranet? The whole point of split-brain DNS is in disconnecting your zone from the public DNS hierarchy; how do you make an exception for a few?

Let's imagine that one company has an internal split-brain zone called `abc.com` and another firm has an internal split-brain zone called `xyz.com`. We could set them up so that `abc.com` can resolve `xyz.com`'s names in three ways:

**Secondary zones** We could create a secondary zone for `xyz.com` on each of the `abc.com` DNS servers. Every time that someone at `abc.com` tries to resolve a name, then their local DNS server would have an `xyz.com` zone right on it, and thus wouldn't go out on the public Internet to resolve the name. This makes for fast `xyz.com` name resolution. The down-sides are that `xyz.com`'s administrators would have to set up their DNS servers to allow the `abc.com` DNS servers to suck the `xyz.com` zone information off their servers, a security issue for some. Additionally, if `xyz.com`'s zone is large—which is often the case with internal zones—then the bandwidth required to constantly retransfer the `xyz.com` zones over the Internet to the `abc.com` servers might be undesirable.

**Stub zones** In the secondary case above, I said that the bandwidth required to transfer the `xyz.com` zones might be unacceptable. In that case, use a stub zone. An `xyz.com` stub zone on an `abc.com` DNS server would work like a secondary zone in that it causes the `abc.com` DNS server to get `xyz.com` zone information from the `xyz.com` DNS servers, but it only transfers the NS and SOA records—a fairly small amount of data. (You would never make a DNS server holding a stub zone for a given domain authoritative for that domain, as it can't answer most questions about the zone.) When someone queries an `abc.com` DNS server for `xyz.com` information, the `abc.com` DNS server sees that it has a local zone for `xyz.com` and would therefore normally look no further. But as the `abc.com` DNS server sees that it's a *stub* zone, then the `abc.com` server knows the name of the DNS servers for `xyz.com` and queries them. A server with a stub zone for `xyz.com`, then, always knows the names and IP addresses of the DNS servers that are authoritative for `xyz.com`. If the `xyz.com` folks change their DNS servers, then you don't have to do anything to keep your stub zones up to date—normal zone transfers will accomplish that.

**Conditional forwarding** Conditional forwarding is very similar-looking to stub zones. With a stub zone, a DNS server looks at a stub zone to find out who to query for information on `xyz.com`; with conditional forwarding, the DNS server is directly configured to treat an `xyz.com` DNS server as a forwarder. Note that if the list of DNS servers for `xyz.com` changed, then you'd have to go reconfigure each of the `abc.com` DNS servers by hand—something you wouldn't have to do with stub zones. But that can be a *benefit* in many split-brain cases, as conditional forwarding is quick and easy to set up. And additionally conditional forwarding requires no permission from `xyz.com` DNS servers. For example, you could decide to set up your DNS servers to conditionally forward any names in `minasi.com` to the server at `68.15.149.117`, because that's one of my DNS servers. You wouldn't need my permission. In contrast, if you tried to create a stub server for `minasi.com`, that would fail, as my DNS server will not do zone transfers except to approved DNS servers. Conditional forwarding *does* have a potential cost, though. If you put a long list of conditional forwarding rules on a DNS server, then the server would have to check that list every time it resolves a name. That could burn up a lot of CPU time and make the DNS server respond more slowly than you'd like.

Summarizing, then, the difference between stub zones and conditional forwarding is that stub zones ensure that `abc.com`'s DNS servers are always up-to-date on `xyz.com`'s DNS servers but require permission to transfer zones from `xyz.com`; conditional forwarding does not require permission to

transfer zones and doesn't automatically keep up-to-date on zones but offers a certain amount of control in that you can say, "I want to know exactly what *that* server knows about xyz.com."

## Designing Your DNS Architecture

By now, you know a lot about DNS. Let's put that knowledge all together to see how to design a system of DNS servers that will serve your organization's needs.

A DNS architecture typically needs to solve several problems:

- ◆ You want performance—fast name resolution through multiple DNS servers and centralized cache through forwarders.
- ◆ But you want to secure your network, so you'll probably slave the internal DNS servers to forwarders that are a small number of hardened systems outside of a firewall.
- ◆ To secure your network further, you will probably want to present one set of DNS names internally and a different one externally so that the outside world only sees a small subset of that firm's computers. You will, then, need to know how to maintain a separate namespace internally and externally. This is the split-brain DNS that we've been talking about.
- ◆ You may have outside entities that you want to be able to see your internal namespace—business partners, clients, telecommuting employees, and others—so you'll need to consider how to accomplish that.

We've covered a lot of this so far, but let's step back and focus on normal and split-brain approaches.

Earlier, we figured out how Megabucks Corporation should place the DNS servers that will resolve names for their internal folks. But now they've got another problem: How should they set up the DNS servers that will hold the megabucks.com zone files? For most firms, it's not as easy as just running the Create New Zone Wizard. Let's look at the kinds of decisions that Megabucks has to make when configuring their IP subnets and DNS names, given that they are both running their own intranet and are connected to the Internet.

### One Scenario: Completely Open on the Internet

We know that Megabucks has about 2000 employees, so let's suppose it has about 2500 computers and therefore needs about 2500 IP addresses. That'd be about 10 class C-sized subnets. In the simplest network layout we could imagine, Megabucks goes out and gets 10 class C networks from an ISP. Every one of those 2540 IP addresses are fully routable on the public Internet. They put one IP address on each one of their computers, and so each computer can ping anywhere on the Internet. (And anyone on the Internet can ping any one of those computers.) They then register the domain megabucks.com with Network Solutions. When Network Solutions asks for the IP addresses of two DNS servers that will act as the authoritative servers for the megabucks.com domain, the Megabucks folks just give them the addresses of two Server 2003 machines, and then run the DNS service on those machines—let's call those two machines `primary.megabucks.com` and `secondary.megabucks.com`. Then they create a primary megabucks.com forward lookup zone on one of the two DNS servers (`primary.megabucks.com`, as you've no doubt guessed), and a secondary megabucks.com forward lookup zone on the other DNS server, `secondary.megabucks.com`. They enable dynamic DNS updates

on the megabucks.com zone, and so the megabucks.com zone is soon filled with about 2500 A records naming every Win2K, XP, or 2003 system on the Megabucks network.

Notice that for an internal Megabucks system to resolve the name of another internal Megabucks system, then that system (or its DNS server) ends up asking either primary.megabucks.com or secondary.megabucks.com. Notice also that whenever someone in the public Internet tries to resolve a megabucks.com name, such as when she tries to visit www.megabucks.com or sends mail to somebody@megabucks.com, her DNS server also gets its name resolution query answered by the same two servers, primary.megabucks.com and secondary.megabucks.com, using the very same megabucks.com zone.

In short, in this scenario, Megabucks' internal DNS and external DNS are the same.

What's wrong with this? Well, technically there's nothing illegal about it, but this scenario would trouble most security experts. Using the same DNS server for your internal network as you use to allow external people to resolve names in your domain exposes your entire domain to the Internet. What concerns the security folks—and please understand that I do not by any means consider myself a security expert—is that there's a general principle of security that goes something like, “The less that you tell the weasels, the harder it is for the weasels to attack you.” (Others call it “security through obscurity.”)

For example, suppose a potential slimeball looked at all of those A records. That's a complete listing of the names and IP addresses of all of the workstations on your network. Everybody knows that many users are pretty lax about things like passwords and security on their own workstations, so they'd be a good starting point—probably an easier cracking job than the servers. If you're running Active Directory, then you get even more information from DNS than usual; for example, DNS will tell you the names of the system's domain controllers. That's not a bug—DNS under Windows 2000 and later is *supposed* to do that, remember? The bottom line is that most firms would prefer for the DNS server that the public Internet sees to only know a few records—the obligatory SOA record and NS records, as well as an MX record or two so that the company can receive Internet e-mail, as well as A or CNAME records for its Web and perhaps FTP servers.

## A Better Scenario: Split-Brain DNS

Now let's see if we can do a better job for Megabucks with split-brain. As you've read a number of times by now, I recommend this setup for most people.

Megabucks likes those 2500+ routable IP addresses, so it decides to stay with them. But it'd like the public to see just a small subset of the megabucks.com DNS information, while allowing its internal users to see everything—and that not only means everything in the internal megabucks.com network, but the rest of the Internet as well.

### A SPLIT-BRAIN DESIGN

Take a look at Figure 7.86 to see how Megabucks can change its network to make things work a bit more to its liking.

To keep the diagram simple, I reduced the number of internal name-resolving DNS servers from 20 to just 2—instead of NS01 through NS20, we've only got NS01 and NS02. There are several concepts in that diagram, but the single most important is that now we have *two* primary DNS servers for megabucks.com and two sets of secondary DNS servers for megabucks.com.

**FIGURE 7.86**

Using two sets of primary/secondary DNS servers for megabucks.com zone

The servers `primary.megabucks.com` and `secondary.megabucks.com` are still primary and secondary servers for the `megabucks.com` domain, and they are still the two authoritative DNS servers for the domain, as far as Network Solutions is concerned. But now those zones are static, not dynamic, and they contain just a handful of records, as I suggested at the end of the last section. There's an SOA record, two NS records (one for primary and one for secondary), MX records to point to the publicly available mail servers, and A or CNAME records to point to the Web servers, FTP servers, and any other servers that Megabucks wants the outside world to see. These two DNS servers are *not*, however, the primary and secondary DNS servers as far as the internal Megabucks systems are concerned.

**TIP** Let me underscore this. I'm asked often, "We have a registered Internet domain, and we're going to do Active Directory. Right now our ISP hosts our zone—do we have to take that back? Must we become authoritative for our zone?" The answer is, "Absolutely not." Go ahead and leave the public zone on an ISP, where it's (hopefully) safe, sound, and secure. (And someone else's problem.) It'll handle the external requests, and as you'll see, you'll run some servers of your own for the internal ones.

Instead, the DNS servers that previously only did name resolution—the ones that were caching-only servers—now contain a zone: the `megabucks.com` zone. We told `ns01.megabucks.com` that it was the primary DNS server for `megabucks.com`, and authorized dynamic updates for the zone. We told `NS01` that the `megabucks.com` zone had a secondary DNS server as well, `ns02.megabucks.com`. We did *not* tell it that `primary.megabucks.com` and `secondary.megabucks.com` (the external DNS servers) held `megabucks.com` zones; as far as `NS01`'s concerned, it and `NS02` are the only DNS servers for

megabucks.com. ns02.megabucks.com has been set up as a secondary server on megabucks.com and told to pull its zone file from NS01.

Additionally, the workstations inside megabucks.com only know about NS01 and NS02 vis-à-vis DNS servers. Some machines are configured with NS01 as their preferred DNS server, and some are configured instead with NS02 as their preferred DNS server. No workstations are configured with primary.megabucks.com or secondary.megabucks.com as their preferred DNS server. Whether they query NS01 or NS02 for an SOA record for megabucks.com, they'll be told the same thing—that NS01.megabucks.com is the primary DNS server for megabucks.com and therefore is the place to go to reregister with dynamic DNS. (This works just as well if NS01 and NS02 are Active Directory domain controllers and their megabucks.com domain is set up as an Active Directory—integrated domain, in case you're wondering.)

### **SPLIT-BRAIN AS A TWO-WAY MIRROR**

Let's follow a few name resolutions through to see how this meets Megabucks' needs.

First, what happens if someone in the public Internet tries to resolve [www.megabucks.com](http://www.megabucks.com)? That person's local DNS server will ask the root servers where it can find the DNS servers for megabucks.com, and the root servers will reply, "Either primary.megabucks.com or secondary.megabucks.com can answer your name queries about megabucks.com." The person's local DNS server will then ask primary or secondary and will get back the address of the Web server that Megabucks wants the outside world to see.

Well, how about if that person on the outside Internet tries to resolve [ns01.megabucks.com](http://ns01.megabucks.com)? Again, their local DNS server will be directed to primary or secondary. The megabucks.com zone sitting on primary and secondary doesn't include a record for NS01, and there's no way for that person out on the public Internet to know that there are other DNS servers on megabucks.com that could answer the question. As a result, the attempted name resolution for NS01 will fail. That includes any attempts to find domain controllers for the megabucks.com Active Directory, whenever it gets the domain running. So, summarized, outsiders can't see into the megabucks.com intranet's naming service.

Let's look at it from the reverse point of view. What would a person on an internal system be able to do?

Well, first, suppose someone inside Megabucks tried to resolve [www.microsoft.com](http://www.microsoft.com), and presume that information wasn't in their system's local DNS cache. In that case, their workstation would contact one of the internal DNS servers (NS01 or NS02). If the internal DNS server had been asked the question recently, then it'd have the answer in cache. If not, the internal DNS server would forward the request out to secondary.megabucks.com, which would be able to get the answer and reply back to the internal DNS server.

Next, consider the case where someone inside Megabucks tries to resolve the name of another machine inside Megabucks. No problem there—NS01 contains a megabucks.com zone that knows the names of every internal machine, as they all register with NS01, and NS02 has a copy of that zone, as it's a secondary.

Basically, then, split-brain DNS on megabucks.com lets us create a kind of "two-way mirror": People outside the domain can't see in, but people inside the domain can see out.

There *is* one case where things get a little tricky. What about if someone at one of the internal megabucks.com systems tries to resolve [www.megabucks.com](http://www.megabucks.com) or one of the other publicly visible

Megabucks systems? From what you’ve seen so far, that resolution attempt would fail. The internal system would address its query to NS01 or NS02, and both DNS servers contain a zone for megabucks.com. But would there be a www record in that zone? Not by default, as the Web server wouldn’t register itself with the dynamic DNS servers—it’s supposed to be visible on the public Internet, so its preferred DNS server would likely be either primary.megabucks.com or secondary.megabucks.com.

That leads to the unusual side effect that the only people on the planet who can’t get to www.megabucks.com are the people who work for Megabucks. Which might not be so bad, if Megabucks were planning to announce the layoffs on the Web. . . . Seriously, though, the fix here is easy: Just add a static entry into NS01’s megabucks.com zone for www, as well as records for the mail, FTP, and any other servers.

### SECURING SPLIT-BRAIN

Let’s take this a bit further and see how Megabucks could secure their internal systems further. First, clearly they should have some kind of firewall that hinders external systems from talking to their internal systems without invitation; at minimum some kind of stateful tool like a NAT router. But that’s not all; recall that if an internal DNS server doesn’t get a response from a forwarder, then that internal server will initiate a search on the public Internet.

Should that happen, it’s possible that an external DNS server on the public Internet infected with a virus could pass that virus to the internal DNS server. You may recall that we can ward that off with slaving. Megabucks should do two things:

- ◆ First, they should install more than one forwarder for fault tolerance, as I’ve covered before.
- ◆ Second, they should harden the forwarder systems, as you would on any system directly connected to the Internet.
- ◆ Finally, they should slave all of the internal DNS servers to the external forwarders. Each internal DNS server should have the IP addresses of *all* of the external forwarders on its list of forwarders. (Mix their order up a bit to load balance.)

### SPLIT-BRAIN IN A SINGLE-DOMAIN ENVIRONMENT STEP-BY-STEP

Here’s a review of the essential steps and concepts to making split-brain DNS work in a hypothetical bigfirm.biz domain.

**If someone else hosts your domain, leave it that way.** This is a concept that many people stumble on. Assuming that you already have an externally visible DNS server for your zone, that’s great; don’t do anything with it. Leave it nondynamic. Heck, let an ISP host it. If your company’s DNS domain name is bigfirm.biz and huge-isp.com hosts a DNS zone for bigfirm.biz, then go ahead and build your own bigfirm.biz zone on an internal DNS server. That’s the way that split-brain is *supposed* to work. That way, external visitors’ queries are handled by the zone on the huge-isp.com’s DNS servers, which know nothing of your internal network. Remember, as the security experts say, “Security. . . through obscurity.”

**Plan and document your servers.** Decide how many DNS servers you’ll have on your intranet, including what their names and IP addresses will be. Keep that information documented and up to date on a text file, spreadsheet, database, whatever works for you.

**Install the software on the servers.** As you’ve seen in this chapter, install the DNS service on each one.

**Point every DNS server to itself.** Configure every DNS server to point to itself as a preferred DNS server. No alternate DNS servers, just itself.

**Every server must be either primary or secondary for bigfirm.biz.** Make one of your DNS servers the primary DNS server for bigfirm.biz. Make all of the other internal DNS servers secondary DNS servers for bigfirm.biz. If you leave any internal DNS servers without a local copy of the bigfirm.biz zone, then any systems querying that server for bigfirm.biz information will cause the DNS server to search the public Internet’s DNS hierarchy, and the system will end up getting an answer from the externally hosted DNS server—which will almost certainly produce the wrong info. This is an important step—every internal DNS server *must* be primary or secondary for bigfirm.biz.

Once you build your Active Directory then you have the option to make the zone AD-integrated. When you’ve done that, then any of the DNS servers that are also domain controllers for bigfirm.biz can become primaries even if they were secondaries before, as AD-integrated allows for multiple primary DNS servers on a zone. If you go AD-integrated but have DNS servers that are *not* domain controllers then that’s no problem, but they can only act as secondary DNS servers.

**Copy any external records to the internal zone.** There are probably things in the external bigfirm.biz zone—the one that huge-isp.com runs—that you need people inside the network to see to the internal. For example, the www and MX records. People ask me how to automate this and, while I’m sure there’s a way—one could probably do some scripting to do this—there isn’t an automatic method that I know of. Remember that this split-brain stuff is a trifle underhanded as far as DNS is concerned, so we can’t expect too much help if we decide to swim against the current.

**Set up two or more external forwarders.** These are the servers outside of the firewall that all of your internal DNS servers will forward through. You really want these systems to be simple and easily hardened. These do not have to be NT-based systems at all, and I can think of at least one fairly good argument against it: license costs. If you just want a DNS server “appliance,” something that only queries the public Internet’s DNS servers and holds no zones of its own, then it’s kind of expensive to buy a whole Windows Server 2003 license just for that. I’ve set up Linux boxes with BIND, and they offer three benefits. First, there’s the obvious cost factor. Second, you can do it with cast-off hardware. For example, I recently decommissioned a 300MHz server that had 128MB of RAM and had worked fine as a backup domain controller and print server. That’s not really enough hardware for Server 2003, but it’s a fine platform for RedHat, provided I don’t install the GUI. Third, you can, with a little work, strip a Linux box pretty clean, basically removing everything but the BIND DNS software.

**Slave the internal DNS servers to the external forwarders.** This way, the internal DNS servers never show their faces to the public Internet. Be sure to increase the timeout value from its default of five seconds to a more reasonable minute or so—experiment to find what’s best.

**Configure every single machine inside the intranet to use only internal DNS servers.** Every machine inside the intranet must point to one or more of the internal DNS servers. Configure

every workstation and server to point to one of your internal DNS servers as its preferred DNS server and another as the alternate DNS server. *Never* point a machine to an external DNS server, even as an alternate DNS server. If you do, then any queries to the external DNS server for bigfirm.biz information would end up at the DNS server at huge-isp.com, and that's not what you want to see happen.

Follow these steps and you'll have a perfectly running DNS system.

### **SPLIT-BRAIN CHANGES FOR MULTIPLE DOMAINS**

If your only domain is bigfirm.biz, then you'll be able to accomplish split-brain with the instructions above. But if you have more than one domain, or if you're going to be participating in another organization's domain, then you'll need to add one wrinkle: conditional forwarding or secondary/stub zones. We've gone through them in some detail, so I won't recapitulate that here in great detail. But I do want to remind you that you'll have to use at least *one* of these techniques, or multiple-domain split-brain just won't be possible. In simple terms, here's your goal: all of those internal DNS servers must be able to properly resolve names for all of your split-brain domains.

### **Yet Another Scenario: Different Names**

I just explained how to create one set of DNS names internally and another externally, but that's not the way that everyone handles their inside/outside name dichotomy. Some firms just register two different DNS domains and use one on their internal network and the other on their external network. For example, before Compaq and then HP bought them, Digital Equipment Corporation used to use digital.com for their externally visible network and dec.com for their internal network.

Other firms register both the .net and .com versions of their company name, so Megabucks might use the megabucks.com DNS domain for their externally visible systems and megabucks.net for their internal systems.

Still others create child domains. Megabucks might decide to create a child domain named internal.megabucks.com. All of the internal systems would have names like *machinename*.internal.megabucks.com, and we'd place an internal.megabucks.com zone on all of the DNS servers on the internal network. The DNS servers for the parent level, megabucks.com, would all live out on the external network, but there would be no delegation records on that external DNS server to indicate that there is a child domain of megabucks.com called internal.megabucks.com.

Whatever names you decide to use internally, make sure they're registered with the worldwide DNS hierarchy. Otherwise, someone *else* could unwittingly register a domain with that name, and as a result your internal users couldn't resolve any names in that domain. If that's not clear, think back to my example about what would happen if you created a dell.com zone on your internal network: Whenever one of your users tried to surf to [www.dell.com](http://www.dell.com), they'd be directed to one of your Web servers, not the actual Dell ones.

## **DNS Recovery**

Once you've gone to all of the trouble to set up your DNS server, what happens if it fails? How hard is it to get another DNS server up and running to take the place of a dead one? It's quite easy, actually.

## DNS Backup

Once you have your DNS server up and running, back up your server's configuration like so:

1. Stop the DNS service.
2. Start Regedit and navigate to `HKEY_LOCAL_MACHINE\System\CurrentControlSet\Services\DNS`.
3. Right-click the `DNS` folder and choose `Export`. Give the file the name `dns1` and press `Enter`.
4. Now navigate to `HKEY_LOCAL_MACHINE\SOFTWARE\Microsoft\Windows NT\CurrentVersion\DNS Server`.
5. Right-click the `DNS Server` folder and choose `Export`. Name the file `dns2` and press `Enter`.

You've just created two Registry files called `dns1.reg` and `dns2.reg`. Put them on a floppy or some other storage location that's not on the server.

Look in your `\Windows\System32\DNS` directory and copy all of the files with the extension `.dns` to wherever you stored the `.reg` files. Now you're backed up; restart the DNS service.

## DNS Restoration

If your DNS server has failed, you can get another one in its place quickly:

1. Set up a Server 2003 system. Give it the same machine name, DNS suffix, and IP address as the old DNS server.
2. Install the DNS service on the system.
3. Copy all of the files with the `.dns` extension to `\windows\system32\dns`.
4. Stop the DNS service.
5. Locate the two files with the `.reg` extension. Double-click them, one at a time, and confirm that you want them installed in the Registry.
6. Restart the DNS service.

You should now have a replacement for your DNS server. Remember that if all you want to do is move the primary role for a zone from one computer to another, you can just copy the `*.dns` file over to the target computer and run the New Zone Wizard, telling it that you already have a zone file.

## Application: Grafting an Active Directory Domain into an Enterprise with Old DNS Servers

Suppose you bring Server 2003 into your firm, `acme.com`. At a meeting of the IT planning staff, you sell the CIO on the whole idea of the Active Directory as a directory service. Everyone loves the idea (or at least no one has attacked you with a sharp object) until you enthusiastically say something like, "And Microsoft was even smart enough to use DNS as its naming infrastructure!"

All of a sudden, the Unix guys, who have been scowling in the corner, say in unison, "Whaaaaaat?????" They're not dumb. They know what this means. You see, if your firm is like many, your internal DNS servers are probably running on Unix boxes rather than something else. The program that the Unix box is running, BIND, is well understood and fairly stable. The Unix folks know that if the Active Directory uses DNS as its naming system, then that almost certainly means that Server 2003

comes with a DNS server—and while they were able for years to safely shoot down any ideas about using NT 4's DNS server, Server 2003's DNS server is not only a pretty good product, it's pretty well integrated with the Active Directory. No, you don't *have* to use 2003's DNS server to make the Active Directory work, but the Unix guys see the writing on the wall. No way they're polluting their BIND system with some less-reliable DNS server from Redmond, they say. The Active Directory? "I say it's spinach," they say, "and I say I don't like it."

You've got several answers to this objection. First of all, you may be able to make them happy and keep using BIND. Any DNS server that supports RFC 2136 dynamic updates and RFC 2782 SRV records and that allows you to put underscores—which are not exactly kosher, RFC-wise—into host names will support Active Directory. You needn't use Microsoft's DNS server. As you've read, the latest version of BIND meets those criteria, and in fact I've set up the Active Directories using only BIND-based DNS servers.

But perhaps your enterprise is on an earlier version of BIND or some other DNS server and doesn't want to upgrade. What to do? Simple: Get them to delegate a subdomain to your DNS servers. That way, if acme.com doesn't want to have all of its DNS servers assimilated into the Microsoft DNS Collective, then they needn't be. The Unix servers can continue to handle the acme.com top-level domain. You just ask for a subdomain such as win2k.acme.com (some people are proposing *ds.domainname*, as in *ds.acme.com*—the *ds* stands for *directory service*) or some such, and you then put all of the Windows 2000, XP, and 2003 machines in the subdomain. The DNS server that keeps track of them can then be a Server 2003 server without affecting the rest of acme.com.

Why is this an application of understanding zone files? Because someone may decide to make it *your* job to add the records to the BIND servers that delegate the win2k.acme.com zone to your Server 2003 server. And this way, you'll be able to just sit right down and make the necessary modifications. (Although, now that I mention it, there's this vi editor thing you should know about...)

I know that this was a big chapter, but believe me, it was the shortest that I could make it without skipping important details. WINS, DHCP, and DNS are as essential to a functioning network as electricity. I promise you that if you take the time to design and implement a good WINS/DHCP/DNS infrastructure, you'll avoid many troubleshooting sessions.

But what did we set all of that infrastructure up for? One reason was to enable us to build a sturdy Active Directory. In the next chapter, you'll learn how AD works and how to *make* it work.

## Chapter 8

# Active Directory

ONE OF THE MOST important concepts in Microsoft networking is the notion of a *domain*. Put as simply as possible, a domain is just a group of servers and workstations that agree to centralize user and machine account names and passwords in a shared database. That's useful—essentially, really, in a network of any size—because it allows a user to have just one account name and password and use that name and password on the dozens, hundreds, or thousands of machines in an organization's domain. When your company hires a new employee, you as an administrator can just sit down and create a single account for that new employee that she can immediately (well, nearly immediately—we'll learn about “replication” in this chapter and you'll see what I mean) get access to any system in your network that you've allowed her access to. And when it's time to change her password, she does it just once, and the whole domain recognizes that new password.

But centralized user and machine accounts and passwords are just the start. As NT has evolved over the years, NT domains have become a way to centralize other things as well. First, in NT 3.51, came user profiles, a tool that lets you take your desktop and settings with you wherever you log in. They've always been troublesome, but they're getting better and you'll read more about them in the next chapter. Then, in NT 4, domains became a place to centralize “system policies,” a set of instructions that machines use to build and control user environments. Windows 2000's domains could centralize DNS information, as in the Active Directory—integrated zones that you read about in the previous chapter, and offered an improved successor to system policies called “group policies,” which you'll read about in this chapter and the next. Ever since their appearance in 2000, it's seemed to me that group policies are *the* way that Microsoft is making it possible to control not just user environments—desktops, applications, and the like—but also servers and server software. Group policies are becoming sort of the Control Panel for your entire network...and group policies are stored in a domain's database.

Let me stress that you do not *need* a domain to network a bunch of computers running some flavor or flavors of Windows, but it's *far* easier to do virtually everything in Microsoft networking with a domain, so it's really worth your time to learn about domains. In this chapter, we'll start from the basics of what domains are and what they do for you, and then move from there to concepts and planning and yes, I *did* say “planning”—this is *not* a pop-the-CD-in-and-guess-the-right-answers-to-the-wizard's-questions sort of thing. Then we'll get into the nuts and bolts of building a domain, and play with a

small domain. From there we'll take on some troubleshooting and advanced (but necessary) topics and some migration advice, and then finally we'll talk about a useful security feature that you really can't even consider using without a working AD: public key infrastructure.

## What Active Directory Domains Do for Us

I know that some of you already know what domains are for and, if you fit in that category, then feel free to skip this section. If you're wondering what's new in Active Directory in Windows Server 2003, then of course I'll cover that here, but for a quick overview of what's new in AD, please flip back to Chapter 1 for a short summary of 2003's AD-oriented improvements. For those looking for a bit of "why we're here in the first place," here's a look at what domains do for us.

Domains do several things for us. I've suggested a few, but here's a more complete list. They:

- ◆ Keep a central list of users and passwords.
- ◆ Provide a set of servers to act as "authentication servers" or "logon servers" known as *domain controllers*.
- ◆ Maintain a searchable index of the things in the domain, making it easier for people to find resources—"which share do we keep the Sales figures on, anyway?"
- ◆ Let you create users with different levels of powers, from nearly powerless guest accounts to regular user accounts to all-powerful domain-wide administrators. But they also let you create subadministrators, user accounts with *some* of the power of domain-wide admins but not all of their power.
- ◆ Allow you to subdivide your domains into subdomains called organization units or OUs. You can then assign varying amounts of control and power over these OUs to particular individuals. This lets you create what might be called "departmental administrators"—users with lots of power but only over a small group of machines and users.

In the next few sections, we'll take a look at these in greater detail.

## Security: Keeping Track of Who's Allowed to Use the Network and Who Isn't

A network's first job is to provide service—central places to store simple things like files or more complex things like databases, shared printing, or fax services. To make it possible for people to communicate in ways like e-mail, videoconferencing, or whatever technology comes up in the future. And, more recently, to make it easier for people to buy things.

Fast on the heels of that first job, however, is the second job of every network: security. Once, most computer networks were unsecured or lightly secured, but human nature has forced a change and there's no going back. Just as businesses have locks on their doors, file cabinets, and cash registers to protect their physical assets, so also do most modern firms protect their information assets. And no matter what vendor's network software you're using, computer security typically boils down to two parts: authentication and authorization. To see why, consider the following example.

We met Bigfirm in the last chapter. Bigfirm competes with Acme, a well-known firm specializing in devices for removing birds from the desert. Bigfirm is not as well-known but is trying to wrest market share from Acme by selling innovative products to solve a wide range of needs, tools like

perpetual motion machines, skyhooks, X-Ray glasses, and the like. They have a sales manager named Ivana Cellalot; Ivana wants to see how the sales of a new product, Instant Hole, is doing. Bigfirm has it set up so that Ivana can review sales information through her Web browser—she just surfs over to a particular location on one of the company's internal Web servers and the report appears on her screen.

Of course, Bigfirm management wouldn't be happy about just *anybody* getting to these sales report pages, so the pages are secured. Between the time that Ivana asks for the pages and the time that she gets them, two things happen:

**Authentication** The Web server containing the sales reports asks her workstation, "Who's asking for this data?" The workstation replies, "Ivana." The server then says, "Prove it." So the workstation pops up a dialog box on Ivana's screen asking for her username and password. She types in her name and password, and assuming that she types them correctly, the server then checks that name and password against a list of known users and passwords and finds that she is indeed Ivana.

**Authorization** The mere fact that she has proven that she's Ivana may not be sufficient reason for the Web server to give her access to the sales pages. The Web server then looks at another list sometimes known as the *access control list*, a list of people and access levels—"Joe can look at this page but can't change it," "Sue can look at this page and can change it," "Larry can't look at this page at all." Presuming Ivana's on the "can look" list, the server sends the requested pages to her browser.

Now, the foregoing example may not seem to contain any deep insights—after all, everyone's logged into a system, tried to access something, and either been successful or rejected—but understanding how Active Directory works requires examining these everyday things a bit. Here's a closer look at some of the administrative mechanics of logins. First, you need a list of known users, then you need some kind of service that will look someone up upon request and say, "Yes, this is someone that I know." Next, you've got to answer the question, "Hmmm...that service says that the woman that says she's Ivana is indeed Ivana...but why do I believe the service?" And finally, once you've got this service working and you trust its abilities, how can you extend it to authenticating for software other than Microsoft code?

## MAINTAIN A "DIRECTORY" OF USERS AND OTHER NETWORK OBJECTS

Every operating system with even the most minimum security has a file or files that make up a database of known user accounts. Early versions of NT, from 3.1 through 4, only used a single file named SAM, short for the less-than-illuminating Security Accounts Manager. It contained a user's username (the logon name), the user's full name, password, allowed logon hours, account expiration date, description, primary group name, and profile information. Of course, the file was encrypted; copy a SAM from an existing NT 4 system and pull it up in Notepad, and you'll see only garbage. To this day, NT-family systems still use SAMs on workstations, including Windows 2000 Professional and XP. By default, Windows Server 2003 servers also contain and use a SAM. But a small number of systems will hold Active Directory's centralized database. Those servers are called *domain controllers*, and they do not have a SAM. In the old NT 4 and earlier days, domain controllers used a SAM, but ever since Windows 2000 Server arrived they've used something different—an "Active Directory."

Active Directory is SAM's successor—I suppose we could call AD the Son of SAM—and it stores most of its user information in a file called `NTDS.DIT`. But `NTDS.DIT` is different from SAM in a few ways. First, `NTDS.DIT` is a modified database built using basically the same technology as Microsoft's Access database, and Active Directory domain controllers actually contain a variant of Access's database engine in its machinery. (Microsoft used to call the Access database engine JET, which stood for Joint Engine Technology—no, the meaning isn't obvious to me either, I think they just liked the acronym—but now it's called ESE, pronounced “easy,” which stands for the equally useful name Extensible Storage Engine. But I'm kidding a bit when I say that it's an Access database. Microsoft needed Exchange to have a pretty good database engine while shuffling around both information about Exchange user accounts as well as the mail itself. That's probably why they renamed it.) Second, as you'll see demonstrated over and over again, `NTDS.DIT` stores a much wider variety of information about users than SAM ever did.

The information in `NTDS.DIT` and the program that manages `NTDS.DIT` are together called *the directory service*. (As a matter of fact, most folks will never say “`NTDS.DIT`”; they'll say “directory service.”) Which leads to a question: What exactly is a “directory”?

It would seem (to me, anyway) that what we've got here is a database of users and user information. So why not call it a *database*? No compelling reasons; mostly convention, but there *is* one interesting insight. According to some, databases of users tend to get *read* far more often than they get *written*. That allows a certain amount of database engine “tweaking” for higher performance. This subset of the class of databases gets a name—*directories*. I guess it makes sense, as we're used to using lists of people called *office directories* or *phone directories*. I just wish the folks in power had come up with some other name; ask most PC users what a directory is, and they start thinking of hard disk structures. “`C:\WINDOWS`—isn't that a directory?”

Before I leave this topic, I should add a side note about a difference between ADs and the old NT 4–based domains: ADs can be *way* bigger. You can fit about 5000 user accounts comfortably in an NT 4 domain, forcing large enterprises to create multiple domains in order to accommodate all of their user accounts; such a domain design was called a *multimaster* model. In contrast, an AD domain can fit 1.5 million users (or more, depending on whom you talk to) into its Active Directory database—which ought to be a sufficient number of user accounts for even the largest companies. AD lets many large companies that were forced back in the NT 4 days to use multiple domains because of the sheer size of their workforce to consolidate all of their older domains into a single AD domain. That *doesn't*, however, imply in any way that only large enterprises benefit from AD, not at all—AD supports many tools that even the smallest organization can benefit from.

#### **OFFER AN “AUTHENTICATION SERVICE:” DOMAIN CONTROLLERS**

Consider for a moment when your workstation will use that user information located in the Active Directory. When you try to access a file share or print share, the Active Directory will validate you. More specifically, if you're sitting at machine A and try to access a file in a file share on member server B, then B asks A who the heck you are so that B can then determine whether or not to let you get to the file. A and B then end up going over to a domain controller to get you validated. So, again, AD provides a central database of user accounts that Microsoft-based file servers can rely upon for authentication. But let's take a closer look at why that's useful, and how it can be even *more* useful.

Suppose I have 10,000 users, 10,000 workstations (one of which is machine A) and 500 servers (one of which is machine B). Any one of my 10,000 users should be able to get to any one of my

servers and potentially access those servers' files or printers, unless I've specifically denied them access to something. And any one of my 10,000 users should be able to sit down at any one of my 10,000 workstations, log in and do some work. But how would I accomplish this without a domain? I'd have to re-enter every one of my 10,000 user accounts into each one of my workstations' SAM file, and each one of my servers' SAM file. Arrgh.

The beauty of a domain is that we anoint a small number of servers to hold onto a database of users and passwords—the NTDS.DIT—and then provide a service to the rest of the network whereby a system can say, “Hey, I’m server B, and there’s a guy at workstation A claiming to be Mark, is he really Mark?” It’s a central service, just like a file service or a print service or a database service or a Web service.

We could call it a “logon service” or an “authentication service” and then call the small number of servers that provide it “logon servers” or “authentication servers.” But for whatever reason we don’t call them that; rather, Microsoft calls them “domain controllers,” usually abbreviated DCs. And note that I keep using the plural—you really want at least two DCs, *minimum*, in any domain, so that if one fails then you haven’t lost your domain database.

Domain controllers are, then, computers that

- ◆ Run some version of NT Server—to get the latest features of Active Directory, then you’ll probably want your DCs running Windows Server 2003. But you can sometimes get away with having a mix of DCs running 2003, Windows 2000, and even NT 4.
- ◆ Maintain the database of domain information.
- ◆ Ensure that their copies of the domain information are consistent: if you have five DCs in your network, then part of what keeps those DCs busy is a process called *replication* whereby the DCs keep each other up to date on database changes, such as when you create a new user account, change a password, or the like.
- ◆ Provide an authentication service that other computers can rely upon to log on users. (And machines, for that matter, as you’ll see.)

### DEFINING THE DOMAIN: “TRUST”

So now we’ve got a server that can authenticate a user, a DC. But for whom will it do this authenticating? Not just any system. A PC (whether workstation or server) can only use a domain’s DCs to authenticate if that PC “joins” a domain to become a “domain member.” Systems that are not members of any domain can only authenticate using the user accounts in their local SAM file; systems that are domain members can either authenticate a user with those local SAM accounts or ask one of their domain’s DCs to authenticate the user. In the world of Microsoft networking, we say that systems not in any domain *trust* only their local SAM, but that systems in a domain *trust* their SAM and their domain’s DCs. Joining a domain creates a “trust relationship” between the PC and the DCs. Before a workstation will trust a domain controller to provide it with logon services and before a domain controller will trust a workstation enough to *provide* those logon services, Microsoft software requires the agreement both of a domain-level administrator and a workstation-level administrator. When you join a machine to a domain, you are typically logged in using an account that workstation recognizes as a local administrator, but when you try to join the machine to a domain, you’ll see that the domain then comes back and says, “Now I need to see an administrative account that the *domain* recognizes.” Just as a treaty between two countries requires signatures from leaders of *both* countries, so also

does trust between machines and domains require authorization from both local and domain-level admins.

But trusts can go further than that. As you'll see later in this chapter, you can create trust relationships not only between machines and domains, but between domains and domains. Thus, if my PC is a member of the bigfirm.biz domain and if the bigfirm.biz domain trusts the minasi.com domain, then my local DCs can authenticate information about not only user accounts in bigfirm.biz but also about user accounts in minasi.com. What you've seen here, then, is that

- ◆ A domain is a group of machines that trust a given domain's DCs, and
- ◆ Domains can be configured to trust one another.

That brings up another benefit of Active Directory: automatic trust relationships. Under NT 4, trusts tended to be fragile and would sometimes break for no reason. Active Directory enables you to build larger networks by making the process of building and maintaining multidomain networks easier. Where once an administrator of a multidomain network had to build and maintain a complex system of trust relationships, Active Directory lets you build a system of domains called a *forest*. A forest's main strength is that once a group of domains has been built into a forest, the trusts are *automatically* created and maintained. There are additionally smaller multidomain structures called *trees* that also feature automatic trusts; you'll read more about trees and forests later in this chapter.

#### AUTHENTICATING FOR MANY VENDORS

"Please, can't we set things up so I only need to remember *one* password?"

AD domains let us set up a bunch of Microsoft OS-based file and print servers to centralize authentication. But AD can do more. When fully implemented, the Active Directory can save you a fair amount of administrative work in other network functions as well.

For example, suppose your network requires SQL database services. You'll then run a database product such as SQL Server or Oracle on the network. But adding another server-based program to your network can introduce more administrative headaches because, like the file and print servers, a database server needs authentication and authorization support. That's because you usually don't want to just plunk some valuable database on the network and then let the world in general at it—you want to control who gets access.

So the database program needs a method for authentication and authorization. And *here's* where it gets ugly: In the past, many database programs have required their administrators to keep and maintain a list of users and passwords. The database programs required you to duplicate all that work of typing in names and passwords—to redo the work you'd already done to get your Novell, Linux, NT, or whatever type LAN up and running. Yuk. But it gets worse. Consider what you'd have to do if you ran both some version of NT as a network operating system *and* Novell NetWare as a network operating system: Yup, you're typing in names and passwords yet again. Now add Lotus Notes for your e-mail and groupware stuff, another list of users, and hey, how about a mainframe or an AS/400? More accounts.

Let's see—with a network incorporating NT, Oracle, NetWare, and Notes, each user owns *four* different user accounts. Which means each user has *four* different passwords to remember. And, every few months, four different passwords to remember to change.

This seems dumb; why can't we just type those names and passwords once into our Active Directory domain controller and then tell Oracle, NetWare, and Notes to just ask the local

domain controller—we'll have more than one DC—to check that I am indeed who I say I am rather than making Oracle, NetWare, and Notes duplicate all of that security stuff? Put another way, we have a centralized computer that acts as a database server, another that acts as a centralized e-mail server, another as a print server—why not have a centralized “logon” server, a centralized “authentication” server? Then our users would only have to remember (and change) one password and account name rather than four.

Centralized logons would be a great benefit, but there's a problem with it: How would Notes actually *ask* a server acting as an AD domain controller to authenticate? What programming commands would an Oracle database server use to ask a Microsoft “logon server” (the actual term is *domain controller*, as you've already learned) whether a particular user should be able to access a particular piece of data?

Well, if that domain controller were running NT 4, the programming interface wouldn't have been a particularly well-documented one. And third parties such as Oracle, Lotus, and Novell would have been reluctant to write programs depending on that barely documented security interface because they'd be justifiably concerned that when the *next* version of NT appeared (Windows 2000 Server—recall that it was the first version of NT to support Active Directory domains), then Microsoft would have changed the programming interface, leaving Lotus, Novell, and Oracle scrambling to learn and implement this new interface. And some of the more cynical among us would even suggest that Lotus and Oracle might fear that Microsoft's Exchange and SQL Server would be able to come out in Windows 2000 Server-friendly versions nearly immediately after Windows 2000 Server's release.

Instead, Microsoft opted to put an industry-standard interface on its Active Directory, an interface called the Lightweight Directory Access Protocol (LDAP). Now, LDAP may initially sound like just another geeky acronym, but it's more than that—what Microsoft has done by putting an LDAP interface on the Active Directory is to open a doorway for outside developers. And here's how important it is: Yes, LDAP will make Oracle's or Lotus's job easier should they decide to integrate their products' security with NT's built-in security. (They haven't yet, to my knowledge. I guess Microsoft's got to support more than just LDAP to win Larry Ellison's trust.) But LDAP also means that it's (theoretically, at least) possible to build tools that create Active Directory structures—domains, trees, forests, organizational units, user accounts, all of the components. It means that if we like AD but hate Microsoft's AD administration tools, then some clever third party can just swoop in and offer a complete replacement, built atop LDAP commands.

This, after you spend a bit of time with the Microsoft Management Console, may not seem like a bad idea—but I'll leave you to make your own judgment about that once you meet the MMC.

## Searching: Finding Things on the Network

Thus far, I've been talking about the directory service as if it only contains user accounts. But that's not true—the DS not only includes directory entries for people, it also contains directory entries describing servers and workstations. And that turns out to be essential, for a few reasons.

### FINDING SERVERS: CLIENT-SERVER RENDEZVOUS

Client-server computing is how work gets done nowadays. You check your e-mail with Outlook (the client), which gets that mail from the Exchange machine down the hall (the server). You're at your PC (the client) accessing files on a file server (the server). You buy a shirt at L.L. Bean's Web server (the server) from your PC using Internet Explorer (the client).

In those three cases, the copy of Outlook on your desktop had to somehow know where to find your local Exchange server, you couldn't get files from your file server until you knew which file server to look in, and you couldn't order that shirt until you'd found the address of the L.L. Bean Web server, [www.llbean.com](http://www.llbean.com).

In every case, client-server doesn't work unless you can help the client find the server, hence the phrase *client-server rendezvous*. In the Outlook case, your mail client knows where your mail server is probably because someone (perhaps you) in your networking group set it up, feeding the name of the Exchange server into some setup screen in Outlook. You may have found the correct file server for the desired files by poking around in Network Neighborhood in Windows 9x, or in the My Network Places if your workstation is running Windows 2000 Professional or XP Pro, or perhaps someone told you where to find the files. You might have guessed L.L. Bean's address, saw it in a magazine ad, or used a search engine like Google.

Those are three examples of client-server rendezvous; many more happen in the process of daily network use. When your workstation seeks to log you in, the workstation must find a domain controller, or to put it differently, your "logon client" seeks a "logon server." Want to print something in color and you wonder which networked color printers are nearby? More client-server rendezvous.

In every case, the Active Directory can simplify the process. Your workstation can ask the Active Directory for the names of nearby domain controllers. You can search the Active Directory for keywords relevant to particular file shares and printers. And, to use an example of how applications built for AD can exploit AD's built-in tools, Exchange 2000 stores its user information in the Active Directory, so Exchange can use AD's search tools to look up e-mail names, so the Exchange programmers didn't have to reinvent any wheels.

### NAME RESOLUTION AND DNS

But merely getting the name of a particular mail, Web, print, or file server (or domain controller) isn't the whole story. From the network software's point of view, [www.llbean.com](http://www.llbean.com) isn't much help. To get you connected to the Bean Web server, the network software needs to know the *IP address* of that server, a four-number combination looking something such as 208.7.129.82. That's the second part of client-server rendezvous.

In the case of a public Web site such as Bean's, your computer can look up a Web server by querying a huge network of publicly available Internet servers called the Domain Name System, or DNS. The public DNS contains the names of many machines you'll need to access, but chances are good that your company's internal network doesn't advertise many of its machines' names on the Internet; rather, your internal network probably runs a set of private DNS servers.

After its inception in 1984, DNS didn't change much. But 1996 and 1998 brought two big changes referred to as RFC 2782 and RFC 2136 (you read about them in Chapter 7), transforming DNS into a naming system that's good not only for the worldwide Internet but also for internal intranets. Many of the pieces of DNS software out in the corporate world don't yet support 2782 and 2136, so it's a great convenience that Server 2003's DNS server supports those features.

### Creating New Types of Subadministrators

The next network challenge becomes apparent after a network has grown a bit. When a network is small or new, a small group of people do everything, from running the cables and installing the LAN adapter boards to creating the user accounts and running the backups. As time goes on and the

network gets larger—and more important to the organization—two things happen. First, the organization hires more people—*has* to hire more people because there are more servers to tend and user accounts to look after—to handle all the different parts of keeping a network running. And second, networks get political: All of a sudden, some of the higher-ups get clued to the fact that *what those network geeks do affects their ability to retain their power in the organization.*

Both of those things mean that your firm will soon start hiring more network helpers. In some organizations, these newly created positions get to do much of the scut work of network administration, stuff that is (a) pretty simple to train people to do and (b) of no interest to the old-timer network types. Examples of the I-don't-want-it-you-can-have-it jobs in a network include:

**Resetting passwords** For security's sake, we usually require users to change their passwords every couple months or so. We also inveigh against the evils of writing those passwords down, so it's pretty common for users to forget what their most recently set passwords are. Resetting passwords to some innocuous value is something that really needs to be done quickly—the natives get restless when you take a week to let them back on the network—and it's a relatively simple task, so it's perfect for the newly hired, minimum-wage network assistant.

**Tending the backups** For tediousness, nothing matches the sheer irritation of backups. Most of us are forced to use tape drives for backups and, well, some days it seems like tape drives were invented by someone who was abused by network administrators as a small child. They're balky, prone to taking vacations at random times, and you never can predict exactly how much data you can get on 'em—eight gigs one day, three the next, and as a result, *someone* has to be around ready to feed in another blank tape. And somebody's got to label them and keep track of them; ask most network admin types what job they'd most like to give someone else to worry about, and backups are likely to be at the top of their wish list.

Hiring a few low-wage backup watchers and password fixers also gives a firm a sort of a “farm team,” a place to try out folks to see if they're capable enough to learn to eventually become network analysts with more responsibilities (and, they hope, more salary).

But regular old users can't do things like resetting passwords and running backups—you need at least some administrative powers to do those things. Recall that you'd like to hire this “network scut-work” person or persons at a pretty low hourly rate, and that's troublesome from a security point of view. If he can leave this job and go off to one with the same pay level but whose main challenge is in remembering to say, “Would you like fries with that?” then it might not be the brightest idea to give him full administrative control over the network. Is there a way to create a sort of partial administrator?

NT 4 domains gave us *some* of that, as there was a prebuilt group called Backup Operators, but there wasn't a Reset Password Operators group, and besides, all NT 4 offered was a small set of prebuilt groups of types of administrators—the groups were called Server Operators, Account Operators, and Backup Operators—with different levels. There wasn't a way to create a new type of group with a tailor-made set of powers. Active Directory domains change that, offering a sometimes bewildering array of security options.

## Delegation: Subdividing Control over a Domain

In the last section, I offered two examples of things that might motivate a change in how the network works—a growing set of network duties that require some division of labor (which I covered in that section) and growing attention from upper management as it becomes increasingly aware of the

importance of the network in the organization. That second force in network evolution is perhaps better known as *politics*. Despite the fact that it's something of a bad word, we can't ignore politics (it's the eighth layer of the OSI model, after all), so how does Active Directory address an organization's political needs?

To see how, consider the following scenario: Some fictitious part of the U.S. Navy is spread across naval facilities across the world, but perhaps (to keep the example simple) its biggest offices are in San Diego, California, and Norfolk, Virginia. There are servers in San Diego and Norfolk, all tended by different groups. For all of the usual reasons, the officers in charge of the Norfolk facility don't want administrators from San Diego messing with the Norfolk servers, and the San Diego folks don't want the Norfolk guys anywhere near *their* servers, with the result that the Navy technology brass wants to be able to say, "Here's a group of servers we'll call Norfolk and a group of users we'll call Norfolk Admins. We want to be able to say that only the users in Norfolk Admins can control the servers in Norfolk." They want to do the same thing for San Diego. How to do this?

Well, under NT 4, they could do it only by creating two separate security entities called *domains*. Creating two different domains would solve the problem because separate domains are like separate *universes*—they're not aware of each other at all. With a Norfolk domain and a San Diego domain, they could separate their admins into two groups who couldn't meddle with one another. It's a perfectly acceptable answer and indeed many organizations around the world still use NT 4 in that manner—but it's a solution with a few problems.

For one thing, enterprises usually want *some* level of communication between domains, and to accomplish that, the enterprises must put in place connections between domains. We've briefly discussed these connections between domains before—they're called *trust relationships*. Without a trust relationship, it's flatly impossible for a user in one domain to access something—a printer, a file share, a mail server or the like—in another domain. The simple process of having a user in one domain access a resource in another requires a logon; the domain that contains the resource (printer, file share, mail, and so on) must recognize and log in the user. But there's no way for the resource-owning domain to even *try* to log in a user from the user's domain unless the two domains have been "introduced"—that is, unless administrators from each of the two domains have agreed to allow their domains to trust one another.

Specifically, here's how the Navy would solve its problem with NT 4 domains:

- ◆ First, they'd create two different NT 4 domains. NT 4 domains had names of up to 15 characters, so they might call the two domains NORFOLK and SANDIEGO.
- ◆ When created, every NT 4 domain automatically creates a user group called Domain Admins. Anyone in that group has complete and total control over the domain. So they'd just put the people that they wanted to be Norfolk administrators into the Domain Admins group of the NORFOLK domain, and put the people that they wanted to make San Diego admins into the Domain Admins group in the SANDIEGO domain.
- ◆ Once those domains were created, they'd next create a user account for each person at the Norfolk facility in the NORFOLK domain and create a user account for each person at the San Diego facility in the SANDIEGO domain. Similarly, any member servers and workstations in Norfolk would join the NORFOLK domain and member servers and workstations at San Diego would join the SANDIEGO domain.

- ◆ Finally, they'd create a trust relationship between NORFOLK and SANDIEGO or, actually, they'd create *two* trusts, as NT 4-style trusts are one-way only. Two domains can only trust one another if the domain administrators on both sides agree, so both the NORFOLK and SANDIEGO Domain Admins groups would have to cooperate to create the "NORFOLK trusts SANDIEGO" trust and the "SANDIEGO trusts NORFOLK" trust.

This would work, but it might not be the most convenient thing to keep running. For one thing, I've already explained that NT 4 trust relationships can be quirky and unreliable, and this model relies upon two of those trusts. With AD domains, in contrast, the Navy need only create *one* domain and then divide it up using a notion that first appeared in the Microsoft world with Active Directory—a concept called *organizational units*, usually abbreviated *OUs*.

More specifically, the Navy would solve their problem using Active Directory this way:

- ◆ They'd create one domain named (for example) navy.mil. (Recall that AD domains have DNS-like names.)
- ◆ Inside navy.mil, they'd create an organizational unit named Norfolk and another San Diego. They would set up their servers and then place each server into the proper OU.
- ◆ Also inside navy.mil, they'd create a user group named Norfolk Admins, and another named San Diego Admins. They'd create accounts for their users and place any administrators into their proper group, depending on whether they were based in San Diego or Norfolk.
- ◆ Finally, they'd give the San Diego Admins group complete control over the San Diego OU and give the Norfolk Admins group complete control over the Norfolk OU.

Let me clarify two things at this point. First, understand that the San Diego Admins (kinda sounds like a baseball team, doesn't it?) didn't have any power until someone explicitly gave them control of the San Diego OU. There's no magic in Active Directory that says, "Well, there's an OU named San Diego and a group named San Diego Admins, I guess that must mean I should let these Admin guys have total control over the servers in the San Diego OU." You have to create that link by *delegating control* of the San Diego OU to the user group San Diego Admins. (There's a wizard that assists in doing this, as you'll see when we walk through a delegation example later in this chapter.) You'll see that OUs are a useful tool for building large and useful domains.

Second, the fact that AD domains have DNS-like names and OUs are subunits of domains leads people to think that OUs also get DNS-like names. For example, many people presume that the Norfolk OU of navy.mil would be named norfolk.navy.mil or something like that. But that's not true—while you name *domains* using DNS, you name just about everything else in Active Directory using LDAP naming conventions. You can safely avoid a lot of LDAP, but just for completeness' sake, here's the LDAP name of Norfolk: "ou=Norfolk,dc=navy,dc=mil." You'll meet more LDAP later.

## Satisfying Political Needs

"That's *my* data, so I want it on *my* servers!" As information has become the most important asset of many firms—for example, I once heard someone comment that the majority of Microsoft's assets resided in the crania of their employees—some firms have been reluctant to yield control of that information to a central IT group. Nor is that an irrational perspective: if you were in charge of maintaining a five-million-person mailing list, and if that list generated one half of your firm's sales leads,

then you might well want to see that data housed on a machine or machines run by people who report directly to you.

Of course, on the other side of the story there is the IT director who wants Total Control of all servers in the building, and her reasoning is just as valid. You see, if a badly run server goes down and that failure affects the rest of the network, it's *her* head on the chopping block.

So on the one hand, the department head or VP wants to control the iron and silicon that happens to be where his data lives, and on the other hand, the IT director who's concerned with making sure that all data is safe and that everything on the network plays well with others wants to control said data and network pieces. Who wins? It depends—and that's the “politics” part.

What does Active Directory do to ameliorate the political problems? Well, not as much as would be nice—there is no “make the vice presidents get along well” wizard—but AD's variety of options for domain design gives the network designers the flexibility to build whatever kind of network structure they want. Got a relatively small organization that would fit nicely into a single domain, but one VP with server ownership lust? No problem, give her an OU of her own within the domain. Got a firm with two moderately large offices separated by a few hundred miles? Under NT 4, two domains and a trust relationship would be the answer, and you could choose to do that under AD, but that's not the only answer. As AD domain controllers are extremely parsimonious with WAN bandwidth in comparison with NT 4 DCs, you might find that a single domain makes sense as it's easier to administer than two domains, but it's not impossible from a network bandwidth point of view. And bandwidth utilization is our next topic.

## Connectivity and Replication Issues

More and more companies don't just live in one place. They've purchased another firm across the country, and what once were two separate *local* area networks is now one firm with a wide area network need. If that WAN link is fast, then there's no network design headache at all: Hook the two offices up with a T1 link and you can essentially treat them as one office.

That's beneficial because each site will usually contain a domain controller—one of those servers that hosts the Active Directory database and which acts as a machine to accomplish logins. But those domain controllers must communicate with each other whenever something changes, as when a user's password changes or when an administrator creates a new user account. This is called *Active Directory replication*. The same thing happened with NT 4, as NT 4 also allowed you to put multiple domain controllers in an enterprise.

In NT 4, suppose you had two offices connected by a slow WAN link. Suppose further that you had a domain controller in each of these offices. They needed to replicate their SAM database between domain controllers. NT 4's domain controller updates happened every five minutes. That means that a domain controller might try to replicate changes to another domain controller every five minutes, even if they're only connected with a very slow link. All that chatter could well choke a WAN link and keep other, more important traffic from getting through.

AD improves upon that by allowing you to tell Windows 2000 and Server 2003 domain controllers about how well they're connected. The idea is that you describe your enterprise in terms of *sites*, which are basically just groups of servers with fast connections—groups of servers living on the same local area network, basically. You can then define how fast (or probably, slow) the connections *between* those sites are, and AD will then be a bit smarter about using those connections.

In particular, Windows 2000 Active Directory servers compress data before sending it over slow WAN links. Taking the time to compress data requires a certain amount of CPU power, but it's well worth it, as AD is capable of a 10:1 compression ratio! You'd think that would make everyone happy, but some folks would prefer that AD *not* spend CPU power doing the compression and decompression, as they've got bandwidth to burn. For them, Server 2003–based ADs offer an improvement over Win2K-based ADs: you can now choose to shut off compression.

Not only do we often face slow links, we often must live with *unreliable* links, ones that are up and down or perhaps only up for a short period of time every day. Active Directory lets you define not only a WAN link's speed but also the times that it is up. All in all, site control makes life considerably easier for those managing multi-location networks.

## Simplifying Computer Names or “Unifying the Namespace”

We discussed this in the previous chapter, but it's worthwhile revisiting the topic of names, particularly if you're new to Microsoft networking.

Devices on a network mainly identify themselves by some long and unique identification number. On an intranet or the Internet, it's a unique 32-bit address called an *IP address*. Networks also commonly exploit a 48-bit address burned into each network interface card called a *MAC address*. Any Ethernet, Token Ring, ATM, or other network interface has one of these addresses, and conventions that network manufacturers have agreed upon ensure that no matter from whom you buy a NIC, it will have a 48-bit address that no other NIC has. Some parts of Windows NT, 2000, or Server 2003 identify PCs by their IP address (or addresses—a machine with multiple NICs will have an IP address and MAC address for each NIC), others by the PC's MAC address or addresses.

But people don't relate well to long strings of numbers—telling you that you can send me mail to `mark@11001110111101101111110111001000` is technically accurate (presuming that you can find a mail client that will accept network addresses in binary) but not very helpful. It's far more preferable to be able to instead tell your mail program to send mail to `help@minasi.com`, which you can do. Somehow, however, your mail client must be able to look up `minasi.com` and from there find out where to send mail for `minasi.com`. In the same way, pointing your Web browser to `www.microsoft.com` forces the browser to convert `www.microsoft.com` into the particular IP address or addresses that constitute Microsoft's Web site. This process of converting from human-friendly names such as `minasi.com` to computer-friendly addresses such as `11001110111101101111110111001000` is called *name resolution*. It's something every network must do.

So why is name resolution a problem with NT? Because most of the networking world uses *one* approach to name resolution, and up through version 4, NT used a different one.

Most every firm is either on the Internet or has an internal intranet, or both. Intranets and the Internet use a form of name resolution called the Domain Name System, or DNS. DNS names are the familiar Internet names such as `www.microsoft.com`. In contrast, Microsoft networking has for years used a different and incompatible naming system called NetBIOS names, which are simpler—no more than 15 characters long, no periods.

PCs resolve DNS names by consulting a group of servers around the world called, not surprisingly, *DNS servers*. Your company or Internet Service Provider operates one or more DNS servers and your Internet software uses these nearby DNS servers to resolve (for example) `www.minasi.com` to the Internet address 206.246.253.200.

NT-based networks using Internet software don't use DNS for much of their work. Instead, Microsoft invented its own name servers somewhat like DNS but using NetBIOS names; they called these name servers Windows Internet Name Service, or WINS, servers.

That leads to this problem: Nearly every firm is on the Internet—*has* to be on the Internet—and so every firm must give DNS names to their computers. But if they're also using NT, then they need to give their systems NetBIOS names. That in and of itself is not a great burden; what *is* a burden is that these names are important to the programs that use them, and programs can typically need one of the two names and can't use the other of the two.

Let's take an example. Suppose someone wants to log in to an NT 4 domain at Bigfirm. To accomplish that, her workstation must find a domain controller for that domain. Her workstation does that by searching for a machine with a particular NetBIOS name. Let's say that Bigfirm does indeed have a domain controller around named LOGMEIN (its NetBIOS name) that *also* acts as a Web server with the DNS name reptiles.pictures.animalworld.com, as it hosts pages of local reptile pictures. Let's also suppose that for some reason Bigfirm has no WINS servers but has a great network of DNS servers.

DNS names are of no value to the workstation looking for a logon to an NT 4-type domain. You could have the finest set of DNS servers in the world, but it would make no difference—without a functioning WINS server, that workstation would probably be unable to locate a domain controller to log you in. On the other hand, if someone sitting at that same workstation sought to view the reptile pictures on <http://reptiles.pictures.animalworld.com>, she'd just fire up Internet Explorer and point it at that URL. Internet Explorer is, of course, uninterested in NetBIOS names, relying mainly on DNS names. The workstation would quickly locate the Web server and browse its pages, even as that same workstation was unable to detect that the very same server could perform logins.

With the advent of Windows 2000's Active Directory it seemed that NetBIOS would soon go away, taking WINS with it, as AD uses DNS. But there's so much old stuff out there—Windows 9x systems, NT 4 systems and the like—that it appears that even most Server 2003-based networks will still use NetBIOS and WINS to talk to at least some of their clients and software. Eventually, however, WINS will be just a bad memory. But not yet!

## Enabling Centralized Support Tools

Put simply, there just plain aren't enough support people around but there's no shortage of users to support. In 1987, many firms retained one support person for every 100 users; in many companies nowadays, that ratio is more like one support person for every 2,000 users.

That means that where it was once possible for a support person to physically visit every user's PC to perform support tasks, it's just not reasonable to expect any more. Support people need tools that allow them to get their support work done from a central location as much as is possible. And, although not every user is all that happy about it, one way to simplify a support person's job is to standardize each PC's desktop. In some cases, support staffs need software tools to allow them to *enforce* that standard desktop. (As you can imagine, it's a political issue for many firms.)

In NT 4, Microsoft started helping support staffs centralize their desktop control with something called *system policies*. But system policies were lacking in a few ways. The Active Directory improves upon system policies with a kind of "system policies version 2" called *group policies*. AD becomes a great support tool because basically, AD is a database, as you've already read. But in addition to being a database of users and machines, it's also the place that Windows 2000 and later store much of their administrative information. In the following sections, I'll give you some examples.

### AD STORES ZERO ADMINISTRATION INFO

Ever had to rebuild a user's workstation from scratch? How long did it take—would you measure it in minutes, hours, days, or weeks? There are commercial tools such as Symantec's Ghost that can assist in that task, but Windows 2000 and Server 2003 has a Ghost-like tool built right in called the Remote Installation Services, as you read in Chapter 5. RIS lets you take a new computer right out the box, plug it into the network, and boot a floppy. The floppy gets the computer onto the network and locates an Active Directory server. From there, AD takes over and directs the process of getting a working disk image onto the workstation in 30 to 45 minutes, unattended. The information about where to keep those disk images and who gets which ones is stored in AD.

Anyone who's ever struggled with system policies under NT 4 knows that they're no picnic: You've got to generate a NTCONFIG.POL file, put it on a domain controller, and set up replication for NTCONFIG.POL among domain controllers. With Windows 2000, however, all of the system policy stuff—which is now called *group policies*—is stored and automatically replicated by AD.

Ever tried to “push” out an application with SMS or a similar tool? Again, no fun. But one of AD's functions is to store and decide who gets what applications.

### AD SUPPORTS DIRECTORY-ENABLED NETWORKING

Windows 2000, XP, and Server 2003 allow you to control bandwidth within your intranet using QoS (Quality of Service) control in TCP/IP. You can, then, say that a particular person should get more bandwidth on Tuesday afternoons when she needs it for videoconferencing. And where is that information stored? In the Active Directory.

### AD WILL EVENTUALLY REPLACE THE BROWSER

Over the years, Microsoft has gamely tried to support a simple way of browsing the servers on your local network. First called the Browser, then Network Neighborhood, the whole idea was that you could just open up a window and see what was available on your company's network. You'd first see the servers, and then you could drill down into a particular server to see its file and print shares.

The problem with the Browser has always been that Microsoft's networking model grew out of a peer-to-peer paradigm rather than a client-server model. Rather than letting a central server maintain a list of available servers, Microsoft's Browser depended on servers finding each other and electing one of their numbers to act temporarily as the keeper of the server list. It was a good try, but it never really worked that well and over the years, the cry, “Why can't I see [my computer, some server, anything at all] in Network Neighborhood?” has wasted person-millennia of support time.

The Browser still exists in Server 2003, but it's slowly being supplemented by a central list of servers and shared resources maintained on the Active Directory—this is another aspect of the slow passing of NetBIOS that I've referred to before. That list includes the names of servers, the shares available on the system, and the printers available on the system. As more and more AD-aware applications appear, we'll see AD act more and more as the place to go to find network services. But enough overview, let's get down to some details.

## Understanding and Using Active Directory's Features

With the overview out of the way, let's next dig into some details. And AD has a *lot* of details!

NT 4 domain designers had just a few tools: domains, user accounts, machine accounts, groups, and trust relationships. AD designers, in contrast, have all of those things and also the extra tools of organizational units, trees, forests, and sites.

In this section, I'll give you an overview of AD's main enterprise-building tools:

- ◆ Domains
- ◆ User and machine groups
- ◆ Organization units
- ◆ Sites
- ◆ Trees of domains
- ◆ Forests of trees of domains
- ◆ Group policies

## Domains

The typical way to explain an AD domain is to say that it is “a security boundary” and that it uses “multimaster replication.” That's true, but it's not very illuminating, so let's see what it means.

As you've read earlier in this chapter, every network with any kind of security at all needs to keep a list of information about users—the names, passwords, and other information about people authorized to use the system. You also read that once you've got more than one machine, you run into a problem—how to share that list with all of the machines in our company? Recall that you do that by setting up a small number of servers called domain controllers with a database of your users, a database named `NTDS.DIT`. The member servers and workstations still have their lists of *local* user accounts, a list maintained in a file named `SAM`, but in most cases you won't make much use of these local accounts—rather, you configure your workstations and members servers to *trust* the list of users on the domain controllers. When someone tries to sit down at a workstation and claims to be a member of your domain, then the workstation takes the name and password offered by the user and hands it to the DC, saying, “Is this a valid username and password on your domain database?” And, again, if the DC says that the name/password combination is OK, then the workstation *trusts* that the DC is telling the truth.

Where the “security boundary” stuff comes in is if you have more than one domain. If Bigfirm had two AD domains, one named `bigfirm.biz` and the other named `coolstuff.com`, then as an employee of Bigfirm I would have a user account—but the user account would have to live in *either* `bigfirm.biz` or `coolstuff.com`. There's no such thing as dual citizenship. (I could, of course, have more than one user account, but again each one exists in one and only one domain.) Similarly, a workstation, member server, and DC are members of one and only one domain.

As I've said before, the heart of any domain is a database of some kind. But a database of what? I've used the example of user accounts so far—each user account is just another record in the domain database. But what *other* kinds of things do we keep in that database? Lots, in fact. Every machine that's a member of the domain has a machine account. OUs are described by records in the AD; so are sites. Group policies, the linchpin of central AD support, which we'll be talking about a lot for the remainder of the book, are all stored in things called group policy objects or GPOs—and GPOs are just records in the AD database. AD stores records that describe file shares, printer shares, groups of users, DNS information, something called a “contact” that we'll take up later, and more.

In fact, a programmer can tell an AD to store just about anything that he wants in its database. Which leads me to an interesting thing about the particular engine that drives the Active Directory: it's a database engine that uses *multimaster replication*. The second part, “replication,” refers to the

process that ensures that every copy of the domain database matches every other one. In other words, if I'm sitting in the Topeka office and I create a user account, then that new record—the user account—exists only on the Active Directory DC in Topeka at that moment. Part of the job of AD's database engine is to get that new information out to the other DCs as quickly as is reasonably possible—that's replication. The “multimaster” part comes from the fact that you can insert a change into the AD database from any DC. That's a change from many replicated database approaches, including the one for NT 4—with NT 4, you could have lots of DCs, but only one of them accepted database changes. Whether creating a new user account, changing a password, or joining a machine to a domain, the resulting modification to the domain's SAM had to happen on the one machine with the ability to change the SAM database—the machine called the *primary* domain controller. AD mainly does away with the idea of a primary domain controller, and all DCs are basically equal. (That's only “basically” because of something called *operations masters* that I'll cover later in this chapter.)

Take the facts that (1) DCs are just database servers, (2) they do multimaster replication, and (3) that programmers can add whatever kind of data that they want to the domain database, and you now have a kind of interesting result: DCs are collectively the basis of a fairly flexible distributed database system, whether it contains user and machine accounts or not. That's why with Server 2003 Microsoft now offers you the ability to set up a bunch of what are essentially DCs that do multimaster replication amongst themselves...but that do not have a domain. The idea is that some folks might find AD's database engine useful but might not want a domain. For those people, Microsoft offers Active Directory in Application Mode or ADAM.

So when understanding what AD can do and what it requires in mind, remember that it is, at its base, a database maintained by a bunch of database servers. If you have database experience, you'll see some of the ramifications of this:

- ◆ Databases can be more or less flexible—SAM was pretty inflexible and didn't let you add things. AD, in contrast, is very flexible.
- ◆ Databases with more than one database server must solve the problem of maintaining database consistency between the servers. AD's multimaster replication system is nice, but you will, as you'll see in this chapter, sometimes run into problems when one DC just plain can't get up-to-date with the other DCs. That's not a problem that I ever ran into with NT 4's simpler “one master, many slaves” replication model—more power usually means more complexity and more things that can break.
- ◆ Databases use query languages that anyone wanting to write programs or scripts relevant to domain work must know. Active Directory offers several, but the two most common are LDAP and something called the Active Directory Scripting Interface or ADSI.
- ◆ Databases often have size limitations. As you've read, NT 4 domains started falling down around 5,000 accounts. In contrast, Microsoft says that AD can handle a few million objects. That's not a hard limit, however. A former Compaq techie put 100 million records in an Active Directory and not only did it work, it worked *fast!* AD could respond to queries on that directory in a second or two.
- ◆ Databases need defragmentation and garbage collection periodically. Active Directory does some of that automatically, or you can take it offline now and then and give it a thorough cleaning with a tool called NTDSUTIL. (You'll meet that tool in this chapter a few times.)

- ◆ Databases need disaster recovery scenarios. You can back up and restore an AD using the built-in Backup utility that comes with Server 2003.
- ◆ Databases need security, controls on who can modify what, when and where. Active Directory lets you set security down to the record level—if you really wanted to, you could say, “The only person who can modify Joe’s account is Sue.”

That’s basically how domains are structured; now let’s look at a great time saver for managing access to things in a domain: groups.

## User (and Now Machine) Groups

Much of a network engineer’s job involves using the built-in security features of a network OS to enforce company policy. For example, there might be files on the network that only the managers of the Manufacturing division should see. If people were all trustworthy, then you could just mark a file “Manufacturing managers only, please” and leave it at that. But sadly, they aren’t, so NT in all of its forms has always included the notion of file *permissions*, meaning that you can attach a list to any file or group of files, a list that describes who may access those files and what level of access they should enjoy. This way you can protect that Manufacturing-only file by applying permissions to it that restrict its access to Manufacturing managers only.

But how to apply those permissions to just the Manufacturing managers? Well, of course you *could* figure out which of the user accounts belong to those managers, then you could grant access to each of those accounts one at a time. That’d be a lot of work, however, and furthermore, it would *remain* a lot of work, as you’d have to shuffle permissions around every time someone joined or left the ranks of the Manufacturing managers.

A far better answer, and one that Active Directory enables, is to create a special kind of account, which is neither a user account nor a machine account, called a *group*. You’d create a group named Manufacturing Managers—any name will do, actually. Then you can choose particular user accounts to add to that group. Finally, you’d modify the file permissions by granting access rights not to a particular user account or accounts, but instead to the group. Anyone in the group would essentially inherit file access by virtue of being a member of the group.

In other words, if Jane, Sue, and Tom are all promoted to Manufacturing Manager and you were then directed to give them access to the 10 shares that Manufacturing managers have exclusive access to, then without groups, you’d have to visit each one of those shares, adding the three names to each one. In contrast, with groups, you would have already visited those shares a long time ago and just told the shares that anyone in the group Manufacturing Managers had access to those shares. Having done that in the past, *now* all you have to do is to just add Jane, Sue, and Tom to the Manufacturing Managers group, and they instantly get access to the 10 shares.

**NOTE** Both local machine SAMs and Active Directory support groups. As you’ll see, though, SAMs support a smaller range of types of groups.

## BOTH USERS AND MACHINES CAN EXIST IN GROUPS

NT 4 didn’t let you put machine accounts into a group, and that was unfortunate, as it would have often been convenient to create groups of machines upon which to apply system policies. AD under Windows 2000 and later fixes this, and you can now have groups that contain machines, users, or a combination of those two. You cannot, however, apply group policies to groups, oddly enough—you apply them to organizational units, covered a bit later, and yes, you can put machines into OUs.

### GROUPS CAN EXIST INSIDE GROUPS INSIDE GROUPS INSIDE GROUPS

Sometimes it's convenient to put a group inside a group. For example, every server has a group built into it called Administrators. Anyone in the group is, as you'd guess, treated by that server as an administrator, someone with the power to perform any task on that server. But what if I had a group in the enterprise that I wanted to be able to act as administrators on *every* machine? Well, I *could* walk over to every single machine in the company and add each of those enterprise-wide administrators' names to the local Administrators group of each machine. Yuk. No fun.

It's a bit easier to create a group on some computer somewhere called BigDogs or something like that and make all of the enterprise-wide administrators' user accounts a member of BigDogs. Then I can visit each machine in the company and just add the BigDogs group to each of those machines' Administrators group. Sure, it's still a lot of work, but this way I only have to add *one* thing—the BigDogs group—to each Administrators group, instead of having to add a whole bunch of user accounts to each Administrators group. And if someone gets fired or hired, I need only delete/add a user account to BigDogs, and it'll automatically be recognized as a former or present BigDog.

So putting groups inside groups was something of a convenience for administrators. But Microsoft didn't want to have to worry about what might happen if you put group A inside group B, then put group B inside group C, and then accidentally put group C inside group A; that could be confusing for NT to decode. As a result, Microsoft simplified the groups-inside-groups abilities of NT. In general, it figured that there would be groups like Administrators, which really only describes a specific machine; being a member of Administrators for machine X doesn't mean that you have any power at all on machine Y—you'd have to be a member of machine Y's Administrators group for that. As these groups were really only relevant to their local machines, they were called *local* groups.

In contrast, groups such as BigDogs get created on some machine, but they're not really connected to that machine closely. BigDogs was interesting because it could be placed into the local Administrators group of some other machine. Such groups could, one supposes, be called traveling or export groups, but Microsoft called them *global* groups.

To ensure that you couldn't put a group inside a group, which was inside another group, and so on—the more exact way to say that would be “to ensure that you couldn't *nest* groups in more than one level”—Microsoft designed NT to allow you to put global groups into local groups. As a global could not go into a global, and as a local couldn't go into anything, you could not nest groups beyond one group inside another group. The net effect was one level of nesting—a global goes into a local and that's that.

Active Directory extends the notion of groups by increasing the number of group types from two to four and allowing more nesting levels. What used to be called simply a “local group,” which lived on a local SAM, is now called a *machine local* group. There is a new type of group that you can create on the domain level called a *domain local* group. Global groups work largely as they did before, although they're a bit more flexible. And an entirely new type of group, a *universal* group, lets you do just about anything that you want with it, albeit at a price in performance and compatibility with NT 4. Let's take a more detailed look, then, at Active Directory's four kinds of groups:

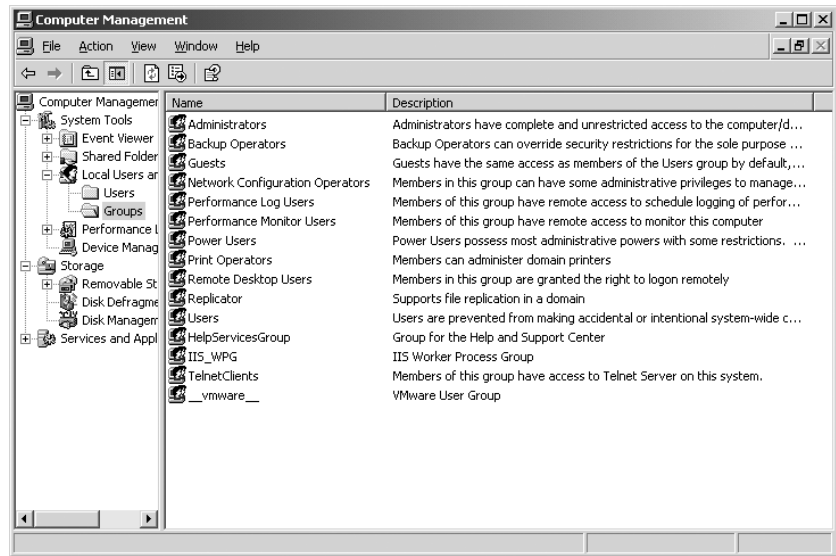

- ◆ Machine local groups
- ◆ Domain local groups
- ◆ Domain global groups
- ◆ Universal groups

### Machine Local Groups

Machine local groups do pretty much what they did before. Every machine has a SAM that contains a bunch of prebuilt groups like Administrators, Power Users, Users, Backup Operators, and the like. If you're a member of the Users group, you can log in to that machine and perform basic functions. If you're a member of the Administrators group, you can do anything. There are other groups as well; you can see a machine's machine local groups by right-clicking My Computer, then choosing Manage. An MMC window will appear. In its left panel, open System Tools. Within that, open Local Users and Groups. Within *that*, open Groups. You'll see something like Figure 8.1.

**FIGURE 8.1**

Machine local groups for Windows Server 2003 machine

Machine local groups can include global groups, as they've been able to since NT 3.1. They can also include

- ◆ Domain local groups from their home domain
- ◆ Universal or global groups from their home domain or any other domain that they trust, whether Active Directory or NT 4 domain

### Domain Local Groups

Active Directory brought two new kinds of groups: domain local groups and universal groups. Universal groups are very powerful, an answer to a prayer. Domain local groups, on the other hand, are, well, enigmatic...I've never found a use for them.

Domain local groups are, like global and universal groups, a type of group that you can only create on a domain controller—it's impossible for a workstation or member server to host a domain local group. You can put a domain local group into any of the local groups on a machine, provided that the machine is in the same domain as the domain local group. In other words, suppose bigfirm.biz has a domain local group called People. Any machine that belongs to bigfirm.biz could put the People

group in any of the machine's local groups—for example, a system could put People into its local Users group. In contrast, a machine from any other domain could *not* include People in any of its local groups.

Domain local groups can contain global groups from any trusted domain. Thus, while People can only be included in local groups in its domain, it can contain global groups from any trusted domain. Domain local groups can also contain other domain local groups, but, as you'd guess, they've got to be from the same domain.

What perplexes me about domain local groups is this: they are basically capable of only a subset of what global groups—which have existed since NT 3.1—can do. So my question is always “why bother—why not use global groups?”

### Global Groups

Global groups are the original “traveling group.” Every since NT 3.1 you've only been able to create global groups on a domain controller, and that's still true. You can put global groups in any local group of any machine living in a group that trusts the global group's domain. You can also now put global groups inside global groups, but only so long as they're from the same domain. When you want to create domain-wide groups of users so that you can easily drop those groups into local groups on a domain, global groups are the most common way to do it.

### Universal Groups

If the artificial division between groups that mainly receive other groups and user accounts (local groups) and groups that mainly exist to be placed in other groups (global groups) seems a bit contrived, well, perhaps it is. Why not just have a type of group that can contain other groups (as with a local group) and that can also “travel” to other groups (as with a global)? Historical reasons, mostly—NT 4 and earlier only supported locals and globals. Active Directory, in contrast, supports a “does it all” group, called a *universal* group. A universal group can contain *any* global or universal group from *any* domain in the forest.

I've thrown a lot of “this kind of group goes into this kind of group” stuff at you; let me summarize it with two graphics. First, Figure 8.2 summarizes a simplified version of the “what kind of group goes into what other kind of group?” relationships. In that figure, I've left out the stuff that I don't think you'll ever make use of. For the sake of completeness, however, I include Figure 8.3, which is more complete.

**FIGURE 8.2**  
Group nesting  
relationships  
simplified

**FIGURE 8.3**

More complete  
group nesting  
relationships

\* In their own domain only

The next logical question, then, is, “Okay, why don’t we use universal groups whenever we need groups?” Two reasons: First, you can’t create a universal group until all of your domain controllers are Windows 2000 or later machines (NT 4 machines can be backup domain controllers in an Active Directory domain, so long as it’s in Windows 2000 mixed functional level), and second, universal groups have a significant effect on the size—and therefore the responsiveness—of something called the *global catalog*.

### “BDCs” IN ACTIVE DIRECTORY

One reader objected to that last paragraph in the *Mastering Windows 2000 Server* book, saying that an NT 4 machine *couldn’t* be a backup domain controller (BDC) in an Active Directory for the simple reason that there *is* no such thing as a BDC under the Active Directory. The issue apparently troubled him mightily as he went on to question my competence and parentage. So in case you too are troubled, here’s why the paragraph’s right. First of all, the NT 4 domain controllers in an Active Directory domain don’t even *know* that they’re in an AD and, in fact, haven’t a clue about what an Active Directory is. They think they’re BDCs in a Windows NT 4 domain, and one—that’s right, just one—AD domain controller is, to the NT 4 BDCs, the primary domain controller. They will accept account updates from no other computer. Second of all, although Microsoft likes to say that all DCs are equal under Active Directory and later, it’s plainly not true. Some domain controllers assume a particular role called Flexible Single Master of Operations (FSMO)—something you’ll read about elsewhere in this chapter—and one of those roles is called the Primary Domain Controller FSMO. If you shut the PDC FSMO down without first anointing another DC as the PDC FSMO, then some pretty bad things will happen to your network. Yes, Microsoft has *largely* decentralized the role of domain controller with Active Directory when compared to NT 4’s domain controllers, but not *completely* decentralized those roles. It seems reasonable, then, to refer to the system running the PDC FSMO role as “the PDC” and the other domain controllers as “backup domain controllers,” even if it *isn’t* regulation Microsoft terminology. (And third, as to that parentage thing, my folks were married a good five years before I was born—I have records to prove it.)

### Mixed versus Native Mode and Universal Groups

For compatibility’s sake, Active Directory domains can include NT 4 domain controllers as backup domain controllers. But because NT 4 domain controllers don’t have the same abilities as Win2K or

Server 2003 machines, an AD domain that includes NT 4 domain controllers must forgo some of its capabilities. One of those capabilities is the notion of heavily nested groups. As universal groups are the most “nestable” of AD group types, an AD domain can’t support universal groups until all of its domain controllers are Windows 2000 or later machines; the last NT 4 domain controller must be shut off.

When first installed, Active Directory domains assume that there’s at least one NT 4 domain controller around. For safety’s sake, then, all new AD domains start up in Mixed mode and will not create universal groups.

Once all of your domain controllers are Windows 2000 or later machines, you can shift your domain to Native mode, which will allow universal groups. And while we’re on this subject, let me mention something new to Server 2003–based ADs: yet another Native mode. Just as you had to tell 2000-based ADs when the last NT 4 DC was gone in order to get the full power out of your 2000-based AD, so also must you sweep either your domain or perhaps your entire forest clean of Windows 2000–based DCs in order to get the full power that 2003-based ADs offer. There’s a sort of 2003 Native mode, although it’s not called that. Instead, if you have a domain and all of its DCs run in 2003, then you can shift that domain into Windows Server 2003 functional level. If you have a forest and all of the domain controllers in all of the domains of that forest run 2003, then you can shift the forest from its default functional level—Windows 2000 functional level—into Windows Server 2003 functional level. You’ll see as this chapter goes on that you’ll need Windows Server 2003 functional level forests before you can use many of 2003’s new AD goodies. (I’ll cover functional levels a bit later.)

### ***The Global Catalog and Universal Groups***

One reason that you sometimes wouldn’t use universal groups is because of their effect on something called the *global catalog*. But what’s a global catalog?

As I’ve hinted so far and as you’ll read a bit later, Active Directory helps you build big multidomain networks by allowing you to create a multidomain structure called a *tree* or a larger structure called a *forest*. Without stealing the later tree-and-forest section’s thunder, let me motivate the global catalog discussion by saying that one of the benefits of having a tree/forest of domains is that anyone from any domain can log in to any workstation from any other domain in the tree/forest. This is great in theory but in practice constitutes a major performance hassle. Suppose you had a forest with 50 domains: Every time you wanted to log in to a workstation, that workstation would have no idea which of the 50 domains to query to authenticate your logon. So it would have to search one domain after the other (“Hey, do you know a guy named Ralph023?”), and the result could be *extremely* slow logons.

The global catalog (GC) solves that problem. It’s an abbreviated version of *every domain in the forest*. Clearly this could get to be pretty big, but the GC remains manageable in size because it only contains a small subset of information from the Active Directory: What users each domain includes and what domain they’re from is one of those pieces of information. (There’s another value here as well, but I’ll cover it later when I discuss forests and trees.)

Another piece of information stored in the GC is the name of each global group in each domain in the forest. That wouldn’t constitute too much space and wouldn’t make the GC grow too much, but universal groups make it a completely different story: The GC not only knows all of their names, it also knows what users are members of each universal group! As a result, heavy use of universal groups could considerably slow down network logons—so it’s a good idea to use universals sparingly.

In case you're wondering, there is not, as far as I know, any tool that lets you directly browse or examine the global catalog—although some search operations use it. (And I *will* cover the GC in greater detail later—this is just a brief look at it.)

### **GROUP SIZE IS LIMITED TO 5000 MEMBERS IF NOT IN WINDOWS SERVER 2003 FOREST FUNCTIONAL LEVEL**

Groups can also contain groups, as you'll see later in this chapter, and that turns out to be useful. For some reason, groups cannot contain more than 5000 members, meaning that if you need a group with more than 5000 members, you'll have to create several groups, each with under 5000 members, and then place *those* groups into a single "super" group, then apply whatever permissions you want to that super group. Yes, it's a pain, but you can fix it...provided you upgrade every single DC in all of your forest's domains. Server 2003-based ADs solve the problem, but, again, you've got to upgrade all of the DCs to get that benefit.

**NOTE** *If the max size on a group is 5000, then what happens with the automatically created group named "Domain Users" that automatically includes every user account in the domain? Every user is a member of that group, and if you build an AD larger than 5000 users, then Domain Users doesn't crash. What's going on? The answer is that Domain Users isn't really a group—it just looks like one. It can be any size you like.*

There are a few more details about groups, but I'll leave them for now and cover them in more detail in Chapter 9. Thus far, you've seen domains, which are a way of defining a collection of users and machines that share the same security rules, and groups, which make managing access to servers easier. Next, you'll see how to subdivide a domain with organizational units.

### **Organizational Units (OUs): Subdomains**

Sometimes a domain is too large an area to cede control of. For example, suppose you've got to hire some people to act as backup operators, so you put them in the Backup Operators group. But suppose that your domain is spread out geographically, and you really only want to hire people to do backups in the St. Louis office—you don't want someone to be able to just waltz into the San Francisco office and log in to one of those machines. You'd like such people to have backup operator power, but not over the entire network—just over a subset of the network.

Or perhaps you need a staff of people who can reset passwords or manage printers or adjust permissions on a set of servers. But you don't want those folks to have those powers over the entire domain. That could be true for either geographic reasons (St. Louis and San Francisco) or organizational reasons (for example, the Marketing department might want their own password-changer person).

The answer in each case is to subdivide the domain into organizational units, or OUs.

### **ORGANIZATIONAL UNITS ARE FOLDERS**

OUs look like folders when viewed with AD's administrative tools. When you create a user account in an AD domain, you can choose to either create the account right in the domain or create it inside one of the folder-like things that you'll see in that domain. When you first create an Active Directory domain, you'll automatically get a folder named **Users** and another named **Computers**. Although it may *seem* that user accounts should go into the **Users** folder and machine accounts should go in the **Computers** folder, that's not the case at all. (That'd be too obvious.) Instead, the only real reason

for the **Users** and **Computers** folders, which are somewhat like OUs but lack an important aspect of OUs (you cannot assign group policies to **Users** or **Computers**) is so that Active Directory has a place to put any user accounts and machine accounts from an upgraded NT 4 domain. The folders are also useful because, if you use some third-party tool to create user accounts and the tool was built in the pre-AD world, then Active Directory will sense that and put any user accounts the tool creates into the **Users** folder.

### WHAT YOU CAN DO WITH OUS

OUs have two main uses. You can

- ◆ Give control of a set of user and/or machine accounts to a set of users, allowing you to, for example, define a set of people who can reset passwords in a particular department without having to make them administrators of greater power than might be desirable and furthermore restrict the range of people whose passwords they can change to a small set of users.
- ◆ Control and lock down user desktops through the use of group policy objects, control tools like NT 4's system policies; despite their name, however, group policies aren't applied to user groups—they apply to organizational units, domains, or sites.

### Using OUs to Create Subadministrators

Or suppose the Graphics department has a bunch of expensive printers shared on the network. They don't want the regular IS people controlling the printers for some reason; they want their local techies to serve as the printer admins. In that case, you could create an OU called Graphics Printers or the like and put the fancy printers into that OU. Then you can give control of that OU and, in the process, of the printers in the OU to a particular user account or perhaps a group containing the names of the admins that Graphics likes.

**NOTE** *The process of giving a user or group of users control of an OU is called delegating control of that OU. Right-click the OU and you can run the Delegation Wizard to make that adjustment. You'll see some examples of that later.*

If the International Trade and Arbitrage department's VP insists on a separate set of administrators for her servers, OUs can meet her needs. Again, just create a separate OU for her servers, a group for her admins, and delegate control of the OU to the group.

You'll see plenty more on the topic of delegation later in this chapter.

### Using OUs to Apply Policies

NT 4 introduced the idea of a *system policy*. Policies let you control user desktops through those users' Registries. You'd place in a centrally accessible location a file called `NTConfig.pol` that contained instructions about what you wanted changed on the user's Registries. NT 4 workstations would then automatically read that file and make changes to their Registries according to the file's orders. In this way, you could control Desktops from a central location.

**TIP** *That sentence seems to imply that system policies only work on NT 4 systems, but that's not true. System policies still work on Windows 2000, XP, and 2003 systems, but only if the domains that those systems live in do not offer any group policies. If a 2K, XP, or 2003 system sees any domain-based group policies then it will ignore any domain-based system policies.*

But what if you wanted to control just a subset of a domain, a collection of machines or users? You couldn't apply a system policy to a collection of machines. You could apply a system policy to a group of users, or at least in theory you could. In practice, groups and policies didn't work so well.

As I've mentioned before, Active Directory domains can offer has a much farther-reaching kind of policy called a *group policy*. (Group policies only work on 2000, XP, and 2003 systems—NT 4, Wintendo, and earlier systems don't pay attention to or use them.) You can apply group policies to subsets of a domain. The subset? Not a group, as the name suggests, but an OU.

### **The OU Policy Exception: Account Policies**

There is one case where you cannot apply policies to an OU: account policies. That means passwords (how long they can be, how often to change them) and account lockout settings. You can also, you will learn, apply policies to *sites*. Here again, policies that change any password or account lockout settings are ignored. That's the really irritating thing about this exception—no warnings. AD lets you create all the site-based or OU-based policies that you like, but if these policies try to do anything with account policies, then they're ignored without a single "are you sure?" Such policies *only* work when applied to an entire domain.

### **MULTIPLE DOMAINS VERSUS OUs: WHEN EACH MAKES SENSE**

Notice in each case cited here that you could *also* accomplish those same ends with multiple domains. International Trade could be its own domain with its own administrators and trust relationships to the rest of the firm. Ditto Graphics. In the first case, all of the administrators could be lumped into a domain off by themselves, and indeed that's been done many times with NT 4—and can still be done for Active Directory.

When, then, should you use one domain divided into OUs, and when should you have different domains? Well, in general, my rule of thumb would be, "Don't use multiple domains unless you must." So the real question, then, is, "When do multiple domains make sense?" In a few cases:

**Replication problems due to poor bandwidth** Probably the best reason. All domain controllers in a domain really need to be online and available to each other all of the time. If one office is in Timbuktu and the other is in McMurdo Base and they don't really share much save very limited WAN support, make them separate domains. Think of it this way: Suppose you had one office in Chicago and another in Sydney (Australia) with an expensive, low-bandwidth link between the two. Suppose also that you had 20,000 people in the Chicago office and 150 in the Sydney office. Every time the Chicago people changed their passwords, you'd have to replicate all of that traffic over the expensive-and-slow WAN link to the domain controllers in Sydney. Not a great use of WAN links. It'd be better to just build two domains.

**Different account policies** With NT 4, you could set account policies—things such as how often users must change their passwords, whether to lock out users who've entered too many incorrect passwords, and how many is "too many"—but you could only set them on a domain-wide basis. As you read a bit earlier, AD has the same constraint, as policies that include account policies will only work if applied to a domain—they're ignored if applied to an OU or a site.

**You don't trust the branch office** Suppose you're a one-domain company with a large corporate headquarters and a bunch of small branch offices. You've got a branch office somewhere with 15 employees. So you put a server—just one—in that building. It serves as the local domain

controller, Exchange server, file server, and print server. (And when you're not around, they use it as the receptionist's workstation.)

This server is left out in the open. Yes, there's a lock on the main front door of the office suite, but it's only locked at night. As the server isn't physically secured, someone could steal it or, with just a screwdriver and a few minutes, could steal its hard disk. That hard disk holds a copy of the Active Directory for the entire company, as you work for a one-domain firm.

If this happened under NT 4, you might end up compromising the passwords of all of your users company-wide, as there are programs around that can read a SAM and crack its passwords, producing cleartext. But no one will ever write an AD password cracker, right? Unfortunately, they already have. I'm told the latest version of *l0phtcrack* ([www.atstake.com](http://www.atstake.com)) will extract Active Directory passwords, although the Web site says nothing about that (and I didn't feel like spending \$250 to download it and find out). But whether an AD password cracker is currently available is irrelevant to what I'm saying. There will eventually be one, rest assured. So physical security is a top priority—these cracker programs in general will only work if you're physically sitting at the DC.

As a result, you can see that by putting one or more of your domain controllers in a location that's not physically secure, you potentially threaten every password in your enterprise. In that case, you might consider separate domains. That way, if the bad guys compromise a single domain's passwords then at least they haven't compromised *all* of the enterprise's passwords.

**Politics** Eighth-layer OSI stuff. Same as it ever was.

**We just found it this way, honest!** Your firm buys another firm, and you have to blend the two organizations. There are third-party tools around that will help assimilate the new domain into your existing domain, but that'll be a big undertaking and maybe you don't have the time to do that just at the moment. In that case, you're living in a multidomain world for a while. *Multiforest*, most likely. If you can, however, I recommend you consider merging the two domains with a tool like Active Directory Migration Tool, which I'll cover later in this chapter.

I know I've said it already, but let me weigh in again with my opinion about multiple domains, or rather, why I'd avoid them. First of all, NT 4 multiple domain enterprises were a major pain, as trusts tended to break. Supposedly this won't happen under Active Directory and thus far I haven't seen it, but in general, the fewer "moving parts" in my enterprise, the better. Additionally, NT has had its growing pains over the years about security. What if the next NT security hole appears in AD trusts? (Again, that is a *thoroughly* fictitious example. No problems of that kind have arisen in trusts since AD appeared in 2000.)

And then there's the issue of bugs in general: I'd prefer to work with the parts of Server 2003 that have been tested most thoroughly. For example, my personal experience with multiple-processor machines running various versions of NT is that they're more fragile and a bit more crash prone. I can't prove it, but my guess is that, if Microsoft has 200 people on campus testing some version of Server, the majority of them have a single-processor machine on their desks. Isn't it logical to assume then that 2003 has been better tested on single-processor machines than multiprocessor machines? For the same reason, ask yourself: Of all of the people beta-testing Server 2003 (or Service Pack 1 or Service Pack 2 or whatever), do you think most of them tested it in a single-domain or multi-domain environment? My guess is the former, which would imply that it's the better way to go for reliability. Understand, however, that these are just guesses on my part.

### OUS VERSUS GROUPS

So far, I've described two kinds of things that hold other things—that is, I've described something called a *group*, which can contain users and/or machines, and I've described something *else* called an organizational unit, which *also* can contain users and/or machines.

So what's the difference? Well, in an oversimplified sense, you put the things that you want to control into an OU. Then you grant that control to a group. If you wanted to, for example, create a subgroup of an enterprise like a department and then designate a group of people who could act as administrators to that department, then the department would be an OU and the desired administrators would be a group. You'd then delegate authority for the OU to the group. But here's some more detail.

A user account can only be in one OU, but it can be a *member* of as many groups as you like. A user account or machine account exists in only one domain in a general sense, but the account may also live in an OU *inside* that domain, much as you or I can live inside some city in a state, but we each live in only one city. In contrast, no matter which city you live in, you can be a member of as many associations—groups—that you like. Put another way.

- ◆ OUs are *containers* that can contain objects in the AD, like user or machine accounts or even other OUs. That's why your user account can exist in only one OU. (Well, it can exist in more than one OU, but only if the OUs are nested—for example, if I modeled my OU pattern on U.S. cities and states, then my user account might live in the Dallas OU, which is contained in the Texas OU.)
- ◆ Groups are, in contrast, just attributes of an object.

You can use groups to assign permissions—you can, for example, deny access to a file to anyone in a given group. AD won't let you do any permission work with OUs; you can't deny access to a printer or a file share to an entire OU.

OUs let you define *logical* divisions in a domain. But knowing about the *physical* subdivisions is important as well: I might not want to transfer that half-gigabyte file to server DISTRIBUTE01 if I know that it's only connected to the rest of the domain with a 56K link. That's where sites come in handy.

### Sites

As you read earlier in this chapter, one of NT 4's weaknesses was the fact that domain controllers replicate data among themselves in a very “chatty,” bandwidth-intensive way. That's not a problem for domain controllers on the same LAN, as there's typically bandwidth to burn on a LAN, but WAN links are nothing to toss away lightly.

AD improves upon that with the notion of *sites*. In addition to knowing about machines and users in an enterprise, the AD also keeps track of the geographic aspects of an enterprise. Each LAN-connected area is called a *site*. Active Directory domain controllers, as well as Windows 2000, XP, and 2003 systems, use the insights that you give it about your physical layout to figure out where the WAN links—the slower and more expensive part of your network—are. It then does two very helpful things: First, it compresses the replication traffic (again, by a factor of as much as 10, quite impressive!), and second, it uses route costing information that you supply to figure out how best to route the replication traffic at lowest cost.

The Active Directory also uses sites in a feature called Distributed File System or Dfs. With Dfs, you can create a file share that contains some important information and then create a “replica” version of that file share on each of your sites. A tool called the File Replication Service ensures that all of those file shares contained the identical information. If you had four sites, for example, then you’d have four replicas. But the four of them all look like just one share to users. When a user attaches to a Dfs share with replicas on multiple sites, then, Dfs uses the AD’s site information to ensure the user gets connected with the *local* replica, if possible.

By the way, if you’ve got experience with Exchange, then all of this will sound somewhat familiar, and it should—Exchange first pioneered the idea of sites several years ago. In fact, I once heard a Microsoft speaker say, “You may have participated in the five-year beta process for Active Directory; you may have known it as Exchange 4.0, 5.0, and 5.5.” (He was, in case you’re wondering, clearly speaking with his tongue in his cheek.)

At this point, you’ve met domains, groups, organizational units, and sites. Next, let’s meet two ways of organizing *collections* of domains: trees and forests.

## Building Multidomain Structures I: Trees

Real-world experience with NT from version 3.1 through 4 showed that people needing multiple-domain enterprises tended to build *hierarchies* of domains, what computer people call *tree structures* despite the fact that computer trees tend to have their roots up top in the air and their “leaves” at bottom. Microsoft designed AD to use DNS as a naming system, and DNS is hierarchical in nature anyway, so Active Directory exploits this happy coincidence and encourages you to build multi-domain enterprises as hierarchies.

**NOTE** *As you read in the DNS chapter, hierarchies of names are sometimes alternatively called namespaces. Thus, if Bigfirm is divided into bigfirm.biz, westcoast.bigfirm.biz, and eastcoast.bigfirm.biz, then you might hear the Bigfirm managers refer to the Bigfirm namespace or perhaps Bigfirm’s Active Directory namespace. All namespace means here is “the system that we use to choose names that make some kind of sense.”*

The first AD domain that you create is called the *root* of the tree. Suppose, following the earlier example, that the root’s name is bigfirm.biz. Domains below it are referred to as *child domains*, as you’ve read. You can decide to divide your organization geographically—for example, eastcoast.bigfirm.biz and westcoast.bigfirm.biz—or organizationally, as perhaps manufacturing.bigfirm.biz, finance.bigfirm.biz, and sales.bigfirm.biz. In case it’s not clear, here’s the rule for naming child domains: A child domain must have a name like *name.parentdomainname*. So, for example, a child domain of bigfirm.biz must have a name like *name.bigfirm.biz*—so eastcoast.bigfirm.biz or westcoast.bigfirm.biz would be fine, and apex.com would *not* be fine, as it doesn’t include bigfirm.biz in it.

You can then create another level if you choose—perhaps sales.eastcoast.bigfirm.biz, manufacturing.eastcoast.bigfirm.biz, finance.eastcoast.bigfirm.biz, and sales.westcoast.bigfirm.biz, manufacturing.westcoast.bigfirm.biz, and finance.westcoast.bigfirm.biz (six domains!)—and another and another, to create as complex a system as you want. Active Directory helps you by automatically creating trust relationships between each domain and its child domains. For example, merely creating westcoast.bigfirm.biz automatically creates a two-way trust relationship between westcoast.bigfirm.biz and bigfirm.biz. This two-way trust means that bigfirm.biz administrators may choose to extend file and print permissions to finance.bigfirm.biz users and vice versa.

And as I mentioned earlier, AD trust relationships are *transitive*. Creating `finance.westcoast.bigfirm.biz` creates a two-way trust relationship between `finance.westcoast.bigfirm.biz` and `westcoast.bigfirm.biz`, but it doesn't stop there: Because `westcoast.bigfirm.biz` and `bigfirm.biz` *also* have a two-way trust, `finance.westcoast.bigfirm.biz` ends up with an automatic trust relationship with `bigfirm.biz`. (If that doesn't sound interesting, then you didn't work with NT 4 and earlier versions, which required you to hand-build every single trust relationship.) Thus, because `eastcoast.bigfirm.biz` trusts `bigfirm.biz` and `bigfirm.biz` trusts `westcoast.bigfirm.biz`, then `eastcoast.bigfirm.biz` trusts `westcoast.bigfirm.biz`.

## Building Multidomain Structures II: Forests

Domain trees, then, offer the benefits of automatic trust relationships, a very good thing. But there's just one minor problem with that—all of the domain names must fit into a nice hierarchy. The child domains must contain the names of the parent domains.

### FOREST BASICS

Suppose in contrast that your enterprise divides into `bigfirm.biz` and `apex.com`, two former rivals that have merged. Suppose further you've decided to go with a multiple-domain enterprise and want to keep some of your firm as `bigfirm.biz` and some as `apex.com`.

It looks like two things are true, then: First, you're probably going to have two domains, and second, those two domains won't fit into a tree.

You can choose to build these two Active Directory domains into a unified structure, but it can't be a tree because of their dissimilar names. Instead, you can choose to create a *forest*. A forest is just a group of trees, as you see in Figure 8.4.

**FIGURE 8.4**

Example Active Directory forest

Here, you see a forest built from the `bigfirm.biz` and `apex.com` trees.

Other than different naming hierarchies, the trees in the forest act like one tree in terms of their trust relationships—Active Directory builds transitive trusts automatically. So, for example, as

eastcoast.bigfirm.biz trusts bigfirm.biz, bigfirm.biz trusts apex.com, and eastcoast.bigfirm.biz trusts apex.com—all automatically.

### **YOU MUST BUILD TREES AND FORESTS TOGETHER**

This sounds great, and of course it's a terrific improvement over NT 4. But hidden in this potentially rich notion of many domains joined into a tree and many trees joined into a forest is a dirty little secret. Here it is: you cannot join already-existing domains into a tree. Nor can you join already-existing trees into a forest. The only way to add a domain to a tree, or a tree to a forest, is to build it from scratch onto an existing tree or forest.

Hard to believe? Well, it's true. Once you place domains in a forest, you cannot move them to another forest. You also can't delete them if they have any child domains. AD's forest structure it, then, painfully inflexible and that's true even if you're completely upgraded to Server 2003.

### **You Can't Glue Domains Together**

So suppose I were to create an AD domain named bigfirm.biz on one network. Then, on a completely separate network totally unconnected to bigfirm.biz's network, I create an AD domain named eastcoast.bigfirm.biz. I cannot then attach the two networks and effect a tearful reunion of parent and child domain. Nor could I build apex.com and bigfirm.biz AD trees in isolation and then connect them, after the fact, to create a forest.

Attaching existing domains to existing trees or forests is called *pruning and grafting* and it can't be done, at least not with the tools supplied by Windows Server 2003. Thus, for example, if Exxon buys Mobil, and Exxon already has a domain named exxon.com and Mobil's got a domain named mobil.com, it's not possible to join them together in a tree with the supplied 2000 and 2003 Active Directory tools.

### **“...But Only the AD Wizard Can Make a Tree”**

(My apologies to Sergeant Joyce Kilmer.) Let's review what I'm saying here. If I've created an AD domain named bigfirm.biz and want to create a child domain in its tree named eastcoast.bigfirm.biz, then I sit down at the machine that I want to be the first DC in eastcoast.bigfirm.biz and create the eastcoast.bigfirm.biz domain, explaining to the Active Directory Installation Wizard, a program named DCPROMO (which you'll meet a bit later) that I want it to be part of an existing tree, bigfirm.biz. Before the wizard will go any further, it demands the name and password of an administrator for the bigfirm.biz domain. DCPROMO will refuse to create a child domain unless it can contact the parent domain right at that moment and get permission. In the same way, if you want to create a second tree in a forest, then the wizard will require that you tell it the name and password of an administrator for the first tree. (What about the third tree or fourth tree—what account do *they* need to provide? From the second to the millionth tree in a forest, you've got to provide an admin account from the first tree in the forest. As you're about to read in the next section, that first tree is “magic.”)

**TIP** You're probably wondering exactly what administrative account you need to create new domains in a forest. The answer is, any account that is a member of a group called Enterprise Admins. You will only find that group in the very first domain that you create in a forest.

### **Combining Domains, Trees, and Forests: Server 2003 to the Rescue, Kind Of**

So suppose you *do* have separate domains, trees, or forests that you want to attach to existing domains, trees, or forests—what do you do? Well, the *best* answer would be if you could link those objects

with one of those nifty AD two-way transitive trust relationships. In some senses, that's all there is to a tree or forest; it's just a bunch of domains strung together with two-way transitive trusts. So if you could build two-way transitive trusts between any arbitrary set of domains, trees, or forests, then you could essentially build whatever kind of AD structure that you liked.

But you can't do that at all under an AD that contains any Windows 2000 Servers as domain controllers. You can *sort of* do it in an Active Directory composed of all Windows Server 2003–based DCs with something called a *transitive forest root trust*. In fact, it's probably the single most significant Active Directory improvement between Windows 2000 Server and Windows Server 2003.

As you've already learned, the neat thing about a forest is that all of its domains trust each other because of transitive trusts—even if domain A doesn't trust domain B directly, it might be that A trusts D, D trusts C, and C trusts B. As these trusts “flow through,” there's a kind of “six degrees of Kevin Bacon” way that everyone trusts everyone. But hooking up that transitive trust relationship between forests wasn't possible until 2003. With 2003, you can create one trust relationship between Forest 1 and Forest 2, and from that point on every domain in Forest 1 trusts every domain in Forest 2 and vice versa. Thus, suppose Bigfirm buys Apex, both of which have an existing forest. Bigfirm wants its forest to work well with Apex's, so they create a single forest-to-forest root trust and trust is universal.

This is good news, but there are a few reasons why this may not be all that Bigfirm and Apex wanted. Here's why.

- ◆ First, this is only possible if both bigfirm.biz and apex.com are upgraded to Windows Server 2003 forest functional level. In other words, they must upgrade every domain controller from Windows 2000 Server to Windows Server 2003. Not *one* DC can be running 2K. That might be expensive.
- ◆ Second, two trusting forests do not exactly equal a single forest as far as some AD-aware software is concerned. That's because, as you'll soon learn, there is another very important bit of “glue” binding forests together in addition to their transitive trusts: the global catalog. Each domain in a forest has its own database of users, machine accounts, and the like, but there is a sort of “database of databases” that contains a centralized summary of most of the important stuff for all of the domains in a forest called the global catalog. Exchange, for example, sees your enterprise as one big firm no matter how many domains it has because Exchange thinks “all domains sharing a global catalog equal one enterprise.” So here's the problem: two separate trusting forests *still have two separate global catalogs*.
- ◆ Third, and this is probably a smaller issue, forest-to-forest trusts are, believe it or not, not transitive *across forests*. By that I mean this: if Forest 1 trusts Forest 2, then as you've seen, all of Forest 1's domains trust all of Forest 2's domains and vice versa. But now let's say that you set up a transitive trust between Forest 2 and Forest 3. Now all of Forest 2's domains trust all of Forest 3's domains (and vice versa). But what about Forest 1 and Forest 3—what relationship do they have? None, as it turns out. Forest-to-forest trusts do not “flow through.” You'd have to build a whole separate trust between Forest 1 and Forest 3 in order to have every forest around trust every other one.

You'll see the nuts and bolts of setting up trusts towards the end of the chapter in the “Migration Strategies” section.

### ***But You Can Rearrange the Tree***

Windows Server 2003 improves upon things in one way—you can *rearrange* domains in a forest. By renaming a domain, you could move it from one tree in a forest to another. There's a price, though—every DC in the forest must be running Windows Server 2003. Still, it's a nice plus for 2003.

### ***Using Migration Tools to Combine Domains, Trees, and Forests***

If transitive forest trusts aren't right for you, and you just simply *must* either merge two domains into one, or perhaps you want to take two domains from different forests and join them together into a single forest, then you'll have to go a bit more complex route: domain migration. You'll start out by either buying a so-called "migration" tool, such as the ones offered by Fastlane, NetIQ, Aelita, and Entevo, or you'll use the free one that ships with 2003 Server—Microsoft's Active Directory Migration Tool (ADMT). ADMT is free but a bit limited, and I'll show you how to use it in the "Migration Strategies" section later.

Migration tools copy user and machine accounts and permission information between one domain and another. You would, then, merge two domains by creating an empty domain in the same tree/forest as one of the domains, then copying the objects from the other domain.

For example, suppose I had two distinct AD domains, *bigfirm.biz* and *apex.com*, and wanted to merge them into a forest. Using a migration tool, I'd work something like this:

1. Create a new empty domain named *apex2.com* (or something like that—you'll run into trouble if you try to work with two domains both named *apex.com*) in *bigfirm.biz*'s forest, using the Active Directory Installation Wizard.
2. Build an old-style NT 4 trust relationship between the *apex.com* domain and the *apex2.com* domain. (Even though they're called "NT 4-style" trusts, they work between Active Directory domains in different forests.) Or, if the domains are both in Active Directory forests that use only Windows Server 2003-based DCs and are at Windows Server 2003 forest functional level, then I could build a transitive forest-to-forest trust. Again, that's only possible in a pure 2003-to-2003 situation.
3. If I built an NT 4-style trust between *apex.com* and *apex2.com*, then I'd also have to build an old-style NT 4 trust relationship in the other direction, between the *apex2.com* domain and the *apex.com* domain. If I'd built a transitive forest trust, then I'd be done building trusts, as forest trusts are two-way.
4. Use the migration tool to copy the user and machine accounts from *apex.com* to *apex2.com*.
5. Now tell the users in *apex.com* to no longer log in to *apex.com*, but instead to log in to their accounts on *apex2.com*.

The process isn't trouble-free, but it works. I'll cover it more in the "Migration Strategies" section later.

### ***The Case for an Empty Root***

Look back to Figure 8.4. In that figure, I drew an extra root domain in addition to *apex.com*, *bigfirm.biz*, and *bigfirm.biz*'s two child domains. I did that to make the diagram "look" right—we're used to seeing hierarchies end up at a single point.

In a tree, it's simple to see which domain is the root or top-level domain—it's simple to see that apex.com is the top of the apex.com tree and that bigfirm.biz is the top of the bigfirm.biz tree. But when you build two trees (apex.com and bigfirm.biz) into one forest, then which domain is the “top” or “root” domain? Or isn't there a root; perhaps all trees are equal?

In an Active Directory forest built of several trees, there *is* a single forest domain root. It's just not obvious which one it is.

**NOTE** *The root domain of a forest of Active Directory domains is the first domain that you installed in the forest.*

So suppose you came across an AD forest that contained just three domains—bigfirm.biz, apex.com, and consolidated.com. Which domain is the forest root? The answer isn't obvious because the three domains seem to sit at the same level. I don't know of a quick way to find out which domain is the forest root, but here's a slightly slower one. Remember that only the forest root domain contains a group named Enterprise Admins; that's how you'll find the root.

Start Active Directory Users and Computers (Start/Programs/Administrative Tools/Active Directory Users and Computers). In the left pane of the MMC snap-in, you'll see an icon representing a domain; it looks like three tower PCs clustered together. Right-click that icon and choose Find. In the resulting dialog box, there's a drop-down list box labeled In, which lets you tell the program which domain to search in; click it and you'll see that you have the ability to search any one of your forest's domains. Choose one of your top-level domains. Then notice the field labeled Name; enter **enterprise\*** and press Enter. If the search found a group called Enterprise Admins, then you've found the root. If not, drop down the In list box and try another domain until you locate the one with Enterprise Admins.

Suppose bigfirm.biz turned out to be the root domain in my Bigfirm/Apex/Consolidated example. There are probably three domains because there are or were at some time three different business entities that for some reason are one firm now. Who *cares* if the Bigfirm guys happen to be the forest root?

Well, the Apex and Consolidated guys, that's who—whether they know it or not. You see, members of the Enterprise Admins group, which happens to live in the Bigfirm domain, have powers in *every domain in the forest*. They're not members of the Domain Admins group in those domains, but they might as well be, as Enterprise Admins have Domain Admin-like powers everywhere.

That means that although in *theory* Bigfirm, Apex, and Consolidated have separate domains, with those nice, convenient security boundaries, in *practice* the Apex and Consolidated folks have to just kind of hope that the Bigfirm guys don't get the lust for power one day and decide to do something scary in the Apex or Consolidated domains. So you can see why Apex and Consolidated might be a bit nervous.

The answer? Don't create three domains, create four. The first domain—the root domain—should be some domain that you're never going to use, e-gobbledygook.com or something like that. Create one administrative account in that domain, including it in the Enterprise Admins. Let the CIO create it and then have her write down that account name and password, and then stuff the paper on which she's written them into her safe and use the Sopranos personnel-termination procedure on anyone who knows the password besides you and her. (Just kidding. But this *is* a powerful account—you don't want any nonessential people getting access to it.) At the same time, create the other three domains—you'll need the CIO for a while, she'll have to type in the username and password for that Enterprise Admin account in order to create those three domains. Then you can put away the Enterprise Admin account and you'll only need it now and then.

This idea of creating a first domain and then populating it with only an account or two, then doing nothing else with it, is called an *empty root* AD design.

Some firms create an empty root domain even if it's just a one-domain enterprise in case it acquires other companies at some time in the future. It's not a bad bit of bet-hedging, and I'd recommend it to some. Of course, the downside of it is that you've got to have a DC or, better yet, two DCs, sitting around running, doing nothing to support the root domain, and each of them will need a copy of Server 2003. But, again, it may not be a bad investment—an empty root is one case where I'd break my single-domain-preferred preference.

## Finding Domain Controllers for Logins Under AD

All of the machinery that the Active Directory includes enables Active Directory domain members—2000, XP, and 2003 systems—to be a bit smarter about logons than NT 4 domain clients were. Here's a brief look at how AD uses sites and DNS to log in machines and users.

When you start up your Windows 2000 or later desktop machine, it must log in to your Active Directory domain—machines log in as well as people. “Machines” here refers to systems running some version of NT (NT 3.1–4, Windows 2000, XP Pro—Home cannot participate in domains—or Server 2003). They log in, Windows 9x and XP Home systems do not.

The hard part about logons is in finding a domain controller—that is to say, a computer that offers Kerberos logon services. Once your system has found a DC, then transacting all of the Kerberos back-and-forth stuff about checking your password and user ID (or your machine's password and user ID) is very simple. The problem is finding a machine to *present* these credentials to.

In its most basic form, a machine finds a domain controller by asking DNS, “I'm a member of the bigfirm.biz domain. Do you know of any machines in that domain that offer the Kerberos protocol?” As to *how* it queries DNS, remember last chapter's discussion of SRV records? That's how a workstation finds a DC. The DNS server then responds, “Sure, the following systems here do Kerberos, and they use port 88 to do it.” Armed with that information, the workstation can begin logging onto bigfirm.biz—but there's more to it than that. You don't want to be logged in by just *any* DC, you want to be logged in by a *local* DC, so you're not waiting around for a lot of traffic to go over the WAN.

But actually Active Directory organizes its DNS SRV records pretty carefully. AD domain controllers register their SRV records with a domain's DNS dynamic zone, as you saw in the last chapter. But the DCs don't just dump all of the SRV records into the zone willy-nilly; instead, AD creates subdomains (and here “domain” means “DNS domain,” not “AD domain”) in the DNS zone that it uses to store its SRV records. More specifically, recall the AD notion of sites. Suppose Bigfirm has two offices—one in Edenton and one in Bath. Where NT 4 domains have no idea where DCs are physically located, ADs keep track of that information via those subdomains in their DNS zones. When you create a bigfirm.biz AD domain and then define two sites named Edenton and Bath, AD responds by creating a subdomain in the bigfirm.biz DNS zone called “Edenton” and another named “Bath.” DCs that are located in Bath then store some of their SRV records in the Bath subdomain. Not *all* the SRV records because AD wants to maintain two places to find out about DC's availability—first the site-specific subdomain, and then a global subdomain. So every DC writes an SRV record to its site subdomain in DNS and then writes a copy of that the global subdomain. (If *that* sounds complicated, believe me, it *isn't*, at least compared to the reality—I gave you a simplified version of the truth! And yes, I'm tempted to quote Jack Nicholson's character from *A Few Good Men*

at this point, but I'll refrain. I mean, you *could* handle the truth, you just don't need to know most of it in this case.)

The value of all of this work lies in making it possible for a workstation to find a local DC. By creating site-specific DNS subdomains, your workstation can do more than just ask, "Are there any DCs for bigfirm.biz?" Instead, your workstation can ask, "Are there any DCs for bigfirm.biz in the Bath office?" Every 2000 or later machine knows where it logged in last time, as that information lives in the Registry in the entry `DynamicSiteName` in `HKEY_LOCAL_MACHINE\System\CurrentControlSet\Services\Netlogon\parameters`. You can see that on your system, assuming that it's a member of an Active Directory domain, by typing this command:

```
reg query hklm\System\CurrentControlSet\Services\Netlogon\parameters
    /v dynamicsitename
```

You'll get a result that looks like

```
! REG.EXE VERSION 3.0
HKEY_LOCAL_MACHINE\System\CurrentControlSet\Services\Netlogon\parameters
    dynamicsitename      REG_SZ  Headquarters
D:\>
```

In that example, my workstation is in a site named "Headquarters." But how does a workstation know what site it's in? The last DC to log it in tells it. This is most easily explained using the example of a laptop, as they potentially move around from site to site.

Suppose that I was in Bath yesterday, but today I'm in Edenton. I plug my laptop into the Edenton network and turn it on, so that I can log onto the domain. The laptop looks in its Registry and sees that it's in Bath. (It's wrong, that that's what it thinks.) It then contacts DNS and says, "Please tell me the names of the Kerberos servers in Bath," and DNS complies. The laptop then contacts each of the Bath DCs, saying, "Will you please log me on?" The first Bath DC to respond notices from the laptop's IP address that my laptop is in Edenton, not Bath, and replies, "Well, I'd be happy to log you on, but you're not in Bath, you're in Edenton." The laptop says, "Oops," and queries DNS to find the Edenton DCs. It asks the Edenton DCs to log it on and updates its Registry to remember that it's in Edenton for next time.

Now, if all of the Edenton DCs are dead or too busy to respond—the laptop waits 100 milliseconds for each to respond before going on to the next one—then it goes back to DNS and queries not the Edenton DNS subdomain, but the global subdomain. In effect, the laptop says, "Okay, I give up, clearly no one in Edenton's responding to me—I'll take *any* DC for bigfirm.biz." DNS returns the global list of every DC in bigfirm.biz, and the laptop starts working its way through that list to eventually find a machine that will log it onto the domain.

Summarized, then, Windows 2000, XP, and 2003 systems that are members of ADs find domain controllers by first using their knowledge of their site locations and domain names to query DNS for the names of nearby domain controllers. The machines then contact the nearby domain controllers and ask them to log them in. The DC that agrees to log them in first checks that it is the closest DC available, and if it is *not*, then it redirects the machine to a closer DC.

You can find out which server logged you in by opening a command prompt and typing **set**. One of the pieces of information that you'll get is a line starting with `LOGONSERVER=`; to the right of the equals sign is the name of the DC that logged you in.

## Building an Active Directory: Some Hands-On Experience

Let's take a break from the concepts for a while and do a little hands-on work. Let's build a small tree of domains to get a feel for what the Active Directory process looks like. In this tree, I'll create two domains: one called `bigfirm.biz` and another, a child domain called `ecoast.bigfirm.biz`. As I'll want an account that can act as an administrator across the whole tree, I'll also create a user named `bigguy` with those powers.

**NOTE** *If you created `bigdog.bigfirm.biz` in the examples of the last chapter, then you'll use that machine as `bigfirm.biz`'s first domain controller.*

If you want to do something like this, you'll need two machines because every machine can only be a domain controller for one domain; two domains, therefore, would require two machines—more, in fact, if you wanted to start adding extra DCs or member servers.

### Building the First Domain

One of the really nice things about Windows 2000 and later versions of Server is that Microsoft separated the process of installing Server from the process of creating a domain controller. You can do a fairly vanilla installation of Windows 2000 Server or Server 2003 (or have an equipment supplier preinstall it, as companies such as Dell, HP, or IBM do) without having to worry about two of NT 4's biggest pains—that you needed to designate a machine as a domain controller during Setup, and that you couldn't install a backup domain controller unless your computer was connected live on the LAN to the domain's PDC. So you can start this process from pretty much any machine running Windows 2000 Server or Server 2003. (I'll stick to Server 2003 in this example.) But before you do, consider four caveats: memory, DNS, NTFS, and disks. Let's take a minute and consider those.

#### HARDWARE: MEMORY, DISKS, AND NTFS

The memory part is easy. As far as I can see, Server 2003–based DCs use *at least* 136MB of memory. You don't *need* to have 136MB of actual RAM in a machine before using it as an AD domain controller, but if you *don't* have at least that much, be prepared for nearly constant disk activity as Server pages pieces of itself on and off disk. It's a matter of taste, but I found all of that disk chattering extremely annoying and so I originally upgraded my machines to 256MB of RAM—thank heavens memory's finally dropped in price—and now buy all systems with at least 1GB of RAM. You'll hear a lot of people talking about how you need gigahertz-plus systems to run 2003, but in my experience it's RAM that's important—I have a workgroup DC that runs on a 400MHz Pentium II with 512MB of RAM and I'm pretty satisfied with its performance. (And don't forget to use ECC RAM!)

Next, you'll get better performance out of your Active Directory servers if you can put two separate physical SCSI, EIDE, or FireWire hard disks in your system. SCSI has always been the performance leader, but nowadays I'd say that small servers could work well with two EIDE or FireWire hard disks. If you go with two EIDE hard disks, make sure that they are on different EIDE channels; two EIDE drives on the same channel cannot operate simultaneously. It's not that they won't work in that case, just that they won't work *as quickly*.

The third consideration is relatively easy. Active Directory servers *need* an NTFS partition, so before trying to make a server a domain controller, be sure that it's got at least one NTFS partition.

### DNS: AD's FOUNDATION

The final, and most important, caveat is about DNS. The Active Directory stores its list of domain controllers and global catalog servers in DNS, as you've already read, and it uses dynamic DNS to do it. Recall that a computer registers itself with the dynamic DNS zone by first requesting the SOA record for that zone and then reading the SOA record to determine the name of the primary DNS server for that zone. Then the computer contacts the primary DNS server and registers itself. That means that for you to even *think* about setting up a domain called bigfirm.biz your would-be new domain controller must do the following:

- ◆ Ask its preferred DNS server to get the SOA record for bigfirm.biz. Thus, before you try to convert a system to an Active Directory domain controller, you should really reexamine the DNS server or servers that this system will use to make DNS requests. You're almost certainly doing split-brain DNS of some kind, so double-check that when your soon-to-be domain controller asks DNS for the name of the primary DNS server for bigfirm.biz that it gets the right answer.
- ◆ Your soon-to-be DC will then try to send dynamic updates to the DNS server pointed to by that SOA record. That DNS server had better be willing to accept those updates, or you are not going to be able to make this computer a domain controller.

As I've said, my example will create an AD domain called bigfirm.biz. That's a domain that I've registered, and I run a zone by that name *that is not dynamic*. I registered the domain and set up a simple non-dynamic zone on it for some specific reasons. First, I didn't want to use a domain example that someone was using, as I was concerned that they might not like having lots of people trying to register with their no-doubt-nondynamic DNS server. Second, I wanted to *ensure* that the primary DNS server associated with bigfirm.biz wasn't dynamic so as to be 100-percent sure that you'd have to master split-brain DNS before you could get the AD to work.

If you followed along with my example in the previous chapter, then you have a system running with IP address 192.168.0.2 (or perhaps .1) called BIGDOG running a DNS server that contains a local zone for bigfirm.biz. That machine points to itself for a preferred DNS server, and so when it asks, "Who's the primary DNS server for bigfirm.biz?" then the answer will be, "You are." If you've followed previous chapter's instructions, then you also have that zone set up to be dynamic, and so you'll be able to make this an Active Directory domain controller.

As a matter of fact, inasmuch as you've set up split-brain DNS, you *could* call your AD anything. You could create a microsoft.com AD. But if you *did*, then recall that your DNS server would never be able to find the *real* microsoft.com!

Before going any further, you might want to just take a moment to find out which DNS server your computer will try to send the updates to. Sit down at the machine that you intend to make the first domain controller of bigfirm.biz—I recommend the BIGDOG system we created in the last chapter—and log in, then open up a command prompt. Now use `nslookup` to do a preflight DNS check.

```
E:\>nslookup
Default Server:  bigdog.bigfirm.biz
Address:  192.168.0.2
```

```
> set type=soa
> bigfirm.biz
```

```

Server: bigdog.bigfirm.biz
Address: 192.168.0.2

bigfirm.biz
    primary name server = bigdog.bigfirm.biz
    responsible mail addr = admin.bigfirm.biz
    serial    = 48
    refresh  = 900 (15 mins)
    retry    = 600 (10 mins)
    expire   = 86400 (1 day)
    default TTL = 3600 (1 hour)
bigdog.bigfirm.biz    internet address = 192.168.0.2
>exit

```

As you saw in the previous chapter, `nslookup` starts out by telling you which server it's getting its answers from and, as I want BIGDOG to point to the DNS service on itself, then the results you see above are initially encouraging. Then I type **set type=soa** because I want to retrieve the SOA record. Then I enter **bigfirm.biz** and `nslookup` retrieves and displays the info in the SOA record, which includes the *primary name server*. That is the machine at 192.168.0.2, so I'm in business, as I'm *sitting* at 192.168.0.2 and that's the machine that I intend to make a DC.

Remember that this does not mean that you *must* put DNS on the machine that will be your DC, this is just one answer. Refer back to the discussion in the previous chapter about the steps to making split-brain DNS work properly for AD. And you may have modified your AD setup and, if so, then use `nslookup` to ensure that your computer returns the results that you wanted. For example, if you've decided to call your AD `mydomain.com`, then you'd ask `nslookup` for SOA information on `mydomain.com`. And, again, recall that I'm setting things up so that the primary DNS server and the DC for `bigfirm.biz` are the same systems; there's no particular reason why you'd have to do that, unless you wanted to create an Active Directory–integrated zone (remember that AD-integrated zones are great, but they only allow you to put DNS on domain controllers). If you've got enough machines, then go ahead and set up this DC on a machine at 192.168.0.10 or something. Just make sure that the system's preferred DNS server points at whatever machine is the primary for `bigfirm.biz` or at a DNS server that acts as a secondary for `bigfirm.biz`. For example, if you've got three machines and wanted to build an example that mimicked big networks more closely, then you might do this:

- ◆ Put Windows Server 2003 on all three systems.
- ◆ On a computer at IP address 192.168.0.2, set up DNS and create the primary zone for `bigfirm.biz`, as we've already done. Call the system BIGDOG.
- ◆ On a computer at IP address 192.168.0.6, set up DNS and make it a secondary DNS server for `bigfirm.biz`. It's kind of like what we did in the previous chapter with the machine named `ns1.ecoast.bigfirm.biz`, but without the delegated subzone. Call the system `ns2.bigfirm.biz`.
- ◆ On yet another computer give it IP address 192.168.0.20 (these are all arbitrary addresses that I'm using, of course). Don't put DNS on it. But set its "preferred DNS server" to the address of either DNS server.

You needn't build your example with this much complexity, of course; I just didn't want you to get the idea that in the real world there's only one DNS server in an enterprise, or that every DC must be built on the same machine as the primary DNS server for a zone.

Of course, none of this is a problem if all you're going to do is just read the text and follow along with the screen shots.

### RUNNING DCPROMO

To convert a Server 2003 system to a domain controller—it must be a server, you can't make a Professional machine a DC—click Start/Run and then type in **dcpromo**. That starts the Active Directory Installation Wizard, as you see in Figure 8.5.

**FIGURE 8.5**

Starting  
DCPROMO

You use this not only to convert member servers into domain controllers, but the reverse as well, to “demote” a domain controller to a member server.

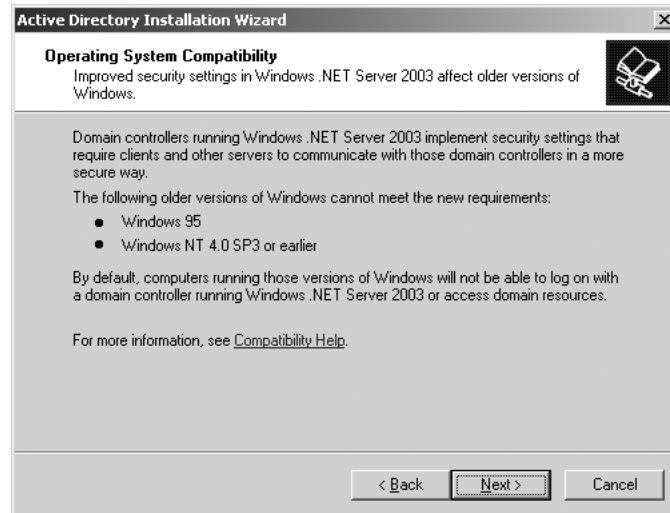

**TIP** At this point, let me note a convenient improvement of Server 2003–based DCs over 2000–based DCs. You can rename a 2003–based domain controller. Yay!

The wizard asks a series of questions and then, based on the answers to those questions, sets up a new tree, forest, or domain or creates another domain controller in an existing domain. Click Next and you’ll see a screen like Figure 8.6.

This page warns you that if you create a domain based on Windows Server 2003 systems, then you’ll have to bid your Windows 95 systems adieu because of something called SMB signing. The idea with SMB signing is that Microsoft wants to be very certain that it’s not going to be easy for anyone to hack an AD system. So they require that any communications between a client and a domain controller must be 100 percent sure that no one’s intercepting and changing those communications. In the past, some networks have been prey to a class of attacks called “man in the middle” attacks whereby I would sit on the network between you and a server and intercept your communications, modify them, and pass them along, thus enabling me to both listen in and change the communication. One way to be pretty sure that a communication has not been tampered with is to digitally sign that communication, and NT first started supporting that in Service Pack 3 for NT 4. SMB signing’s been around a while, but it’s never been mandatory. 2003–based ADs *make* it mandatory. And there’s the rub.

**FIGURE 8.6**

Warning: DOS and Windows 95 are outta here!

You see, Windows 95 does not support SMB signing and Microsoft doesn't offer any software to *make* it support SMB signing, so Windows 95 and DOS clients are simply out of luck—"take a walk," it says to the old guys. Windows 98 can add the functionality with a piece of client software that comes on the Server CD, the Active Directory Client for Windows 98, so you'd have to add that before any Windows 98 systems could talk to a 2003-based AD domain. NT 4 has the ability, but again you've got to upgrade to at least SP4 to make that happen. I can't see that being a problem, however, as anyone still using NT 4 has already gone to SP 6A, or at least I pray that they have...you'd be open to too many attacks otherwise.

Now that you know the risks to old systems inherent in running a 2003-based AD, click Next to see Figure 8.7.

**FIGURE 8.7**

Are you creating a new domain?

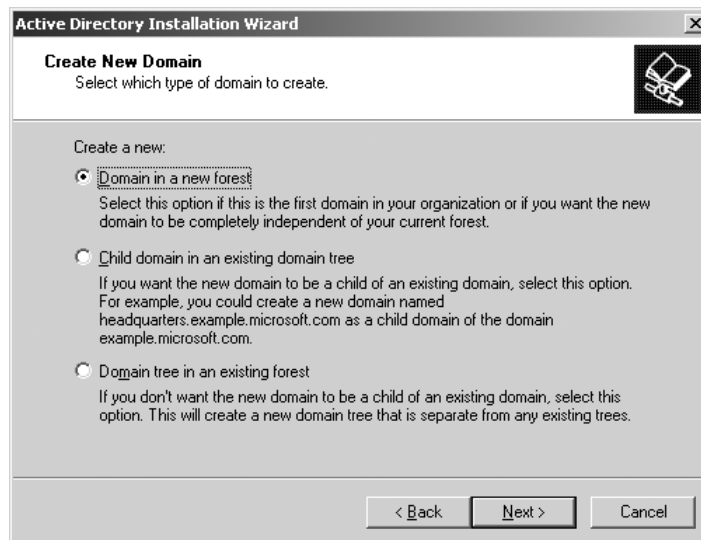

The way that you create a new domain is simple: Set up a machine as the first domain controller for that domain. Building a domain's first domain controller and creating a new domain are exactly the same thing. But you wouldn't have just one domain controller for most domains. For one thing, each site within a multisite domain will usually have at least one DC, to enable logons. Another reason you'd have multiple DCs on a single domain—whether single- or multiple-site—is to handle many logon requests. As you know, login requests don't space themselves out nicely throughout the day. Instead, most login requests happen all around the same time, first thing in the morning. The more DCs, the more logons your domain can handle. The second, third, fourth, and further domain controllers in a domain were called *backup* domain controllers under NT prior to Windows 2000, but Active Directory doesn't give them any special name because they're all supposed to be equal. As you'll see in the later discussion on FSMOs/operations masters, however, that's not true.

**TIP** So would it be a good idea to make all of your Server 2003 machines into domain controllers, to speed logons? No. Making a server a DC takes up memory and CPU power. Additionally, too many DCs means extra LAN chatter as they keep each other updated on changes to the Active Directory. The warning at the bottom of the screen is trying to say that non-DCs have a SAM with local accounts, and DCs instead have an NTDS.DIT. DCPROMO deletes a computer's SAM contents when the computer becomes a DC. There's a kind of optimal number of DCs that you should have in a network and that number varies from network to network. Personally, I monitor the `lsass.exe` process to get a feel for when to add a DC.

The first question that DCPROMO asks, then, is whether to create a whole new domain or just another DC in an existing domain. We're creating a new domain, so I select that and click Next. That leads to the screen in Figure 8.8.

**FIGURE 8.8**

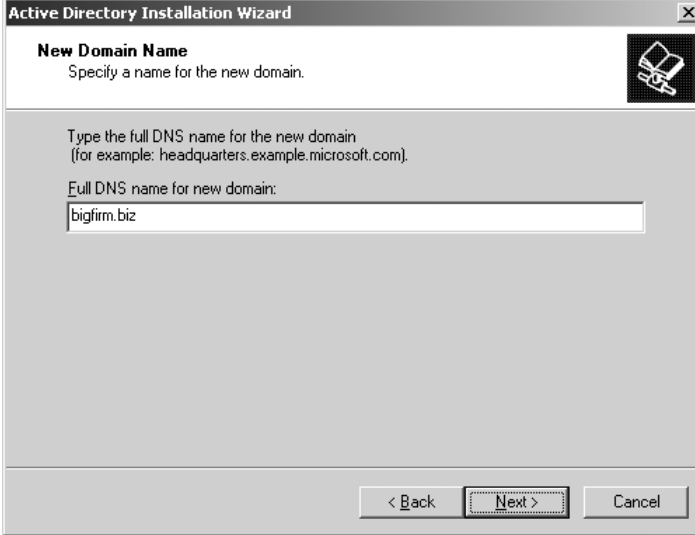

Choosing to create an altogether new tree, a child domain in an existing tree, or new forest

Recall that Active Directory lets you build domains into trees and trees into forests, so logically the Active Directory Installation Wizard must know where to put this new tree—in an altogether

new forest or in an existing forest, right? This is the first domain in a new tree, and the first tree in a new forest, so I choose that and click Next to see the screen in Figure 8.9.

**FIGURE 8.9**  
The domain's full  
DNS name

The screenshot shows the 'Active Directory Installation Wizard' window. The title bar says 'Active Directory Installation Wizard'. The main heading is 'New Domain Name' with the instruction 'Specify a name for the new domain.' Below this, it says 'Type the full DNS name for the new domain (for example: headquarters.example.microsoft.com).' There is a text input field labeled 'Full DNS name for new domain:' containing the text 'bigfirm.biz'. At the bottom right are three buttons: '< Back', 'Next >', and 'Cancel'.

Active Directory Installation Wizard

**New Domain Name**  
Specify a name for the new domain.

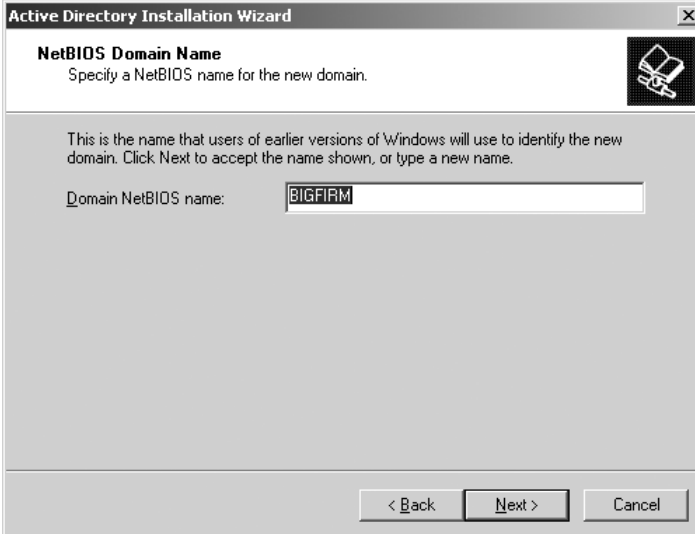

Type the full DNS name for the new domain  
(for example: headquarters.example.microsoft.com).

Full DNS name for new domain:  
bigfirm.biz

< Back   Next >   Cancel

Just type in the name of the new domain, which in this case is bigfirm.biz. Clicking Next leads to the screen in Figure 8.10.

**FIGURE 8.10**  
The domain's  
NetBIOS/legacy  
name

The screenshot shows the 'Active Directory Installation Wizard' window. The title bar says 'Active Directory Installation Wizard'. The main heading is 'NetBIOS Domain Name' with the instruction 'Specify a NetBIOS name for the new domain.' Below this, it says 'This is the name that users of earlier versions of Windows will use to identify the new domain. Click Next to accept the name shown, or type a new name.' There is a text input field labeled 'Domain NetBIOS name:' containing the text 'BIGFIRM'. At the bottom right are three buttons: '< Back', 'Next >', and 'Cancel'.

Active Directory Installation Wizard

**NetBIOS Domain Name**  
Specify a NetBIOS name for the new domain.

This is the name that users of earlier versions of Windows will use to identify the new domain. Click Next to accept the name shown, or type a new name.

Domain NetBIOS name: BIGFIRM

< Back   Next >   Cancel

Unless your network is 100-percent Windows 2000 and later, both servers and workstations, then your network contains machines running network software written in the NT 3.x and 4.x days, when

domain names could be no more than 15 characters long and could not have a hierarchy of any kind. Those older systems—and you know, I tend to want to call them *legacy* systems, as that's been the *chic* term for old software for about 10 years now, but it seems that the current Microsoft term is *downlevel* systems—wouldn't understand a domain named bigfirm.biz, and so they need a more familiar name. For that reason, Active Directory domains have two names: their DNS-like name (for example, bigfirm.biz) and an old-style domain name (which can be anything that you want, but bigfirm seems like a good choice; but whatever you do, *do not* include periods in downlevel domain names—it'll give you headaches later). As network names under NT 3.x and 4.x were chosen to accommodate an old network programming interface called NetBIOS, this old-style domain name is also called a *NetBIOS name*. The wizard will by default offer the text to the left of the leftmost period, so it here offers the NetBIOS name BIGFIRM, which is fine. I click Next and the screen in Figure 8.11 appears.

**FIGURE 8.11**  
Placing system files

Active Directory stores the Active Directory database in two parts, as is often the case for databases: the database itself and a transaction log. Two things to bear in mind here are that the actual Active Directory database file should be on an NTFS volume for better performance and that it's a good idea to put the transaction log in a different physical hard disk than the Active Directory database. (You see them on the same drive in the screen shot because the machine I was doing this on had only one physical hard disk.) Putting the transaction log in a different physical drive means that the system can update both the AD database and the log simultaneously, and believe me, in a production environment, you'll see a significant difference in performance by using a two-drive system rather than a one-drive system. As I mentioned earlier, you can do this with SCSI, FireWire, or EIDE drives, but if you use EIDE drives, make sure they are on different EIDE channels so that they can run simultaneously without a significant performance hit. But we're not finished with drives yet; click Next and you'll see why, in Figure 8.12.

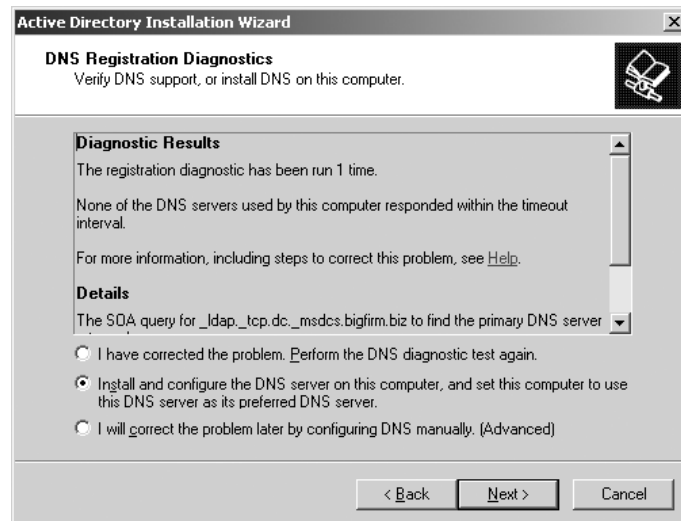

**FIGURE 8.12**  
Placing the  
SYSVOL volume

Remember the caution earlier on that you need at least one NTFS drive on an Active Directory server? This is where you'll use it. Anyone who's ever set up an NT 4 domain controller will soon realize how cool this is. You see, NT 4 stored a lot of important user configuration and control information in a directory named **NETLOGON** on the primary domain controller—system policy files, default profiles, and login scripts. But *backup* domain controllers needed the **NETLOGON** information as well, so network administrators had to somehow ensure that all of the files from the PDC's **NETLOGON** would somehow get copied to the BDC's **NETLOGON**s. With Active Directory, however, that's not a problem: All of that data goes into a directory called the **Sysvol** directory, which is *automatically* replicated to other domain controllers. It's an excellent labor saver and a hidden plus for Active Directory, at least over NT 4 domains. I click Next, and it's time to start worrying about DNS, or at least I'll have to if I get a screen like Figure 8.13.

**FIGURE 8.13**  
DCPROMO's not  
happy about DNS

This is a really nice improvement in 2003 over 2000—when 2000’s DCPROMO failed, it wasn’t very helpful. Here, DCPROMO is saying, “This computer can’t seem to contact any of its DNS servers.” What happens here is that DCPROMO tries to find and contact the DNS server for `bigfirm.biz`. (See, I *told* you that DNS was important!) Some trouble occurred along the way, leading to this warning message. Basically one of two things can go wrong with DNS here:

**DCPROMO didn’t get a response from any of the DNS servers for `bigfirm.biz`.** That’s what happened here, nearly—it was Bigdog’s local DNS servers that didn’t respond to *it*. Check connectivity and re-try the `nslookup`.

**DCPROMO got a response from the DNS servers for `bigfirm.biz` but found that they didn’t accept dynamic updates.** Suppose I’d already set up a machine as the DNS server, but the machine was an NT 4 server. The DNS service that shipped with NT 4 didn’t include support for RFC 2136, probably because NT 4 shipped before RFC 2136 was released. RFC 2136 supports the idea of dynamic updates, which are very important to the way that AD maintains information about sites and domain controllers. I tend to get this error a lot because when I set up my DNS zones beforehand, I sometimes forget to make the zones accept dynamic updates.

If you get this error message then it means you don’t have DNS set up right. I strongly recommend you cancel DCPROMO and fix DNS before going any further. DCPROMO *does*, you will note, offer you the option to just set up a DNS server on this system, *but never take the option*. Always take the time to get DNS right before running DCPROMO, or you’ll run into trouble with attaching extra domain controllers to a domain, as well as problems joining workstations and member servers. Once you’ve got it working, you won’t see a screen like the last figure; instead, you’ll see Figure 8.14.

**FIGURE 8.14**  
DCPROMO is  
happy about DNS

**TIP** *If you’re still having trouble with DNS, then hang on a bit and we’ll revisit it in the upcoming section “AD-Related DNS Design and Troubleshooting.”*

Now that all's well, click Next and one more warning appears, as you see in Figure 8.15.

**FIGURE 8.15**

Choose whether NT 4 RAS servers will be in the network.

This isn't the clearest screen in all of Active Directory. NT has, since its inception, supported what is called "the anonymous login." The idea is that you don't have to be authenticated to do a few things—not big things, but a few things. One of those things is NT 4's RAS. In order to authenticate a dial-in client to an NT 4 domain the RAS software would ask the NT 4 domain controller a few things about the account, basically just looking at a few attributes of the user's account. Here's the problem: suppose the RAS server is a member server, and not a domain controller. It wants to authenticate the user, but really lacks the credentials to just go up to a DC and ask about the user, so the RAS server has to be kind of sneaky in getting the information that it needs to figure out if the dial-in person is valid or not. It's not just the username and password; you have to be approved to dial-in in order to dial-in. Merely having a domain account isn't enough. So the RAS server has to ask the DC if this account is valid for dial-in. The RAS server doesn't have any rights to ask the DC that kind of thing, so it just uses this long-standing "back door" in NT, the anonymous login. Once anonymously logged in, a RAS server can ask if a user is on the "OK for dial-up" list. Where this presents a problem is that the anonymous login is clearly a dumb idea, as you've probably figured out. Microsoft clearly agreed, as they offer you the option when building ADs to disable anonymous logins.

The problem with that should be clear: NT 4 RAS servers won't work in a domain without anonymous logins. So while slamming the anonymous door's a good idea, it might irritate your dial-in users, presuming that you haven't upgraded your RAS servers to 2000- or 2003-based servers. So DCPROMO offers you the option to leave the door open.

This isn't a "forever" choice. Once you have your AD up and running, open up the tool Active Directory Users and Computers; inside it you'll see a folder called **Built in**. Inside that is a group named **Pre-Windows 2000 Compatible Access**. To become NT 4 RAS-compatible, just add the **Everyone** group. Once you've zapped your last NT 4 RAS server, just take **Everyone** out.

Choose which makes sense for you right now and click Next, and you'll get a screen like Figure 8.16.

**FIGURE 8.16**  
Directory Services  
Restore Mode  
password

One of Win2K and Server 2003's at-boot-time options is to rebuild a damaged Active Directory database to restore it to an earlier version that is internally consistent, but which has probably lost a lot of information. You don't want just anyone doing that—a malicious individual telling a DC to rebuild its database is basically telling it to *destroy* its database—so Windows 2000 or Server 2003 asks for a password that it'll use to challenge anyone trying to rebuild the AD database. Fill that in and click Next, and you'll see the screen in Figure 8.17.

**FIGURE 8.17**  
Confirming your  
choices

Read this last screen carefully, and if you did anything you didn't like, back up and make the changes before clicking Finish! The reason is simple: Once the Active Directory setup process starts, you'll see a screen like Figure 8.18.

**FIGURE 8.18**

Starting up the AD creation process

You'll be seeing *that* screen for a goodly time, at least 20–30 minutes in my experience. You can speed that up a bit with two hard disks, as mentioned before, but it takes a while. The reason to be double-sure before clicking Finish is that, if you realize after the AD creation process is underway that you want to go back and redo something, then you have to *first* sit through the entire AD creation process, *then* you get to reboot the server—never a quick process with Server—and *then* you get to run the Active Directory Installation Wizard again to break down the domain, *then* you get to reboot again, and finally you run the Active Directory Installation Wizard a *third* time, getting all the settings right this time, and of course, once that's done, it's another 20–30 minutes waiting and a reboot. Total elapsed time between "Oops, I clicked Finish and didn't mean it" and "Ah, now it's finally fixed" can be on the order of an hour and a half—plenty of time to kick yourself. Anyway, once the directory's ready, the wizard ends with a screen like the one in Figure 8.19.

**FIGURE 8.19**

Final DCPROMO report

Once it's done, you'll have to reboot this new domain controller. Note, by the way, what this message says—that you now have a site named Default-First-Site-Name. Remember sites? AD needs at least *one* site to function, and Microsoft figured that a lot of us wouldn't give a hoot enough about sites to bother naming one, so you start out with Default-First-Site-Name. We'll see how to do some site preparation later in this chapter.

## Preparing the DC for the Second Domain

Next, you'll set up the first DC in another domain—`ecoast.bigfirm.biz`. But, as always, you need to get DNS ready, so, go to the DNS server at `bigdog.bigfirm.biz` and create a new zone: `ecoast.bigfirm.biz`. (I know that's not exactly what we did in the last chapter, but I'm trying to minimize the number of machines you'll need to follow along.)

You've already seen how to do this, but here's a summary and reminder:

1. Open the DNS snap-in at Bigdog.
2. In the Forward Lookup Zones folder, right-click and choose New Zone, then run the resulting wizard to create a new primary zone for `ecoast.bigfirm.biz`. Be sure to allow dynamic updates.

If you like, you can then right-click the `bigfirm.biz` zone and choose New Delegation to introduce parent (`bigfirm.biz`) and child (`ecoast.bigfirm.biz`), but it's not really necessary. Surprised? Think about it—you're doing split-brain DNS, which means you're creating zones that are pretty much disconnected from the whole DNS hierarchy. This will work either way because, recall, you will make sure that every single DNS server in your intranet has a local copy of the `ecoast.bigfirm.biz` zone, whether because that DNS server is a primary server for `ecoast.bigfirm.biz` or a secondary.

Next, set up a machine that'll be the domain controller for `ecoast.bigfirm.biz`. Call it `svr1.ecoast.bigfirm.biz`—remember to set its domain suffix to `ecoast.bigfirm.biz`—and give it an IP address of `192.168.0.7`. Also, ensure that it uses `192.168.0.2` for its preferred DNS server.

Once you've booted your fully outfitted `svr1.ecoast.bigfirm.biz`, look in the `ecoast.bigfirm.biz` zone on the DNS server at `bigdog.bigfirm.biz`; SRV1 should have registered itself. If not, recheck that you made the zone dynamic, that the DNS suffix is `ecoast.bigfirm.biz`, and that SRV1 points to `.2` for its DNS server. Also, try an `ipconfig /registerdns` command to force a dynamic registration. Finally, when you're looking at the DNS zone for `ecoast.bigfirm.biz`, don't forget to refresh (F5) before you look to see if SRV1 made it to the zone.

Once again, you'll make life easier if you're 100 percent sure that DNS is working before you start adding new domains or domain controllers with `DCPROMO`, or even just adding member servers and workstations. In the next section, I'll show you how to do that, and also how to check a number of potential DNS problems.

## Using DNS to Troubleshoot DCPROMO and Logon Problems

After all that hard work you still might run into a DNS-related AD problem. It might show up in one of three cases:

- ◆ You're trying to add a second (or third or fourth or *whateverth*) domain controller to an existing domain, or
- ◆ You're trying to create a new domain in an existing forest, or
- ◆ You're trying to log on to a domain and you get an error message along the lines of “no domain controller found.”

Furthermore, you wouldn't *see* an error message necessarily, but if a member server couldn't find a DC to log it on for more than a week then that member server would probably not find itself a member of the domain any more, as workstations and member servers are expected to change their passwords once a week.

Now, if the problem crops up when you're running DCPROMO on the *first* domain controller on the first domain in the forest, then I've already covered what to do about it—check the SOA record and ensure that your would-be domain controller is contacting the correct DC. But if you see any of these other symptoms, then the probable cause is this: The machine contacted DNS to look up the SRV records for a domain controller and was unsuccessful. But you have a terrific troubleshooting tool at your fingertips—`nslookup`.

In the particular case of SRV1, you need to know that it can do two things. First, it must be able to log onto `bigfirm.biz`, because you'll have to prove that you're a pretty important person—an enterprise administrator—before DCPROMO will let you add a new `ecoast.bigfirm.biz` domain to the forest. Thus, you'll give DCPROMO a name and password from a `bigfirm.biz` account, and DCPROMO must then use that name and password to log you on. But DCPROMO can't do that if it can't find a DC for `bigfirm.biz`—and finding a DC is DNS's job. Second, once DCPROMO is satisfied that you have the credentials to proceed, then it'll need to start creating the subdomains and SRV records that will naturally get created when it creates the new domain `ecoast.bigfirm.biz` for you. Again, DNS enters the picture, as DCPROMO will need to find the primary DNS server for `ecoast.bigfirm.biz` before it can start writing those records.

AD stores the SRV records for domain controllers and global catalog servers under the following names:

- ◆ Global catalog servers (and I'll cover GCs in more detail later) are stored on a site-by-site basis under the name `_ldap` in domains named `_tcp.sitename._sites.gc._msdcs.domainname`, and all of the domain's global catalog servers are stored under the name `_ldap` in the domain named `_tcp.sitename.gc._msdcs.domainname`. In both cases, the SRV records for GCs will use port 3268.
- ◆ Domain controllers' SRV records are stored also on a site-by-site basis under the name `_kerberos` in domains named `_tcp.sitename._sites.dc._msdcs.domainname`. An all-in-one collection of all domain controllers in all sites is stored under the names `_kerberos` in a domain named `tcp.dc._msdcs.domainname`. Remember when I said a while back that AD creates subdomains to provide places to store SRV records for DCs so as to reveal their site location? This is what I was talking about.

So, for example, suppose you're sitting at `srv1.ecoast.bigfirm.biz`. You want to use `nslookup` to check that the would-be DC for `ecoast.bigfirm.biz` can find a DC for `bigfirm.biz`. At this point you have only one site, `default-first-site-name`. To find a domain controller, `srv1.ecoast.bigfirm.biz` would ask DNS if there was an SRV record named `_kerberos._tcp.default-first-site-name._sites.dc._msdcs.bigfirm.biz`. An `nslookup` run would look like this:

```
C:\>nslookup
Default Server:  bigdog.bigfirm.biz
Address:  192.168.0.2

> set type=srv
> _kerberos._tcp.default-first-site-name._sites.dc._msdcs.bigfirm.biz
Server:  bigdog.bigfirm.biz
Address:  192.168.0.2
```

```

_kerberos._tcp.default-first-site-name._sites.dc._msdcs.bigfirm.biz
  SRV service location:
    priority      = 0
    weight        = 100
    port          = 88
    svr hostname  = bigdog.bigfirm.biz
bigdog.bigfirm.biz  internet address = 192.168.0.2
>

```

If you're doing this for a different domain, then remember to replace "bigfirm.biz" with the AD domain's name and replace default-first-site-name with whatever your site is named.

Recall that if your system can't find a DC in its site, or if no DCs in the site respond, then it simply asks for the complete list of all DCs in all sites. This is clearly a short list in this simple one-DC network, but the SRV lookup is, again, for `_tcp.dc._msdcs.domainname` or, in this case, `bigfirm.biz`:

```

> _kerberos._tcp.dc._msdcs.bigfirm.biz
Server:  bigdog.bigfirm.biz
Address: 192.168.0.2

_kerberos._tcp.dc._msdcs.bigfirm.biz  SRV service location:
  priority      = 0
  weight        = 100
  port          = 88
  svr hostname  = bigdog.bigfirm.biz
bigdog.bigfirm.biz  internet address = 192.168.0.2
>

```

You can do the same searches for global catalogs by just replacing the `.dc.` with `.gc.` and `_kerberos` with `_ldap`—you can see an example here, where I search for all global catalog servers across all sites:

```

> _ldap._tcp.gc._msdcs.bigfirm.biz
Server:  bigdog.bigfirm.biz
Address: 192.168.0.2

_ldap._tcp.gc._msdcs.bigfirm.biz      SRV service location:
  priority      = 0
  weight        = 100
  port          = 3268
  svr hostname  = bigdog.bigfirm.biz
bigdog.bigfirm.biz  internet address = 192.168.0.2
>

```

Notice the port, 3268; you will see other records returned in some cases that have the `_ldap` name but that only run on port 389—those are not global catalog servers.

I cannot stress how powerful these `nslookups` are. They are the *key* to troubleshooting logon failures—and, as logon failures make creating new DCs or simply logging on fail, they're pretty useful.

But that just shows that you'd be able to log on to `bigfirm.biz` when running `DCPRMO`. How to ensure that `srv1.ecoast.bigfirm.biz` can find the zone for `ecoast.bigfirm.biz`? Recall that we did something like that before—just run `nslookup`, set `type=any`, and query on `ecoast.bigfirm.biz`. `nslookup` should return a primary name server of `bigdog.bigfirm.biz`.

## Build an Enterprise Administrator

You're not quite ready yet to create `ecoast.bigfirm.biz`. As you've learned, you'll need an enterprise administrator. You *could* use the built-in administrator account at `bigfirm.biz`, but this is a great time for some more useful hands-on examples: creating an account in `bigfirm.biz` and making it all-powerful.

### CREATING A FORESTWIDE ADMINISTRATOR

Before creating `ecoast.bigfirm.biz`, you'll need to create an administrative account that will be recognized as an administrator throughout this domain forest that you're creating. Creating user accounts is covered later in Chapter 9, but here's a quick cheat sheet on creating a forestwide admin.

Once that first domain controller for `bigfirm.biz` is up and running, log in as its local administrator as that's the only extant account at the moment. Because `bigfirm.biz` was the first domain created in the tree, it's a little bit special and, you may recall, is called the *forest root*. It's special because any other trees or domains that you create after this first domain sit below that first domain.

### Running Active Directory Users and Computers

Anyway, once you're logged into the `bigfirm.biz` domain controller Bigdog, click Start/Administrative Tools. The first time you do this, you'll notice that you've got three new tools: Active Directory Sites and Services, Active Directory Domains and Trusts, and Active Directory Users and Computers. As you can guess, you create user accounts with Active Directory Users and Computers, ADUC to its friends. This application is also the tool you use to modify user accounts. When started, its first screen looks like Figure 8.20.

**FIGURE 8.20**  
Opening ADUC  
screen

This is showing you the current domain, `bigfirm.biz`. In the right pane, you see five things that look like folders—`Builtin`, `Computers`, `Domain Controllers`, `ForeignSecurityPrincipals`, and `Users`. Although it'll be no surprise when I tell you that the folder labeled `Users` contains user accounts, I want to stress that it's not *necessary* to use that folder—`DCPROMO` creates that folder to provide a

default place to keep user accounts. If for some reason you wanted to create all new user accounts in the folder labeled **Computers**, nothing would stop you and you could make everything work just fine. If you knew at this point that your domain would be subdivided into an OU called **Hatfields** and another called **McCoys**, then you could create those OUs right now and create each new user account in either the **Hatfields** OU or the **McCoys** OU.

### Creating a New User Account

I'm going to be unoriginal here, however, and have you create a user account in the **Users** folder. To do that, just right-click the **Users** folder. The context menu will offer a submenu labeled **New**, and one of the options will be **User**; choose that and get a screen like Figure 8.21.

**FIGURE 8.21**

Creating the new user account

The screenshot shows the 'New Object - User' dialog box. At the top, it says 'Create in: bigfirm.biz/Users'. Below this are several input fields: 'First name' with 'Big', 'Initials' (empty), 'Last name' with 'Guy', 'Full name' with 'Big Guy', 'User logon name' with 'bigguy' and a dropdown menu showing '@bigfirm.biz', and 'User logon name (pre-Windows 2000)' with 'BIGFIRM\' and 'bigguy'. At the bottom are buttons for '< Back', 'Next >', and 'Cancel'.

Much of this is self-explanatory, but let's go through this screen. First you fill in a first and last name as well as a full name. These three characteristics are largely just labels of very little use save for displays and searching. The fifth field, **User Logon Name**, is the "magic" name, the one that this user will use to log in. Note that you can add an **@** suffix to the name and a domain name, giving you a logon name that looks like an e-mail name. Now, there's some complexity in that name that's not immediately apparent, so let me digress a bit about logon names.

### User Principal Names (UPNs) or Logon Names

As I've explained and as you already know if you worked with NT 4, it was possible to have an enterprise built of many different domains that trusted each other, where *trusted* in this context meant "allowed each other to share security information and logins." Thus, if I had a user account named **Mark** that was built in a domain named **ORION** but wanted to log in to a machine that was a member of a different domain named **AQUILA**, then the **AQUILA** machine would in general refuse to log me in unless the **AQUILA** domain *trusted* the **ORION** domain. I'd then log in to the machine from **AQUILA** by telling it three things: my username, password, and domain. If I'd merely tried to log in as **Mark** from **AQUILA**, the login would have been refused, as no **AQUILA** domain controller would have a **Mark** account—only the **ORION** ones would. By saying that I was "Mark from **ORION**," I told the **AQUILA** machine how to find a domain controller that could vouch for me—I was telling it, "Go find one of the **ORION**

domain controllers, they can verify that I'm me." (This also had another benefit—it was possible to have both a Mark account in ORION and a Mark account in AQUILA, and they'd be completely separate. They could have different passwords and in fact different people could use them.)

In a multidomain AD world, you can still do that. If I already had ecoast.bigfirm.biz built and I wanted to log in to a ecoast.bigfirm.biz machine with a Mark account from bigfirm.biz rather than ecoast.bigfirm.biz—two different domains, recall—then I could sit down at a ecoast.bigfirm.biz machine and, as before, say, "I'm Mark from bigfirm.biz," by typing **mark** into the username field, selecting Bigfirm from the Domain drop-down list, and filling in my password. The ecoast.bigfirm.biz machine would then know to go find a bigfirm.biz domain controller to verify my login.

The point is this: simply saying, "My username is Mark, log me in" doesn't provide enough information, any more than my telling you, "Hi, my name is Bill" would lead you to believe that I was a former president of the U.S.—there are *lots* of Bills around. I could be a lot more specific by adding a last name in my attempted deception ("Hi, my name is Bill Clinton"). So also anyone wanting to log into a domain has always needed to provide what might be called a first and last name—that is, a username and the name of the domain that the username resides in. In NT 4 terms, my "full name" looks like *domainname\username*, so that Mark from ORION would be ORION\Mark. As a matter of fact, you'll still find this useful in an AD world, so long as you use the NetBIOS name of the domain for *domainname*. For example, Mark from bigfirm.biz could be shortened BIGFIRM\Mark.

That *domainname\username* structure is a little lame, though, for reasons I'll make clear in a page or two, so AD introduced a new kind of full name. When logging on to an AD, instead of logging on by specifying a domain and a username, you can enter just one name that identifies (through a somewhat indirect method) your username and domain. Microsoft calls that newer kind of logon name a User Principal Name or UPN. (I'd have called it a universal login name, but who knows, maybe Microsoft liked UPN as an acronym better than ULN.)

What I think you'll find interesting about UPNs, though, is what they look like; here's an example: **mark@acme.com**.

*Waitaminute, I hear you cry—that's an e-mail address!*

Nope, it's not. It just *looks* like one and, as it turns out, for a fairly good reason. Stay tuned a few pages and I'll make it make more sense. For now, though, just understand that the "modern" way to log onto an AD forest is with a UPN, a UPN looks like an e-mail name, and a UPN does double-duty of providing your username *and* domain.

You can see that a UPN stands in for name *and* domain simply. Just sit down at a Windows 2000 Pro or XP Pro desktop that is a domain member and try to log in. (You may have to click the Options button to make the username, password, and domain fields visible.) In the Username field, type a name followed by an @, and you'll see the Domain field gray out. Once Winlogon, the program that puts up the Log on to Windows dialog up, sees an @ symbol, then it knows that it's getting a UPN, not a *username/domainname* pair, and so it grays out the domain field.

Getting back to this account that we're creating, you see that by default Active Directory Users and Computers suggests that BigGuy's UPN should be **bigguy@bigfirm.biz**. Presuming that you agree and create his account with that UPN, he can then sit down at any machine in the forest and log in with just **bigguy@bigfirm.biz**, and a password, without having to fill in a domain name.

### **UPN Suffixes and the Global Catalog**

At this point, you may be thinking, "Big deal—how does that save any typing?" Whether you type into one field of the Winlogon screen that you're *someone@somedomain* and a password, or whether you

alternatively type into the Name field that you're *someone* and type into the Domain field that you're from *somedomain* with a given password, what's the difference? What's the big deal?

Well, now, *that's* the interesting part.

You see, you can basically specify any domain name that you like after the name. When I first played with ADUC and saw that AD suggested that I give Bigguy the UPN `bigguy@bigfirm.biz`, I assumed that there was an iron-clad relationship:

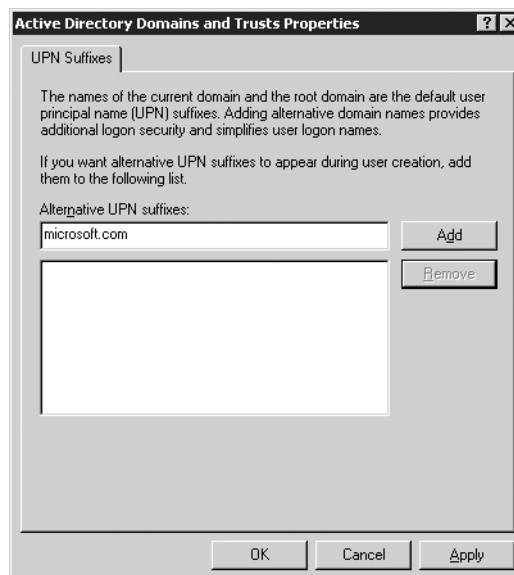

UPN = user account name + “@” + AD domain name

I mean, it certainly seemed a reasonable assumption given this example. But my assumption was wrong. If I wanted to, I could give BigGuy's UPN the suffix `@microsoft.com`, even though I clearly don't own the `microsoft.com` domain name. The latter part of a user's UPN need not have *anything to do with the user's domain*. You could have domains `bigfirm.biz`, `apex.com`, and `greatstuff.com`, with user accounts scattered throughout the three domains, but you could then give everyone UPNs like `somename@bigfirm.biz`. You can see the specifics on how to add more possible UPN suffixes to your AD in the “How Do I Add a UPN Suffix?” sidebar.

### HOW DO I ADD A UPN SUFFIX?

In the example about UPN suffixes and the global catalog, I suggested that I could give Bigguy a UPN of `bigguy@microsoft.com`. But a bit of clicking around ADUC doesn't yield any obvious ways to give myself the `microsoft.com` suffix. How do I get the DSA to let me use another suffix? Follow these steps:

1. Click Start/Administrative Tools/Active Directory Domains and Trusts.
2. In the left pane, there's a list of the domains in your enterprise. Above that list is a line Active Directory Domains and Trusts; right-click that and choose Properties. You'll see a dialog box like the one shown here.

*Continued on next page*

**HOW DO I ADD A UPN SUFFIX? (continued)**

3. Fill in the suffix that you'd like, such as microsoft.com or whatever. Click Add.
4. Click OK.
5. Close Active Directory Domains and Trusts.

***So What's the Point of Using E-mail Like Logon Names?***

This raises two questions. First, why would you do this, and second, how does it work? The answer to the first question is that obviously Microsoft intended the name to be your e-mail name, such as joe.blow@bigfirm.biz.

At this point, I must confess that I figured Microsoft did this merely to give me yet another reason to buy Exchange. But I wronged them. Here, instead, was Microsoft's reasoning.

In large corporations, you might have hundreds of domains, and those domains don't have nice names such as THIRDFLOOR or MARKETING; instead, they're the CORP0123X domain. So when teaching a user how to log on, techies had to tell the user, "You are johnax12 from domain CORP0123X with password YiKeSiWiLiNeVeRrEmEmBeRtHiS72." Folks had trouble remembering all of that. So Microsoft wanted to simplify it. It wanted to give every user a unique name. So Microsoft asked: Do users currently have a name that is relatively unique? And the answer was yes, their e-mail name. So if johnax12 has the email name johnax@bigfirm.biz, or perhaps j9391@aol.com, then we can let him use that as his logon name. And note that I offered an AOL e-mail name. There's no reason you can't give a user an e-mail name from another domain because it's *not really an e-mail name*. The system never *uses* it as an e-mail name.

Basically, Microsoft let us have users log onto forests using names that *look* like e-mail names for one and only one reason: It makes user training easier.

That leads to the second question: How do we make this work? Sure, it's lovely that I can log on to my very complex corporate network as mark@microsoft.com, but how does my workstation find out that my *real* logon name is mmina in a domain named bigfirm.biz? By adding a new step to logons. I log in as mark@microsoft.com, and then my workstation has to say to itself, "Well, 'mark'...if that's your real name! Let's find out who you *really* are," and then proceeds to "crack" my logon name. But how does it do that? With the help of an Active Directory service mentioned a few times before in this chapter called the *global catalog* (GC). The GC service runs on one or more domain controllers, and among other things, it keeps an index relating people's UPNs—their logon names—to the names of their actual domains. Thus, if I created an account for myself with UPN mark@microsoft.com and tried to log in to a bigfirm.biz machine, that machine would quickly pop over to a local GC server (which, by the way, the machine finds by looking it up in DNS—that's one of the many examples of Active Directory services that systems use DNS to find) and ask the GC server, "Where does mark@microsoft.com *really* live?" The GC server would reply, "In bigfirm.biz," and so my workstation would then contact a domain controller in bigfirm.biz (finding a DC for bigfirm.biz in DNS) and log me in. So the GC is a pretty positive thing, as it speeds up logons. But it *does* have one disadvantage: It can keep you from being able to log in—where your workstation once only needed to find a DC to log in, it now needs to first find a GC, and then a DC.

### **Handling Branch Offices and Global Catalogs**

If your workstation cannot find a global catalog server in a multidomain Active Directory forest, then you cannot log in. So it's a good idea to have more than one around. (As far as my experiments show, you don't need a GC to log in to a single-domain forest.) But there are workarounds for this.

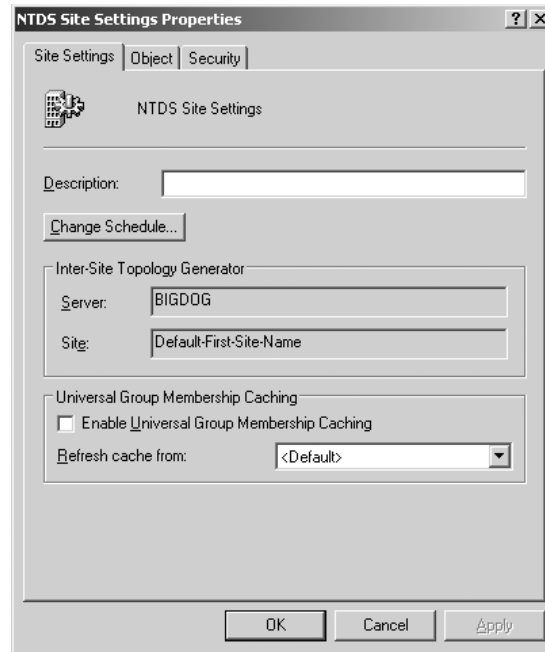

First, you can tell your local DC to accept logons even when it can't find a GC with a Registry entry, according to Microsoft Knowledge Base article 241789. Just create an entry in `HKEY_LOCAL_MACHINE\System\CurrentControlSet\Control\Lsa` called `IgnoreGCFailures` of type `REG_DWORD` and set it to 1. It's not a really great idea, however, as it means that your workstation will skip a security step while logging you on—it bypasses checking your universal group membership. That's important because you may be a member of a universal group that has been denied access to the workstation, and normally that'd be a reason to deny you the logon. But I mention it for those cases when a successful logon that ignores a universal group denial is more important than denying a logon because a workstation can't find a global catalog.

Second, you can use Windows Server 2003–based DCs. 2003-based DCs cache information that they've gotten from GCs, if you tell them to. You turn on GC caching at the site level rather than on a DC-by-DC basis. Here's how.

1. Open Active Directory Sites and Services—Start/Administrative Tools/Active Directory Sites and Services.
2. In the left pane, you'll see a folder labeled **Sites**; open it and you will see an object that looks like a skinny three-story pale yellow building; this represents a site. If you have only one site, then you'll have only one building; if you have more than one, then you'll have a building for each site. In the case of my simple example, you'll probably only have one site named `Default-First-Site-Name`. Click the site's object.
3. In the right pane, you'll see three objects: a folder-like icon labeled **Servers**, an object with an icon that looks something like a certificate labeled **Licensing Site Settings**, and an object with an icon that looks like a building with a cyan-colored gear growing out of it. (It looks like it's either a flying saucer hovering next to the building or a frame of stop-action footage just before an unpleasant industrial accident.) That object is labeled **NTDS Site Settings**. NTDS means NT Directory Service, an old name for Active Directory. Right-click it and choose **Properties**, and you'll see a dialog like Figure 8.22.
4. Note the **Enable Universal Group Membership Caching** check box; if you check this, then you'll tell AD to have all of the DCs in that site cache GC info.

That's *how* to do it, but *should* you do it? That's a tougher question. You might change a user's status and want that change in status quickly propagated throughout the network, but if the branch office's WAN link is offline then of course you wouldn't see the effects of those changes at that branch office. If that branch office is caching, then the user will get logged on, although with the old status, and that might be bad. On the other hand, if you'd left caching off, then *no one* from that office could log on if the branch office's WAN connection was down. It's basically convenience versus security, and you'll have to make that call yourself.

**FIGURE 8.22**  
NTDS settings  
for a site

### Creating Global Catalog Servers

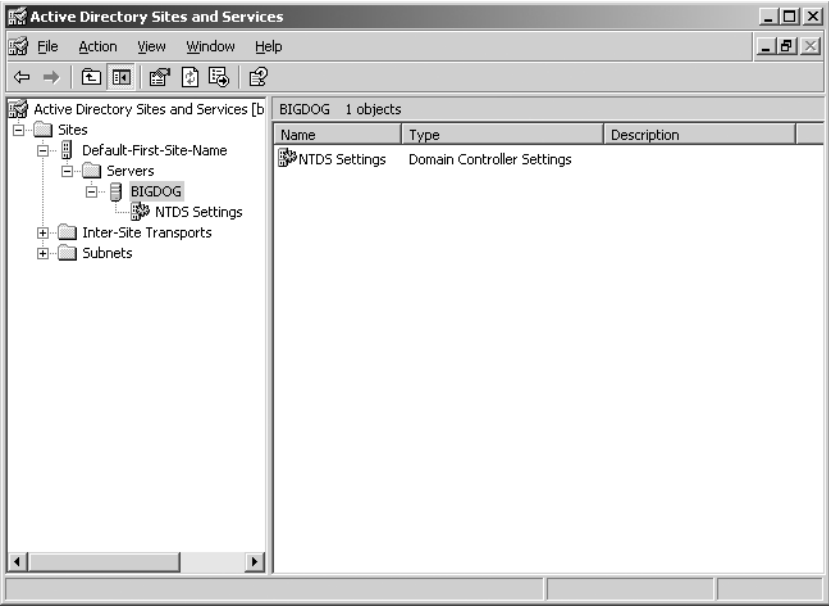

Before leaving GCs to return to the nuts and bolts of creating a user account, let's see how to create more global catalog servers. Only domain controllers can be global catalog servers. You can make any DC a GC by opening Active Directory Sites and Services which is, again, in Administrative Tools. Recall that in the left pane you'll see an icon—or icons—representing different geographic sites on your network, and if you've only created a basic AD and haven't done any work on your sites yet, then AD will have automatically created one site called Default-First-Site-Name. Inside each site's folder you'll find a folder named "Servers." Open a site's Servers folder and you'll see icons representing every domain controller. Open any domain controller's icon and you'll see a folder named **NTDS Settings**, as you see in Figure 8.23.

Note that this is *not* the same **NTDS Settings** folder as the one that we looked at when setting up a site to do GC caching. *That* **NTDS Settings** folder referred to settings for an entire site; *this* one refers to settings for just a domain controller. (Notice also that calling the folder **Servers** is misleading—it contains objects for domain controllers only, not servers in general.)

Right-click the **NTDS Settings** folder and choose Properties, and you'll see a properties page like the one in Figure 8.24.

To make a DC act as a GC, just check the box labeled Global Catalog, click OK, and then close AD Sites and Services. As a rule of thumb, you'd like to see two GCs on every site. And if you're a one-domain enterprise, then you should, at least according to a Microsoft AD expert, make every *one* of your DCs into global catalog servers.

**FIGURE 8.23**  
Active Directory  
Sites and Services

**FIGURE 8.24**  
NTDS folder  
settings

***Finishing Up the User Account***

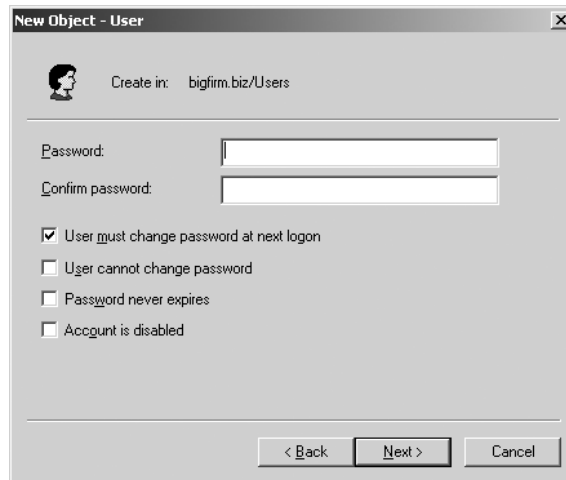

Anyway, let’s return to Active Directory Users and Computers, where we were in the middle of creating the bigguy account. Notice that ADUC automatically creates a downlevel username. This is the name

that bigguy would be recognized as if he tried to log in to an NT 4 or earlier server. Simply sticking with bigguy for a downlevel name seems fine, so I click Next and the screen changes to Figure 8.25.

**FIGURE 8.25**

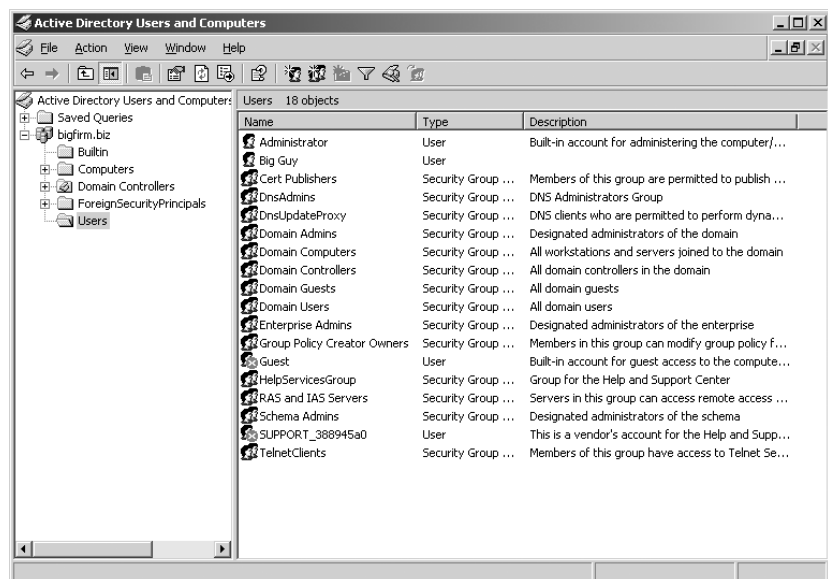

Setting a password

A straightforward screen; un-check “user must change password at next logon” then click Next and I’m asked to confirm the account information and click Finish. Opening the Users folder, I can see that bigguy is now created, as you see in Figure 8.26.

**FIGURE 8.26**

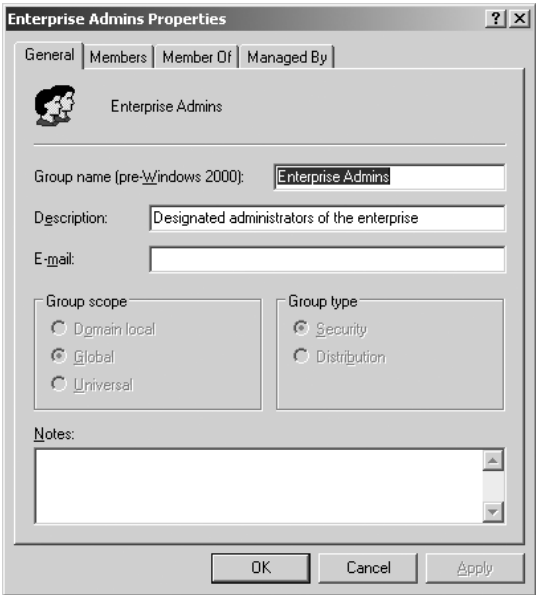

Contents of the Users folder after creating bigguy

Notice the groups that DCPROMO automatically created when you build a domain controller. The one we’re interested in is the group named Enterprise Admins; as you read earlier, anyone in that group is recognized as an administrator all around the forest. Adding bigguy to that group is simple.

First, open the Enterprise Admins group by either double-clicking it or by right-clicking it and choosing Properties, and you see something like Figure 8.27.

**FIGURE 8.27**  
Enterprise Admins  
folder properties

Clicking the properties page Members tab shows the list of members of Enterprise Admins, as you see in Figure 8.28.

**FIGURE 8.28**  
Members of Enter-  
prise Admins

Notice that the local administrator account for the bigfirm.biz domain controller is an Enterprise Admin. DCPROMO sets that up automatically. Recall that bigfirm.biz is the root domain, and there's got to be at least one forestwide administrator. By clicking the Add button, you get a dialog box like Figure 8.29.

**FIGURE 8.29**

Adding bigguy to Enterprise Admins

Now, veterans of Windows 2000 will recognize this dialog for what it is: a lame cop-out. Under Windows 2000, you'd get a dialog box that showed you all of the users in the domain (or actually the first 20,000 of them, and you could adjust that), and you'd just pick the user that you wanted to add to the group. But that dialog's gone. Instead, now you've got to type in Bigguy's name and click Check Names. The dialog then checks the AD for a name that matches what you typed in. Microsoft did this, I'm told, because it could take *hours* for the Windows 2000—vintage Select Users, Contacts or Computers dialog box to populate itself on a large domain, and they got some flack over that. Their answer seems to have been, “Hey, if you don't like our nice helpful list of users, then the heck with you—go type in the names yourself.”

This isn't a totally unforgiving dialog box, though. If you type **b** and press Check Names, then it'll see that you only have one user whose name starts with **b** and will fill in Bigguy. If there is more than one user starting with **b**, then it'll show you them and you can choose the one you want. Or you can click the Advanced button and be offered a Find Now option where you can use wildcards and become pretty specific about what you want it to find. All in all you can easily get used to this new dialog box...I just wish the old one were available as an option.

For now, just select the bigguy account, click OK, and bigguy's a forestwide administrator.

**TIP** By the way, even now bigguy isn't a complete Superman in this domain. There is a group that the Enterprise Administrators aren't a part of—the Schema Administrators. This group can, as its name suggests, make changes to the forest's schema, which includes changing what the global catalog stores. By default, the only member of the Schema Administrators group is the default Administrator account on the PDC of the domain that is the forest root (or, for the purists, “the default administrator on the machine that happens to serve in the role as PDC FSMO for the domain that is the forest root”). Also, machines in the domain would not allow bigguy to sit down and administer them—they would not recognize him as an administrator. To fix that, put bigguy in another group, Domain Admins. So to make bigguy truly a Big Guy, add him to Schema Administrators and Domain Admins. Or put Enterprise Administrators inside Schema Administrators.

## BUILDING SUBDOMAIN CONTROL WITH AN ORGANIZATIONAL UNIT

You read earlier that one of AD's strengths is that it can let you grant partial or complete administrative powers to a group of users, meaning that it would be possible for a one-domain network to

subdivide itself into Uptown and Downtown, Marketing and Engineering and Management, or whatever. Let's look at a simple example of how to do that.

Let's suppose that there are five people in Marketing: Adam, Betty, Chip, Debbie, and Elaine. They want to designate one of their own, Elaine, to be able to reset passwords. They need this because "I forgot my password, can you reset it for me?" is probably the number one thing that Marketing calls the central IS support folks for. The central IS folks are happy to have someone local to Marketing take the problem off their hands, freeing them up to fight other fires.

Here's the process:

1. Create an organizational unit called Marketing. (You can call it anything that you like, of course, but Marketing is easier to remember later.)
2. Move Adam's, Betty's, Chip's, Debbie's, and Elaine's already-existing user accounts into the Marketing OU.
3. Create a group called MktPswAdm, which will be the people who can reset passwords for people in the Marketing OU. (Again, you can actually give it any name that you like.)
4. Make Elaine a member of the MktPswAdm group.
5. Delegate password reset control for the Marketing OU to the MktPswAdm group.

If you want to follow this along as an exercise, get ready by creating accounts for Adam, Betty, Chip, Debbie, and Elaine as you did for BigGuy, except don't make them administrators. Or do it from the command line: type **net user username /add** and you'll get a basic user account built in the Users folder. For example, create Adam like so:

```
net user adam /add
```

You've got to be sitting at the domain to do this. You can create domain users from any other system at the command line, but you must then add the option **"/domain"** as in

```
net user adam /add /domain
```

### ***Creating a New Organizational Unit***

Creating a new OU is simple. Just open up Active Directory Users and Computers, right-click the domain's icon in the left pane, and choose New/Organizational Unit. A dialog box will prompt you for a name of the new organizational unit. Fill in **Marketing** and click OK and you're done.

### ***Moving User Accounts into an OU***

Next, to move Adam, Betty, Chip, Debbie, and Elaine to the Marketing OU, open ADUC, open your domain (mine's bigfirm.biz, yours might have another name), and then open the Users folder. (If you created the five accounts somewhere other than Users, then look there.)

You can move all five users over by clicking Adam, then holding down the Control key and left-clicking the other four accounts. Then right-click one of the five accounts and you'll get a context menu that includes a Move option; select Move and you'll get a dialog box asking you where to move the "object." It'll originally show you your domain name with a plus sign next to it; just click the plus sign and the domain will open to show the OUs in your domain. Choose Marketing and click OK,

and all five accounts will move to the Marketing OU. In ADUC, you can open the Marketing OU and you will see that all five accounts are now in that OU.

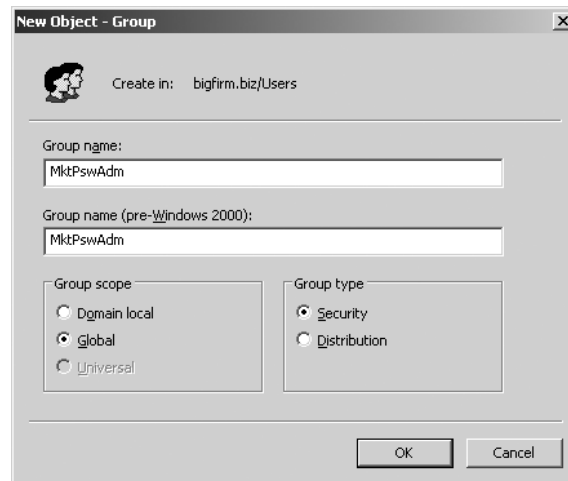

*Or...* if you want to use a new ability in Server 2003, try out drag-and-drop. In ADUC, click the **Users** folder in the left pane. You will be able to see the contents of **Users** in the right pane. In the left pane you'll not only be able to see **Users**, you should be able to see the Marketing OU as well. Select the users and then drag them from the right pane to the Marketing OU, and release the mouse button. Instant OU movement! (What's that you say, you're not impressed? Well, believe me, when you do a lot of user management, you'll find it a nice bit of lagniappe. Trust me on this.)

### **Creating a MktPswAdm Group**

Next, to create a group for the folks who can reset Marketing passwords. Again, work in ADUC. Click **Action/New/Group**. (You can also right-click the Marketing OU and choose **New/Group**.) You'll see a dialog box like Figure 8.30.

**FIGURE 8.30**

Creating a new group

You see that the dialog box gives you the option to create any one of the three types of groups in an Active Directory. A global group will serve our purposes well, although in this particular case—the case of a group in a given domain getting control of an OU in that same domain—then either a domain local, global, or universal group would suffice. I've called the group **MktPswAdm**. Click **OK** and it's done.

Next, put Elaine in the **MktPswAdm** group. Right-click the icon for **MktPswAdm** and choose **Properties**, as you did earlier when creating **bigguy**. Click the **Members** tab, then the **Add** button, then Elaine's account, then **Add**, then **OK**, and you'll see that Elaine is now a member of **MktPswAdm**. Click **OK** to clear the dialog box.

### **Delegating the Marketing OU's Password Reset Control to MktPswAdm**

Now let's put them together. In ADUC again, locate the Marketing OU and right-click it. Choose **Delegation** and the first screen of the **Delegation of Control Wizard** will appear, as you see in Figure 8.31.

**FIGURE 8.31**

Opening screen of the Delegation of Control Wizard

The wizard is a simplified way to delegate, and it'll work fine for our first example. Click Next and you'll see Figure 8.32.

**FIGURE 8.32**

Before selecting a group

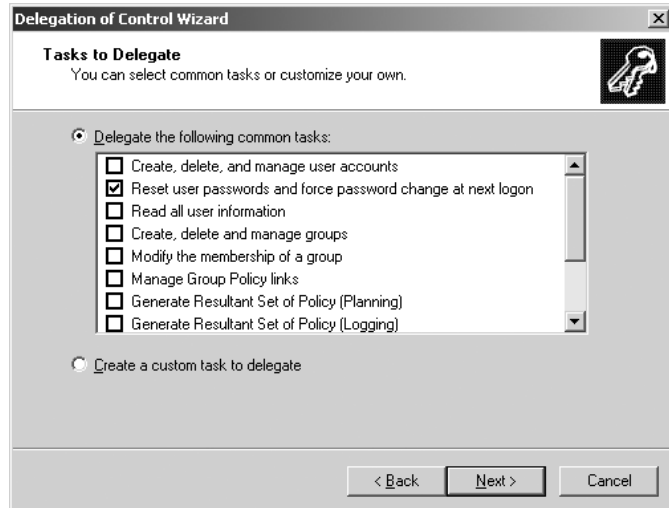

Next, you've got to tell it that you're about to delegate some power to a particular group, so you've got to identify the group. Click Add and choose the MktPswAdm group. After choosing MktPswAdm and clicking OK to dismiss the Add dialog box, the screen looks like Figure 8.33.

**FIGURE 8.33**  
MtkPswAdm  
selected

Now click Next, and you'll get a menu of possible tasks to delegate, as you see in Figure 8.34.

**FIGURE 8.34**  
Options for  
delegation

Once you do a bit of exploring here, you'll see that there are many, many functions that can be delegated. Rather than force you to wade through a long list of things that you'll never care about, however, Microsoft picked the top dozen or so things that you'd be most likely to want to delegate, one of which is the ability to reset passwords. I've checked that in the figure; press Next and the final screen in the wizard appears, as you see in Figure 8.35.

**FIGURE 8.35**

Confirming your choices

Click Finish, and it's done.

Remember, delegation lets you designate a set of users who have some kind of control over a set of users and/or computers. You accomplish that by putting the controlling users into a group, the things that you want them to control into an OU, and then delegate control of the OU to the group.

**TIP** Or, to put it in a bit more eccentric fashion, think of it this way: *The victims go into an OU, the oppressors into a group.*

### ADVANCED DELEGATION

Although that's a nice—and useful—example, it only hints at the power of delegation. You actually needn't use the wizard to delegate, it just makes things simpler for a range of common applications. Here's how to more directly manipulate delegation.

**TIP** *Even if you're not terribly interested in delegation, stay with this example. It shows how to navigate the three levels of progressive complexity in Server 2003 Security dialogs, which is something you'll be doing a lot of as an admin in a 2000, XP, and 2003 world.*

First, open up ADUC and click View/Advanced Features. New things will pop up on the screen, as in Figure 8.36.

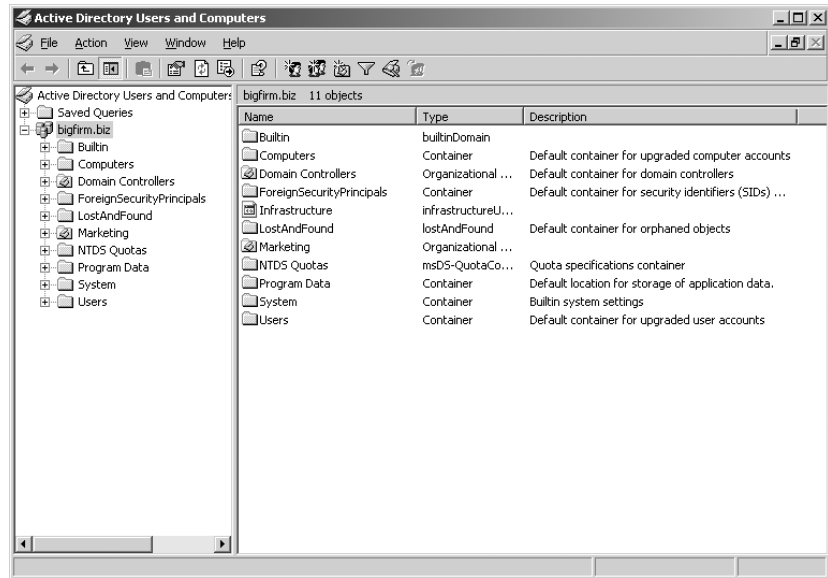

Right-click **Marketing** and choose Properties. You'll get a properties sheet with a tab labeled Security. Click it, and you'll see something like Figure 8.37.

Here, I've scrolled down a bit to show what the dialog box tells you about the MktPswAdm group. It appears that the group has powers that can only be described as “special,” which isn't all that helpful. This is the top level of a 2003 Security dialog. Think of it as the overview level of security information. But I quite frankly find this top level view pretty limited. About all it really tells me is that there are ten entries in this dialog—you can't see that because they don't all fit in here—and you may recall that each of these entries are called Access Control Entries or ACEs. The list in total is called the Access Control List or ACL, pronounced “ackull,” rhyming with “shackle.”

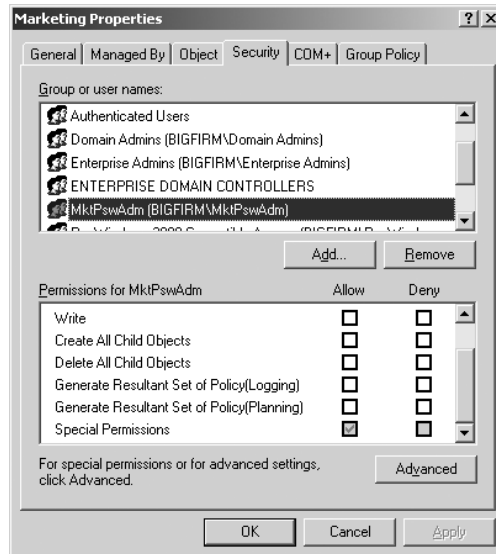

**FIGURE 8.36**

ADUC with View  
Advanced Features  
enabled

**FIGURE 8.37**

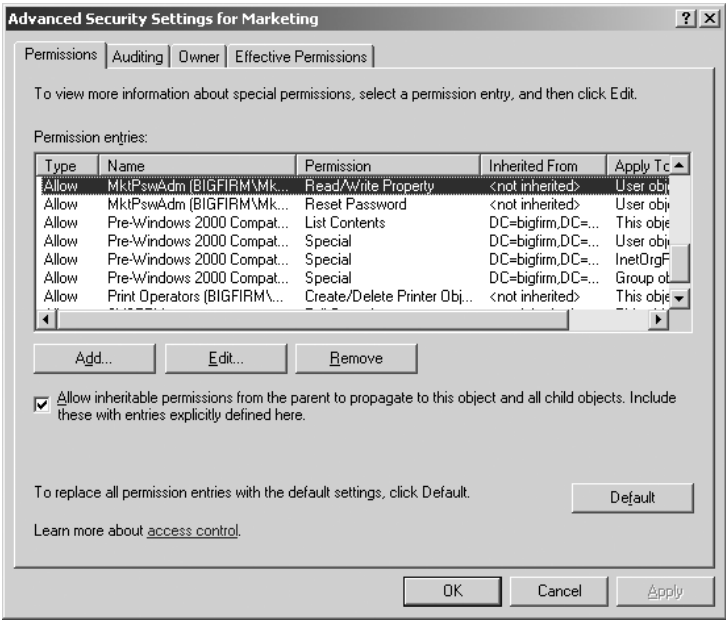

Security tab on  
Marketing OU

In theory you should be able to click any of the ACEs in the top part of the dialog box and in the bottom part you see what powers that ACE gives the thing named in the ACE. For example, you see in the figure that MrkPswAdm has “special” powers. That’s one reason that I don’t like this dialog all that much, as “special” doesn’t tell me much. The other reason is that this dialog box only shows a really simplified list of possible powers, and so what you see will be sometimes misleading. That’s why it’s nice that you can zoom in one level by clicking the Advanced button. If you do that in ADUC, you’ll see a screen like Figure 8.38.

**FIGURE 8.38**

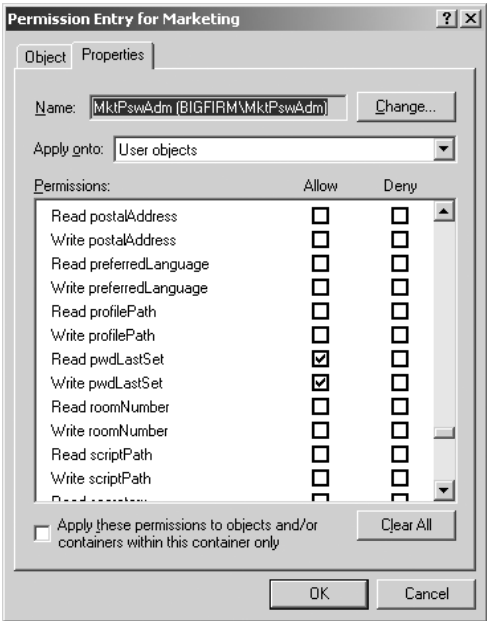

Advanced security settings for Marketing OU

Scroll down to highlight MktPswAdm and you see two entries for it. One gives the power to read and write some kind of property, and the other gives the power to reset passwords. The “reset password” makes sense...but what’s the “read and write property?” Click it and choose Edit and you’ll see something like Figure 8.39.

**FIGURE 8.39**

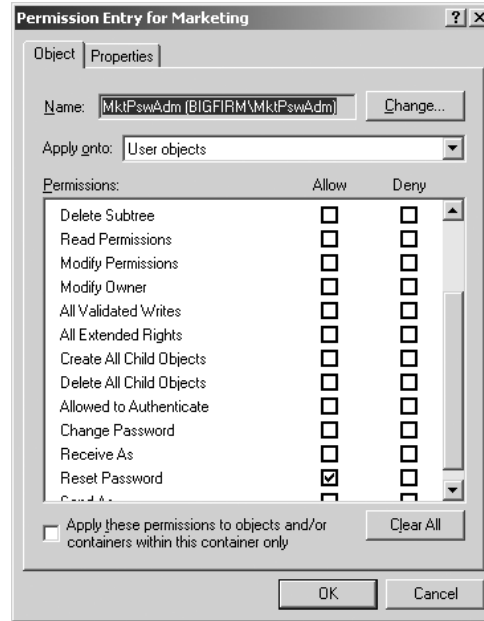

Specific MktPswAdm abilities

Here you see that we've given MktPswAdm the ability to read and write a user's properties, but *only* the pwdLastSet property—AD-ese for “current password.” Go back and look at the other record for MkwPswAdm and Edit it and you'll see Figure 8.40.

**FIGURE 8.40**

Giving the power to reset passwords

As you can see from the figure, there are a *lot* of powers that you can grant to a particular group in controlling a particular OU!

Where might you make use of this? Well, you gave MktPswAdm the ability to change passwords, but you didn't take it away from the groups who originally had it—the domain admins, enterprise admins, and the like can still reset passwords. That's not a bad idea, but if you really ever *do* come across a “feuding departments” scenario, wherein Marketing wants to be sure that they're the *only* people who can administer accounts, then you'd first delegate the Marketing OU to some group, and then you'd go in with the Security tab and rip out all of the other administrators.

**TIP** And to see a step-by-step example of a more advanced delegation, look back to the end of Chapter 5, where we created a new kind of group called *Installers*.

### HOW DO I FIND OUT WHAT DELEGATIONS HAVE HAPPENED, OR UNDELEGATE?

Time for some bad news.

Suppose you're not the administrator who set up the Active Directory. Suppose, instead, you're the *second* administrator, the person hired to clean up a mess that some guy—who's now gone—made. You know these kind of administrators, the “mad scientist” variety: the guys who just click things in the administrative tools until they solve the problem...they think. And *document*? Heck, real administrators don't document. After all, this network was hard to design, it should be hard to understand!

So you're wondering what this guy did. How did he change the company's AD from the default AD that you get when you run DCPROMO? That's a hard question to answer. First, of course, the OUs that he created are obvious—just look in Active Directory Users and Computers and you'll see the new folders. But what delegations did he do?

Sad to say, there is no program you can run that will compare the standard AD structure and delegations to the current AD structure and delegations and spit out a “this is what changed” report. About the best you can do is to right-click all of the containers—the domain itself, **Users**, **Computers**, and any OUs—and choose Properties and look in the Security tab. (Don't forget to do View/Advanced before doing that, or the Security tab won't appear.) So let me offer a really heartfelt piece of advice: Always document delegations. *Always*. Try to control who can do delegations and make clear that delegations are only authorized sparingly.

While I'm here, I should also mention that although the Delegation of Control Wizard is a nice little tool, it's only a *delegation* wizard, not an *undelegation* wizard. If you want to remove MktPswAdm's ability to change Marketing passwords, you've got to go into the Security tab, find the references to MktPswAdm, and rip them out.

### CREATING A SECOND DOMAIN

But suppose you're not happy with just one domain; that OU stuff just wasn't enough for the boss. Resigned to politics, you're ready now to create the second domain, ecoast.bigfirm.biz. Recall that one machine can only be a domain controller in one domain, so you need a second machine to act as DC for ecoast.bigfirm.biz before you can create that domain. Starting from srv1.ecoast.bigfirm.biz, start DCPROMO.

DCPROMO starts out as before. Tell it that you're creating a new domain but not a new tree, choosing the option Child Domain in an Existing Domain Tree. Before you go any further, DCPROMO asks you to log in, as you see in Figure 8.41.

**FIGURE 8.41**

Establishing credentials for creating a child domain

Notice that for some reason you've got to specify account and domain—the UPN doesn't work here. Here, I've filled in bigguy's login information. DCPROMO pauses a bit to authenticate the bigguy account. Once I've filled that in, I click Next and the screen in Figure 8.42 appears.

**FIGURE 8.42**

Naming the child domain

The screenshot shows the 'Active Directory Installation Wizard' window, specifically the 'Child Domain Installation' step. The window title is 'Active Directory Installation Wizard'. The subtitle is 'Child Domain Installation' with the instruction 'Select the parent domain, and specify a name for the new child domain.' Below this, there are three text input fields. The first is labeled 'Parent domain:' and contains 'bigfirm.biz', with a 'Browse...' button to its right. The second is labeled 'Child domain:' and contains 'ecoast'. The third is labeled 'Complete DNS name of new domain:' and contains 'ecoast.bigfirm.biz'. At the bottom of the window are three buttons: '< Back', 'Next >', and 'Cancel'.

DCPROMO now needs to know which domain to add a child to and what to call the child. You can fill in that the parent's name is `bigfirm.biz`, or just press the Browse button and chosen from the domains in the forest. The child domain will be named `ecoast.bigfirm.biz`, but DCPROMO just wants you to type in **ecoast** for the child name, and it then assembles it and the parent domain into the complete name `ecoast.bigfirm.biz` for the child domain.

You'll then progress through DCPROMO much as with the first domain, so I'll spare you the screens—but notice Figure 8.43.

**FIGURE 8.43**

NetBIOS name for child domain

The screenshot shows the 'Active Directory Installation Wizard' window, specifically the 'NetBIOS Domain Name' step. The window title is 'Active Directory Installation Wizard'. The subtitle is 'NetBIOS Domain Name' with the instruction 'Specify a NetBIOS name for the new domain.' Below this, there is a text input field labeled 'Domain NetBIOS name:' which contains 'ECOAST'. At the bottom of the window are three buttons: '< Back', 'Next >', and 'Cancel'.

The `bigfirm.biz` domain got the downlevel name (or NT 4 or NetBIOS name, take your pick, they all mean the same thing) of `bigfirm`. But how to name the child domains with the more complex names? Just take out the periods and take the leftmost 15 characters? Do some kind of truncated name

with tildes on the end, in the same way that long filenames get converted to 8.3 names? Well, you can actually give your domains any downlevel name that you like, but the default ones are just the leftmost portion of the domain name, as you see in the figure. As *ecoast* is the leftmost portion of the domain name, the domain gets the downlevel name *ecoast* by default.

From this point on, you'll just answer DCPROMO's questions as you did for the first domain, so I'll spare you those screens. Another 20 to 30 minutes of Active Directory setup and the second domain is done.

Before leaving here, let me make a few points about using DCPROMO to build domains. First, as you've already read, get DNS ready before starting. Second, DCPROMO's kind of rigid about the order in which you create domains. The first domain that you create in a forest is the forest root domain, and there's no changing that. Third, you've got to add domains by creating them; you can't create a domain *green.com* and another *yellow.com* separately and then decide later to merge them into a forest. Instead, you must first create *green.com* as the first domain in a forest and then create *yellow.com* as the first domain in a new tree but in an existing forest.

## Other Active Directory Objects: Contacts, Shared Folders, Printers and More

You might have noticed when you right-clicked the domain in the Active Directory and chose New, there were three other things that you can create:

- ◆ Contact
- ◆ Shared Folder
- ◆ Printer
- ◆ MSMQ Queue Alias
- ◆ InetOrgPerson

None of them are quite what they appear to be, so let's take a minute and see what they're good for.

### INETORGPERSO AND MSMQ QUEUE ALIAS

These two objects are new to Server 2003 and are of kind of limited value to the general AD-using public, but here's the short version of what they're good for. InetOrgPerson object is an entry describing a person, but in a way compatible with Sun's iPlanet directory service. MSMQ Queue Alias supports a Microsoft service called Microsoft Message Queue. I haven't found a use for this yet, but I imagine that MSMQ-using tools like Exchange and Microsoft Operations Manager will create objects of this type automatically.

### CONTACTS

Another object that you can create is called a "contact." It's something that acts very much like a user account...but *isn't* a user account. It doesn't have a password and cannot log on to the network.

So what good is it?

Open up a real-live user account, and you'll see that it's got bunches of tabs. There are places for information such as street address, e-mail address, manager's name, phone numbers, home page, and other items. You can, therefore, use your Active Directory as a kind of low-octane Human Resources database. This won't be news to Exchange users, as Exchange has kept a database like this for years.

So, for example, if you created a bunch of users and took the time to type in all of their managers' names in the Manager fields, then you could do queries such as, "Show me all of the users whose manager is Evelyn Wilson."

If that sounds interesting, then you might want to be able to include information on people who *aren't* users on your network—friends, family, business associates, and so on. Contacts let you do that. Once you create a contact, you'll see that it has fields for that same kind of information as user accounts do: phones, addresses, managers, and the like. From a Windows 2000, XP, or 2003 system, then, you could click Start/Search/For People and, in the Look In drop-down box, specify the Active Directory. The Search for People dialog box then lets you search by names, e-mail addresses, and the like. Once you find a person, you right-click his record and choose Send Mail and it starts up your mail client, with the e-mail address all filled in. AD, then, becomes a kind of simple contacts database.

The whole notion of first looking up a name in AD and then right-clicking to send that person mail is a bit cumbersome. I think, however, that this wasn't Microsoft's main idea; I believe, instead, that you can make this more useful if you're running Exchange 2000 or Exchange Server 2003. I don't use Exchange, however, so I can't say. Additionally, as you *can* query the Active Directory with LDAP, you could in theory build or use any of a number of tools to query your AD-based contacts database. I say *in theory* because also in theory you should be able to look up names in Outlook 2000 from an LDAP-compatible server. As I said, I don't use Exchange. But I *do* use Outlook as a mail client, and I've tried telling it to look up people's names in the AD. So I should be able to type into the To field a name in the database, such as Mike Smith and then Outlook should automatically fill in Mike's e-mail address. I've not been able to make that work and the folks that I've asked at Microsoft about it just kind of look bewildered and say, "Well, I guess it *should* work, but we all use Exchange, so I've never tried it. . . ." People tell me that Office XP's brand of Outlook can use an AD to look up names. Anyway, the bottom line is that contacts are apparently of quite limited value unless you're running Exchange 2000 or 2003.

## SHARED FOLDERS

You'd think that creating something called a *shared folder* in the Active Directory would, well, *share* a folder. But that's not what happens. Instead, creating a shared folder in the Active Directory just puts a notice in the AD saying, "Someone shared a folder at the following location, and it's got the following stuff in it." This is known as *publishing* a share in the AD.

For example, suppose we create a directory on C:\ on BIGDOG called JUNK and share it as JUNK. (Just create the directory JUNK in C:\, then right-click its folder and choose Sharing. Click the radio button Share This Folder, and then OK.) Then copy a few files to the folder, so that there's something in there.

Now go to Active Directory Users and Computers and right-click some folder—the domain icon, the Users folder, or whatever—and choose New, then Shared Folder. You'll see a dialog box like the one in Figure 8.44.

Create a name for it—I've used Company Documents—and fill in the address of the share as \\servername\sharename and click OK. You'll then see an icon that looks like a hard disk on a network cable in Active Directory Users and Computers. Double-click it and you'll see something like Figure 8.45.

**FIGURE 8.44**

Creating a shared folder in AD

**FIGURE 8.45**

Modifying the shared folder object's properties

Take a look here and you can see where this would be useful. You can fill in the Description field, or, even better, you can click Keywords and fill in words that describe the share.

Now how's that useful? Just as with the contacts, you can search for shared folders. Open up Active Directory Users and Computers, right-click the domain and choose Find, and you'll see that one of the things that you can search for are shared folders—just type in keywords and you'll get the folders that match those keywords. Click the folders and they'll take you straight to the shared data.

This has several advantages over the standard Network Neighborhood operation that you're probably familiar with:

**Keywords** First, obviously, you can search for the content that you're seeking, rather than wandering around Network Neighborhood hoping that someone has named a share in a meaningful way.

**No broadcasts** All of that data in Network Neighborhood/My Network Places gets there because every single server and, usually, every single workstation broadcasts its presence every 12 minutes. You'd be amazed how much network bandwidth is wasted with those broadcasts. Once you shut them off by disabling NetBIOS over TCP/IP—which you can't do in a practical sense now, but it will make sense for many networks by 2007 or so—then you'll get a bunch of bandwidth back, up to 15 percent on some networks.

**You disconnect the users from the UNC's** To find this company data in a standard non-AD system, I've got to just somehow know that the data is sitting on BIGDOG in a share called Junk. In such a network, you refer to the share by its UNC (Universal Naming Convention), `\\bigdog\junk`. But what if I moved the data to `\\server1\data`? Then I'd have to tell everyone to stop looking on BIGDOG and instead look on SERVER1. *But* if everyone is instead searching the Active Directory, or if they know that the folder published in the AD as Company Data is the place to go, then they are completely unaware of the data's UNC. When I move the data from `\\bigdog\junk` to `\\server1\data`, then, all I need do is to modify the published item in the Active Directory.

All in all, this notion of publishing shares is a big step forward. It *does* require teaching users to find and exploit shared folders a bit differently, though.

You may have one question: Why do you have to go through the extra step of publishing a share? When you shared `\\bigdog\junk` in the first place, why wasn't there a little check box on the Sharing dialog box saying something such as, Publish to the Active Directory? I have no idea. And do you want to hear something totally bizarre? Back when this first appeared, in the Windows 2000 beta, *the check box was there*.

Even stranger: printers. A *printer* isn't really a printer, it is, like a shared folder, just a published entry in the AD to the effect that there's a printer shared somewhere, complete with descriptive information on it. But here's the odd part: When you share a printer, *it publishes itself*. You need do nothing. Strange, no?

## AD-Related DNS Design and Troubleshooting

We covered DNS in the previous chapter, but mostly from the point of view of DNS in a generic setting—the things that you need to make DNS work with or without the Active Directory.

### Choosing Your Top-Level Domain: .com, .local, or Something Else?

DNS is connected to names, so part of your AD planning involves coming up with an AD name, and of course the first part's easy—if you're Acme or Bigfirm, then that'll be your AD name. But is it bigfirm.biz? Or something like bigfirm.local? What's .local all about?

Well, if you're going to run your own DNS system and don't care if it's visible to the outside Internet, then you needn't use a standard .com, .org, .biz (and so on) top-level domain (TLD). Many folks use .local, as in bigfirm.local. Or there was an Internet standard working its way through the committees that suggested using .pri—for private. It's a good idea, but I haven't heard much about it. Still, I can't imagine that ICANN will ever create an official .local or .pri TLD. So if you want to be "with it" name-wise, then go with *something.pri*.

Does it matter what TLD you use? Possibly, but not likely. Here's the scenario that we're concerned about: You call your AD bigfirm.local. Then, a few years down the road, ICANN approves a new TLD, .local. Someone else registers the now-publicly-available bigfirm.local domain and sets up a Web server, mail server, and so on. Someone inside your network tries to access their stuff but can't get to those servers, as the local domain has that name.

Again, in my opinion we won't see a .local TLD anytime soon, so I'm not sure that it matters whether you use .local, .pri, or, as some are doing, .ds for *directory service*.

## Building an AD-Friendly DNS Infrastructure

In my example Active Directory, I made life a bit easier for you by starting out with a guaranteed AD-compatible DNS infrastructure, one built atop a dynamic DNS zone running on a Windows 2K or later server. But you may not have the luxury of a network whose DNS options are wide open, and you don't *need* that luxury—AD works well with non-Microsoft DNS servers, and I've built a couple of forests without any Microsoft-based DNS servers at all. In this section, you'll first understand what AD needs of DNS and then you'll see the various ways to make different DNS configurations work with AD.

### WHAT AD NEEDS FROM A DNS SERVER

The Active Directory absolutely needs two things of its DNS server:

**Support of underscores in DNS names** Yes, I know I told you not to use underscores in your machine names, but no one told Microsoft apparently—some important subdomains of your AD need underscores in their names. Every DNS server that I know of will tolerate underscores, but not all do by default, so you might have to turn this feature on with yours. Microsoft's DNS servers from NT 4 onward tolerate underscores by default. (I'm not even sure that it's *possible* to make a Microsoft DNS server reject names with underscores.)

**Support of SRV records** Recall that SRV records are a generic way to store information about a server's abilities in DNS. Simplified, SRV records store two pieces of information about a server's abilities—the protocol that it supports and the port that it runs that protocol on. For example, you could in theory use SRV records to ask a domain, "What is your Web server's address?" by making an SRV record request for a server running the HTTP protocol (the Web protocol, as you may know). Similarly, Windows 2000, XP, and Server 2003 systems locate Active Directory domain controllers via SRV records, asking the domain's DNS servers, "Do you have any SRV records for a server running the Kerberos protocol in the Kempsville site?" They also locate global catalog servers—which, recall, are essential for logons—by requesting SRV records for servers running the LDAP protocol on port 3268. Without those records, machines cannot find a domain controller...and not much happens in AD if you can't find a DC.

Furthermore, AD is light-years easier to run if it supports:

**Dynamic DNS** You’ve already seen that 2K, XP, and Server 2003 systems register their host records via dynamic DNS. But AD domain controllers rely upon dynamic DNS for more than that—DCs create subdomains and register SRV records via dynamic DNS. Now, DDNS isn’t 100-percent essential, as you could simply punch in all of the SRV records by hand—sounds like fun, doesn’t it?—but I strongly recommend that you make your DNS zone dynamic.

### **YOU DO NOT NEED TO USE A MICROSOFT DNS SERVER**

I said this before, but I want to stress it. Most people use a Unix or Unix-derivative machine running a program called BIND to act as their DNS server. Active Directory can work perfectly well in an environment where a Unix-based BIND server acts as its DNS server, so long as it’s a version of BIND that supports SRV records (RFC 2782) and dynamic updates (RFC 2136) and permits machine names with underscores. (I know—I’ve done it. I successfully created a three-domain AD forest using a single DNS server running BIND on Linux. Worked like a charm, dynamic zones and all.) Or you might be using Lucent’s QIP DNS/DHCP replacement, a good alternative to either BIND or Microsoft’s DNS.

In that case, you need not configure a Windows 2000 or Server 2003 system as a DNS server.

### **WHAT TO DO IF YOUR CURRENT DNS SERVER ISN’T AD FRIENDLY**

But, as the song goes, we can’t always get what we want. What do you do if you don’t have a DNS infrastructure doesn’t want to do things Microsoft’s way? You do have a few alternatives.

Generally the issue is that DNS admins are concerned about enabling dynamic DNS. They think—rightly—that it creates one more potential security problem. But all’s not lost in that case. Let’s examine the possibilities.

### **If Your DNS Supports SRV and Underscores but Not Dynamic DNS**

If you can’t convince your DNS folks to adopt any of the suggestions that follow this one, then let me get the worst case DNS scenario out of the way. In this scenario, we’ll leave dynamic DNS shut off.

I hope that none of you ever have to *do* this, but it’s a chance to highlight an interesting feature of AD that you may find useful for troubleshooting. It’s a last-ditch way to stitch together a DNS zone that will make an AD happy.

Let’s say that you’re working with a modern DNS server that supports SRV records and underscores, but no dynamic updates. How to make it AD friendly? With the help of a file named `netlogon.dns`.

Back when Microsoft was first putting AD together, they talked to a lot of their big customers about what AD would require and some of those customers balked. They had a big BIND infrastructure that, well, *worked*—Unix-based systems often have the interesting characteristic of being complex to get working, but once they’re working, you can pretty much leave them alone and they require almost no care and feeding—and so they didn’t want to change those servers one whit.

“Not changing them one whit” included dynamic DNS—it has to be admitted that dynamic DNS offers some potential security issues, and so flipping the switch to turn their BIND servers into *dynamic* BIND servers met some opposition. SRV records were no problem; underscores were no problem. But DDNS was a sticking point.

So Microsoft engineered the AD to offer a compromise.

Every DDNS-aware computer writes its own A (host name) records into DDNS by itself. But the AD *really* relies upon all of those SRV records, and *they* are written to the zone files by the Netlogon service. Whenever you reboot a domain controller, or restart its Netlogon service, or if some time has gone by without an update, then the Netlogon service contacts the primary DNS server and registers its SRV records.

But it also does something else: It writes those records to an ASCII text file called `NETLOGON.DNS`, stored in `\WINDOWS\SYSTEM32\CONFIG`. Try it—go to any AD domain controller and use Notepad to look at `\WINDOWS\SYSTEM32\CONFIG\NETLOGON.DNS`. It's a bunch of SRV records.

Those companies that are *completely* anti-dynamic DNS, then, *could* set up their DNS to support AD like so without dynamic DNS. Here's how our fictitious bigfirm.biz domain might do it, using an NT 4 DNS server (I use NT 4 to stress how much latitude you've got in your choice of DNS servers here)—you'd do the same thing with a nondynamic BIND server:

1. First, set up a bigfirm.biz zone as a primary zone on a DNS server. Call the zone file `bigfirm.biz.dns`.
2. Enter A records for each domain controller.
3. Go to each AD domain controller and restart its Netlogon service.
4. Copy the `\WINDOWS\SYSTEM32\CONFIG\NETLOGON.DNS` file from that DC to a floppy or a file on the network.
5. Once you've got all of the `netlogon.dns` files, merge them into one big ASCII file on the primary DNS server for bigfirm.biz.
6. At the bigfirm.biz DNS server, stop the DNS service.
7. In `\WINNT\SYSTEM32\DNS`, open the file `bigfirm.biz.dns` with Notepad.
8. Add in the extra lines with the SRV records that you collected when you merged all of the `netlogon.dns` entries into a single file into `bigfirm.biz.dns`.
9. Save the `bigfirm.biz.dns` file.
10. Restart the DNS service (or, if it's a Unix box, the daemon).

That DNS server—and any of its secondaries—can now support an Active Directory. So why wouldn't everyone do this? Well, first of all, it's a lot of work collecting all of those `netlogon.dns` files. And, second, it's not very, well, *dynamic*. If you ever take one of these DCs offline, you'd have to delete its zone records. And every time you put a new one on your network, you'd have to collect and merge *its* SRV records. Not much fun...but definitely possible. If all else fails DNS-wise, you can always do this dynamic-DNS-by-hand approach to DNS.

### **Using NT 4 DNS Servers in an AD**

Can you use NT 4 DNS servers for an AD? Sure, with some work. My first guess was that NT 4's DNS didn't do SRV records, as their RFC appeared not terribly long before NT 4's release. And in general I was right. But if you install Service Pack 6a on an NT 4 system a funny thing happens...the DNS server now supports SRV records! So, if you wanted, you really *could* do the hand-built zone file routine that I outlined previously, even on a DNS server running atop NT 4.

Sound like too much work? It probably is. But there's a completely useful potential function for an NT 4 DNS server in an AD.

Use it as a *secondary* DNS server. Recall that a simple standard DNS setup for a given zone has just one primary DNS server and any number of secondary DNS servers. And recall that the only DNS server that accepts changes to a zone is the primary. The secondaries just accept their zone copies from the primary using a standard zone transfer—in other words, secondary DNS servers really don't ever need to support dynamic DNS.

You could, then, have a single Win2K Server— or Server 2003—based DNS server as the primary server in a zone. That would accept all of the dynamic updates from the various servers and workstations and boil them down to a standard DNS zone file. Then it would copy that zone file to the secondaries, which could be running NT 4 with Service Pack 6a. Then, whenever a workstation needed to look up an SRV record so that it could find a global catalog server or a DC, the NT 4 systems could easily answer the request.

#### ***Upgrade to DDNS/SRV Compliance or Replace It***

If you have DNS servers that don't support underscores and SRV records, then you must change your DNS infrastructure to make the AD work. Either upgrade your existing non-Microsoft DNS servers to newer versions of their software that support DNS or replace them with Windows 2000 or later servers. Heck, those Unix guys are *always* eager to replace their well-known BIND systems on the Sun boxes with Microsoft stuff—they're all closet Microsoft junkies, really! (Joking, joking...)

#### ***Create and Delegate Your Domain to an AD Child Domain***

If bigfirm.biz has an existing set of DNS servers that do not and never will support SRV, DDNS, and the like, then one answer is to create a child portion of your current DNS names and delegate the control of those names to a Windows 2000 system. For example, if you've already got several hundred Unix, Windows, and NT machines in an Internet domain named bigfirm.biz and the DNS server for bigfirm.biz is an ancient BIND implementation, then you can always tell the old BIND server that there's a new subdomain (a *zone* in DNS-ese) called win2k.bigfirm.biz (which would contain machines with names such as bluebell.win2k.bigfirm.biz, rover.win2k.bigfirm.biz, or metrion.bigfirm.biz) that will have its own name server. Of course, that name server will be one of your new Windows 2000 or Server 2003 servers. The Active Directory doesn't insist upon having RFC 2782, 2136, and underscore support for *all* of the company's machines—just the AD DCs.

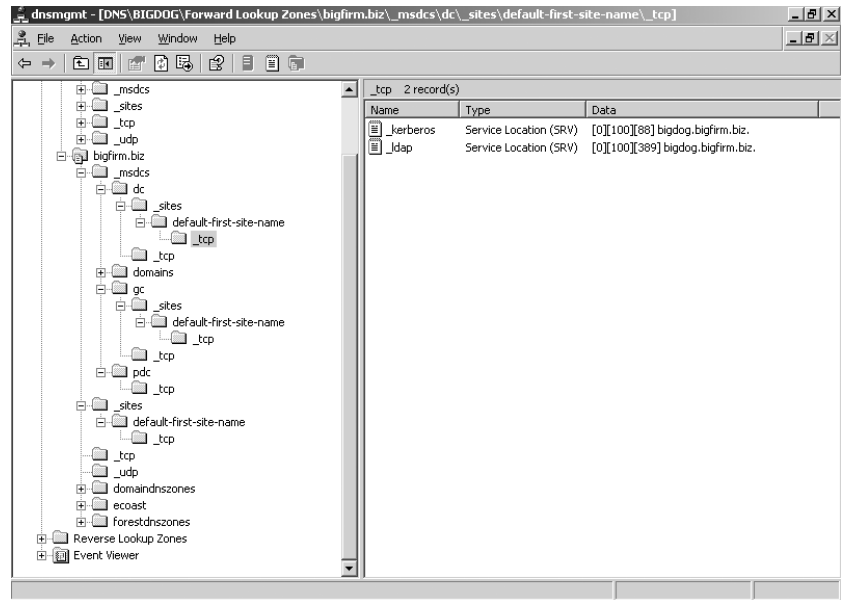

#### ***Delegate the AD-Specific Subdomains***

The previous solution is a good one, but it troubles many people, as they want their systems to have names such as *something*.bigfirm.biz instead of *something*.act-dir.bigfirm.biz. So they'd like the AD situated at the firm's "top level," so to speak, but they don't want the top-level DNS to be AD friendly. There *is* a work-around in this case. But it's a bit trickier.

Create an Active Directory and look in the DNS zone and you'll see that the AD has created a bunch of folders in your DNS zone, as you see in Figure 8.46.

**FIGURE 8.46**

DNS subfolder structure in an AD domain

Notice that bigfirm.biz has four folders:

- ◆ \_msdcs
- ◆ \_sites
- ◆ \_tcp
- ◆ \_udp

Thus, just as there's a DNS domain named bigfirm.biz, there are also now subdomains named \_msdcs.bigfirm.biz, \_sites.bigfirm.biz, \_tcp.bigfirm.biz, and \_udp.bigfirm.biz; DCPROMO created them. (I'm sure you've noted the underscores in the subdomain names—what *were* those Microsoft folks thinking, anyway?) Those are subdomains just like one named AD.bigfirm.biz would be. DCPROMO created them as simple folders in the same zone file as bigfirm.biz, but there's no reason why you couldn't have created them as four separate domains, four separate zone files potentially on four different servers. (You've probably noticed that bigfirm.biz has other subdomains as well—that's because it's a forest root domain.) It gets the extra subdomains named domains.bigfirm.biz, domaindnszones.bigfirm.biz, and forestdnszones.bigfirm.biz for forest root info rather than domain info, so ignore those extra domains. Any nonforest root domain only gets \_msdcs, \_sites, \_tcp, and \_udp.

Recall that the really important DNS records aren't so much the A (host) records for the DCs, it's the SRV records. So if you leave the top bigfirm.biz zone static and just punch in the host records by hand and then create the subdomains by hand *on a DNS server that supports DDNS*, then everyone's happy—the DCs can write their SRV records and the workstations.

So if bigfirm.biz's zone were hosted on a static DNS server, then all you'd have to do would be to first set up a DNS server that supports dynamic DNS (and SRVs and underscores, of course). Then, on the new DNS server, set up the four subdomains. Then go to the static DNS server

with the bigfirm.biz zone and delegate the four zones to the new DNS server—just as I showed you how to create the ecoast.bigfirm.biz zone in the previous chapter. Set the four new zones to dynamic. Finally, hand-enter A records for the domain controllers in the static bigfirm.biz zone—and you’re done.

### **Create a Parallel “Split-Brain” Windows-Based DNS for Your Microsoft Systems**

You saw in the previous chapter how to do this. If you want to run an AD named bigfirm.biz, then one way to do it is to set up a Server 2003 system as a dynamic DNS server. Then create a bigfirm.biz zone and make it dynamic. Do *not* register this server as an authoritative server with Network Solutions or whoever the parent domain is—you do *not* want visitors from the public Internet. Then set up the Microsoft boxes so that they all look to this one DNS server as their DNS server. As that server has a zone named bigfirm.biz, then any queries about bigfirm.biz will end up being answered out of that zone. The DNS server will also accept dynamic DNS registrations. You can take it a step further and set up more DNS servers so as to spread out the name resolution load in your intranet, and use DHCP to tell different Microsoft systems to use different DNS servers. But make sure that these DNS servers are secondary DNS servers for the internal bigfirm.biz zone. Forward the DNS servers to a server outside your firewall—actually, *slave* the internal DNS servers for security’s sake.

And don’t forget to copy any externally visible records for bigfirm.biz, such as www.bigfirm.biz to the internal bigfirm.biz’s zone. Again, I’ve discussed this in greater detail in the previous chapter, so look that over before adopting this approach.

## **Operations Masters/FSMOs**

Thus far, you’ve seen how to set up AD domains, the DNS that it requires to run, and a bit of user and group management. Those are the basics of AD setup.

But there’s more to AD planning than that. Making an AD run also requires knowing about

**Operations masters** a particular function that some DCs must assume.

**Time synchronization** believe it or not, AD simply will not run unless all of the AD members and DCs all agree on what time it is, to within five minutes.

**Domain database synchronization** DCs in a domain all have a copy of the Active Directory database, and all of the DCs should have the same data in their database copies.

**Sites** AD gives YOU the ability to divide up Your network into sites so that AD can best use (or *not* use) Your WAN bandwidth. You *could* create an AD and just tell it that the 200 offices across the world that comprise your company are just one big site and the AD would work, kind of ... but it’s silly not to use the tools that Microsoft gives you to define and exploit sites.

In the next few sections, we’ll take on this kind of intermediate-level AD planning and operation. First, we’ll take up operations masters.

### **Multimaster versus Single-Master Replication**

As I’ve mentioned before, one of the things that differentiates AD domains, and DCs, from NT 4 and earlier domains, is *multimaster* replication rather than *single master* replication. Under NT 4 and earlier

products, you had one DC called the primary domain controller, which held a copy of the SAM, the file that contained the user accounts. That SAM on the PDC was the only one that you could modify. All other DCs in an NT 4-and-earlier domain were *backup* DCs. They could authenticate people, but not accept changes to their accounts. If, for example, you work out of your firm's Tulsa, Oklahoma, office, which has a BDC, then that local BDC can log you in sometime in the morning without having to communicate with the PDC, which I'll place for the sake of argument in Columbus, Ohio. But if a local Tulsa administrator wants to change your password, then she starts up the NT tool named the User Manager for Domains. It's not obvious, but at that point User Manager for Domains locates and connects with the DC in Columbus over a WAN link. At that point, the administrator can do things like create new accounts or perhaps reset your password, and the DC in Columbus would eventually replicate that new information to the BDC in Tulsa (and other BDCs as well, of course). But if the WAN link is down, then User Manager for Domains will refuse to let her do any account maintenance. Because only one DC holds the "master" or writeable copy of the SAM, this approach to maintaining a database of users is called a *single-master* replication system.

AD improves upon that with multimaster replication. Under multimaster, *any* DC can accept changes to the user account, so in the Tulsa example, a local Tulsa admin could start up an administration tool such as User Manager's successor, Active Directory Users and Computers, and make a change to a user's account, even if the link between Tulsa and Columbus was down. As any DC can accept changes, any DC is then a "master," hence the phrase *multimaster*.

**WARNING** You only get multimaster replication once your AD domain is in Native mode ("Windows 2000 domain native functional level" in 2003-speak) or Server 2003 domain functional level. Mixed-mode domains and Server 2003 interim-mode-domains use a single-master replication scheme because of the continued presence of old NT 4 BDCs, which can't handle the needs of multimaster replication.

## But Not Everything Is Multimaster

In general, the Active Directory tries to carry this notion of decentralized control throughout its structure. In general, all DCs are equal, but, to paraphrase George Orwell, some DCs are more equal than others. Those DCs are the ones that serve in any of five roles called either *operations master* or Flexible Single Master of Operator roles. By the way, no one says *flexible single master of operator*; it gets acronym-ized to FSMO and is pronounced "fizz-moe." Strictly speaking, FSMO was the phrase that Microsoft used through most of Windows 2000's development process, but they renamed FSMOs to *operations masters* late in the beta process. As a result, you'll hear some people say *operations master*, but the FSMO name has stuck with many, even now in the days of Server 2003, probably because it's quicker to say "fizz-moe." (And more fun.) So, for example, the phrases *domain-naming operations master* and *domain-naming FSMO* refer to the exact same thing.

Certain jobs in the AD just need to be centralized, and so we end up with FSMOs. For example, take the job of creating new domains. Suppose I've got a domain bigfirm.biz and someone decides to set up a new domain controller and thereby create a child domain, hq.bigfirm.biz. Creating a domain causes AD to build a lot of data structures—a domain for hq.bigfirm.biz, more work for the global catalog, changes to the overall forest AD database, and so on. Now imagine that two people both try to create a new domain named hq.bigfirm.biz at roughly the same time. That could be a nightmare—the parent domain would be receiving conflicting requests to modify the AD database, there might be potential security issues, and it might keep the whole forest from functioning.

## Domain Naming: A FSMO Example

What's that you say? The chances of trying to create two identical domains "at roughly the same time" are unlikely? Not necessarily. If you have two offices in your enterprise, and you only connect the two offices to synchronize their domain controllers once every few days—and you can do that; AD only *requires* that you sync DCs every 60 days at the maximum—then you could easily have two different people try to create a domain with the same name, in each office, within a span of a few days. You don't want that happening, so AD chooses one DC to act as a sort of central clearinghouse for new domain creation and whenever you run DCPROMO to create a DC in a previously nonexistent domain (and therefore to create a new domain), DCPROMO stops and locates the one DC in the entire forest that is the "keeper of the domain names." That DC is said to be the *domain-naming FSMO* or *domain-naming operations master*. If DCPROMO on the new would-be DC cannot establish contact with the domain-naming FSMO, then it flatly refuses to go any further.

Let me repeat that: If you have a worldwide enterprise with dozens of domains, hundreds of offices all around the world, thousands of domain controllers and hundreds of thousands of workstations, there is one and only one computer that serves as the domain-naming FSMO. If it were, for example, in the Okinawa office and you were in the New York office sitting at a server trying to create a new domain in the forest, then your computer would be unable to proceed until it contacted the Okinawa computer and got its OK on building the new domain. Putting subsequent systems on that domain would not require contacting Okinawa.

## Why Administrators Must Know about FSMOs

Lest you get the idea that I'm saying that this is a terrible failing on AD's part, understand that I'm *not* saying that. You don't create domains all that often, one hopes, so this isn't much of a hardship, in my opinion. In general, you won't think about the DCs that act as FSMOs in your forest much at all. But you *do* need to do a little planning about which DCs will be FSMOs, and you need to know how to assign a particular FSMO role to a particular DC.

Which reminds me: you *do* have to manage the FSMO roles by hand. The AD automatically picks a particular DC to act in each FSMO role—the first DC that you install—but it's not bright enough to move those roles around. So, for example, consider this scenario. Your company decides to play around with AD and sets up its first DC on a "junk" machine in a test lab—say, the old 200MHz system with 128MB of RAM. They see that AD works pretty well, and so start buying some "big guns" to be the production DCs—Pentium 4s, Itaniums, or whatever. They roll out these big DCs and things seem to work pretty well.

Until one Monday, folks come to work and the AD apparently still thinks it's the weekend because AD's not working. Administrators find that they can't create new user accounts or join machines to a domain. Someone has tried to install Exchange 2000, but it complains about not having the authorization to change something called the *schema*. The Cleveland office was scheduled to create a new child domain, but that's refused, too. The remaining NT 4 domain controllers—perhaps the firm has decided to run in Mixed mode for a while—complain that they can't find the PDC, and account changes like password resets are clearly not getting to those NT 4 backup domain controllers.

What happened? Well, someone was playing around in the lab that weekend and needed an extra machine with which to do some experimenting. The 200MHz system was just sitting there, still running Server 2003 and acting as an AD domain controller. But it wasn't really relevant anymore, the weekend noodler reasoned, as the firm now has several dozen big DCs running. So our experimenter wiped the hard disk on the 200MHz system and put Linux on it.

You see, by default, AD assigns the FSMO roles to the first DC that you install. Which means that 200MHz system has been quietly serving in a very important role. But now it can't. And AD isn't smart enough to figure that out and then to nominate a new computer in that role. You might say that our "sparkling" forest has lost its "fizz moe." It's now your job to transfer the FSMO roles to other DCs.

*That's why you care about FSMOs.*

**NOTE** *Actually, there is one case where AD automatically moves the FSMO role: when you use DCPROMO to demote a domain controller that holds one or more FSMO roles into a member server. DCPROMO finds another appropriate domain controller and moves the FSMO roles to that DC. In that case, decommissioning the Pentium 200 would have resulted in no problems. So perhaps the best advice here is, "When you want to get rid of a domain controller, always use DCPROMO to decommission it before FDISK it."*

## FSMO Roles

There are five FSMO roles in AD:

- ◆ Schema
- ◆ Domain naming
- ◆ RID
- ◆ PDC
- ◆ Infrastructure

There is only one schema FSMO in the entire forest, and similarly only one domain-naming FSMO. Each domain in the forest, however, has its own RID, PDC, and infrastructure FSMO.

### SCHEMA

*Schema* is the word for the structure of the AD database—the fields. It's the list of things in the database, like username, password, and so on. In some senses, it's the directory to your Active Directory.

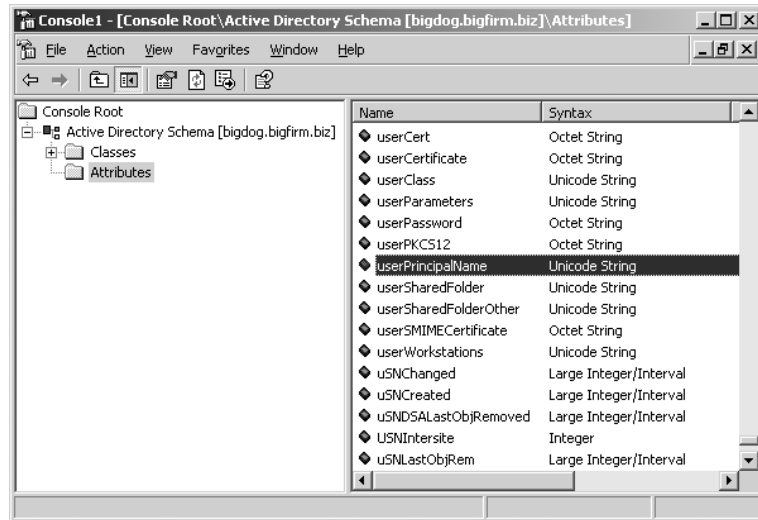

#### **Examining the Schema with the Schema Snap-In**

You can look at the schema with the Active Directory Schema snap-in. It's not sitting in Administrative Tools, however; follow these steps to run it.

1. Open a command prompt and type **regsvr32 schmgmt.dll**. You should get a message box that says DllRegisterServer in schmmgmt.dll succeeded. Click OK to clear it.
2. Click Start/Run and enter **mmc /a**, then press Enter to start the Microsoft Management Console in Author mode.
3. Click Console, then Add/Remove Snap-in.
4. In the resulting dialog box, click the button labeled Add, which will raise yet another dialog box, Add Standalone Snap-in.
5. In the Add Standalone Snap-in dialog box, locate and click the object labeled Active Directory Schema, then click the Add and Close buttons.
6. Back in the Add/Remove Snap-in dialog box, click OK to close.

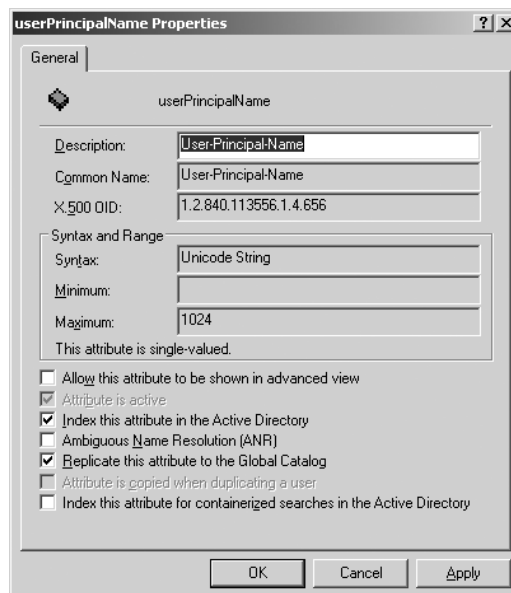

You'll then see a screen like Figure 8.47.

**FIGURE 8.47**  
Schema Manager  
snap-in

Here, I've highlighted the part of the schema that tells us that there's an attribute called userPrincipalName, which, you know by now, is the login name. Double-click it and you'll see a dialog box describing its properties, but they'll probably be grayed out, even if you're an Enterprise Admin. Recall that even Enterprise Admins can't modify the schema—you must be a member of the Schema Admins group to do that. But if you're a Schema Admin, then you'll see the properties page with everything enabled, as in Figure 8.48.

**FIGURE 8.48**  
Properties page for  
User Principal Name

Notice the check box labeled Replicate This Attribute to the Global Catalog. You can, using the Schema Manager, control what does and doesn't replicate in the GC.

### ***The Schema and Your AD***

Will you change the schema very much or very often? Probably not. But there are few things that you should bear in mind.

First, remember that there is only one schema for the entire forest; it's not meaningful to talk of changing the schema for a particular domain, as any changes to the schema are changes to the schema of an entire forest. So a bit of innocent schema-dabbling will affect every domain controller in every domain in the forest, as all of those DCs will have to be notified of the changes and thus will have to make room for the new schema items in their copy of the schema, which burns up some CPU and disk time.

Second, when will you change the schema? Usually the only thing that you'll do that will cause the schema to change will be adding new server-based applications such as Exchange 2000, server-based apps that were designed with the Active Directory in mind.

### ***Keeping Schema Changes Orderly***

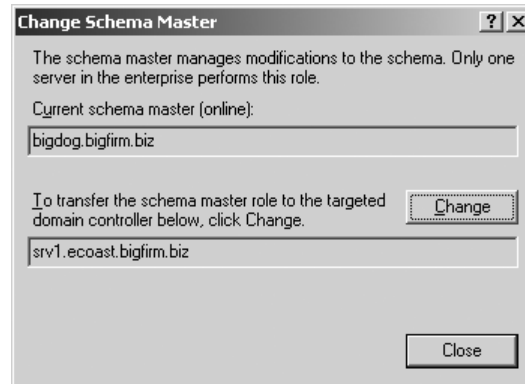

Inasmuch as schema changes affect the whole forest, it's reasonable to say that the schema *does* change—we want it to change in an orderly fashion—it'd be really bad if two people both modified the schema at the same time.

For that reason, and because there's only one schema for the entire forest, there's only one computer that can approve schema changes in the entire forest. That computer is said to have the *schema FSMO* role. By default, the AD places the schema FSMO role on the first domain controller that you install in the first domain of the forest. So the first DC that you set up should be a well-protected one!

You can see which computer is the schema FSMO computer, or move that role to another computer, like so:

1. Right-click the object labeled Active Directory Schema and choose Change Domain Controller.
2. In the resulting dialog box, click Specify Name and type in the name of the domain controller to which you want to transfer the schema FSMO role. If you're not going to transfer the FSMO role, then any DC will do.
3. The snap-in will think for a minute and refresh its screen. Then right-click the Active Directory Schema object and choose Operations Master to see a dialog box like Figure 8.49.
4. Click the Change button and the system will ask you if you really want to make the change; confirm that you do.
5. Oddly enough, the dialog box for changing the FSMO remains up on the screen, but doesn't offer an OK button (it's disabled)—it only offers a Cancel button, which you'd *think* would un-do moving the FSMO. But it doesn't; the FSMO's already moved. Click Cancel to clear the dialog box, and you've successfully moved the schema operations master.

**FIGURE 8.49**  
Changing the  
schema FSMO

You must be a Schema Admin to move the schema FSMO role.

### **Planning for Schema Changes...and Conflicts**

Before leaving the subject of the schema, let me offer a thought about how it will affect your organization. As I write this in early 2003, there are truthfully very few AD-aware applications. But now let's consider what happens in the near future, when there are many of them.

Let's imagine that we work at a big university with a lot of independent departments. The university's forest has many domains—Chemistry, English, Microbiology, Astronomy, Music, Geology, and others—that all live in a single forest and therefore have only one schema. Now imagine that Astronomy just got a cool new application that will aid its professors in researching something, and so they put it on the AD. It adds a few dozen things to the schema, including a Magnitude field, which stores a star's brightness. Then suppose Geology buys some neat new application that will help them in seismology research, which also adds a few things to the schema—such as a Magnitude field, where they'd store information on earthquake power. What happens when Geology tries to install an application that wants to create a schema field whose name already exists? Well, to make a long story short, it depends...and not all possible outcomes are good.

My point is this: Geology should have *known* when it first installed its app that the app would conflict with an existing one. But how could they have known? Well—and here's the part you won't like—every forest should consider keeping a testing lab up and running all the time, with a DC or two that run a working but independent version of your forest. Prior to rolling out any server-based apps, you should test them out on the test lab to see if they create schema changes that will make AD bellyache.

What's that you say? Astronomy and Geology are used to running things independently, not having to ask each other's permission to run applications? Yes, I can believe that—research and educational institutions have that tradition. But once you make the decision to stitch your organization together into a single forest, then your organizational components must communicate a bit more to keep things working. And *somebody's* going to have to keep that test lab up and running all the time. Which means staffing it and finding space, machines, and software for it. Golly, that argument about how Windows lowers total cost of ownership (TCO) doesn't seem quite as compelling now....

In case it's not clear, I think this is a bit of a weakness in the Active Directory. Basically, in this case, the AD is just another piece of software that says, "If you want to use me, you'll have to modify the way that you do business," and that seems awfully backward to me—sort of like a mouse manufacturer saying, "Gosh, we're sorry that our revolutionary mouse design doesn't fit your hand...have you perhaps considered surgery?"

There's some good news on this front, however, as you incorporate Server 2003 into your network. Once all of your domain controllers in all of your domains in your forest have been upgraded to Server 2003 and you shift your forest to Server 2003 functional level, then your schema becomes less fragile. When collisions are about to occur, a 2003 functional-level forest will automatically keep them from happening, and apparently transparently. I say "apparently" because I can't really test this—there are, as I've said, very few AD-aware apps as I write this, and none that conflict.

### ***Global Catalog Changes and the Schema in Windows 2000***

While I'm here discussing the schema, there's one more side effect of schema changes that you ought to know: what happens when you change the global catalog's structure.

Recall that every schema item has a check box telling AD whether to include it in the global catalog. Check the box, and you tell the GCs, "Listen, there're about 1000 items in the AD, but I only need you to extract a few dozen of them for the GC. I just added a new item." That leads to a non-intuitive result. (At least, nonintuitive from my point of view.)

Suppose the GC used to keep track of, say, 25 items in the Active Directory. You check a box and so now the GC must build a slightly larger GC. How does it do it? Now, *I* would guess that it would just say to itself, "Well, I've got 25 of the 26 already...so I'll just contact my DC partners in the other domains and go get that 26th item."

But it doesn't.

Instead, it says, "Hmm...things have changed. The only way to be absolutely sure that I'm not missing something important is to just *dump the whole global catalog and start over.*" Yikes! This means that any change to the list of items in the GC kicks off a message to every global catalog server in the forest to just flush its copy of the GC and to start contacting other DCs to rebuild the GC from scratch. In other words, get ready for some network activity and a set of global catalog servers that will be fairly unresponsive for a while.

What can you do about this? Two things: Install the server-based apps early on, when there is only a small number of global catalog servers, or wait a bit and make sure that all of your domain controllers are running a version of NT that is later than Windows 2000.

In the first approach, you start out creating your Active Directory by creating your first DC, and you immediately install the server-based applications to that DC. Then, any future DCs will have your augmented schema and global catalog structure from the very beginning, and you'll never see the global catalog servers decide to quit working and have a midday party just because someone installed an application on a server. Some apps make that easier to do; for example, Exchange 2000's Setup program has an option that allows you to only modify the schema. It doesn't install any files—it just makes room for Exchange's schema needs, should you ever decide to install an Exchange server later. If you're even thinking about running Exchange, I suppose it's not a bad idea to pump up the schema in anticipation of a possible Exchange future. (Although I should point out that installing Exchange on a virgin AD roughly triples the number of fields in the schema.)

### GC Changes and the Schema in Windows Server 2003

The second approach just says something like, “Don’t do the Active Directory until you get your hands on Server 2003.” Server 2003 helps out by changing the global catalog’s behavior. Under a forest populated by post-Windows 2000 global catalog servers, changes to the GC only cause the global catalog servers to contact other DCs for just the changes—adding a 26th item to the GC would only cause GC servers to go get the 26th item and add it to the GC, rather than dumping the whole thing and starting over. The neat thing about this is that it works in *any* functional level. Thus, if you have some GCs built on 2000 and some on 2003, a change in the GC will still cause panic amongst the 2000-based GCs but not the 2003-based GCs.

### DOMAIN-NAMING FSMO

You’ve already met this one—I used this FSMO as my example earlier of why you’d need an operations master in the first place. There is only one of these for the entire forest. As with the schema operations master, the AD places the domain-naming operations master role on the first domain controller that you install on the first domain that you install.

You change the domain-naming operations master role with the Active Directory Domains and Trusts tool, which you’ve already met. First, change AD Domains and Trusts’s focus to the machine that you want to shift the domain-naming FSMO role to. Just open AD Domains and Trusts and right-click the object in that MMC snap-in labeled Active Directory Domains and Trusts, then choose Connect to Domain Controller, and you’ll see a dialog box like Figure 8.50.

**FIGURE 8.50**

Changing the focus DC

In this dialog box, you’ll point AD Domains and Trusts (ADDT) to the DC that you want to serve as domain-naming FSMO. Fill in its name in the Enter the Name of Another Domain

Controller field and click OK, and ADDT's screen will then appear unchanged. But you will have shifted ADDT's focus to the other DC—I used `srv1.ecoast.bigfirm.biz` in my example—and you can now change the domain-naming FSMO. Again right-click the Active Directory Domains and Trusts object and choose Operations Master and you'll see a dialog box that looks just like the one in Figure 8.49, except it changes the domain-naming FSMO instead of the schema FSMO. Click Change and you'll modify your forest's domain-naming FSMO.

**WARNING** *The domain-naming FSMO role should only be placed on a DC that is also a global catalog server. Apparently the AD developers got a little lazy and decided that, inasmuch as the global catalog knows about things from all over the forest, the domain-naming FSMO could exploit the GC's knowledge.*

You must be an Enterprise Admin to change the domain-naming FSMO.

### RID POOL FSMO

One of the things that any Native-mode AD domain controller can do is to create new accounts (user and machine) without having to go find some “central” or “primary” DC. In the NT/2000 world, everything has a unique identifier called its *security ID* or SID. SIDs look like this:

*S-1-5-21-D1-D2-D3-RID*

The 1-5-21 applies to all SIDs. What I've called *D1*, *D2*, and *D3* are actually three randomly generated 32-bit numbers. When AD first creates a domain, it generates these three unique 32-bit numbers, and they remain constant for any SID generated in that domain. And it's not just a matter of a separate *D1/D2/D3* for a domain—the local SAM on a workstation or member server also has its own set of three unique 32-bit numbers.

**NOTE** *I know, you're wondering, “How does AD ensure that your computer's D1/D2/D3 is different from one built randomly in, say Pocatello?” My answer is: I don't know. I'd guess that they partially build the D1/D2/D3 from something unique, like the MAC address on the domain controller. But that's just a guess.*

So, for example, if I created a domain named `bigfirm.biz` and it happened to come up with *D1*=55, *D2*=1044, and *D3*=7, then every SID in `bigfirm.biz` would look like *S-1-5-21-55-1044-7-something*, where *something* is a 32-bit number. In other words, all SIDs in a domain are identical, save for the last 32 bits. That last 32 bits is the only *relative* difference between SIDs and is therefore called the *relative ID* or RID. Some RIDs are fixed; for example, the SID for the default Administrator account on a computer.

Anyway, if a DC needs to generate a new SID, then it *knows* what the first part of the SID will be. It just needs a unique RID. So there's one DC in every domain that hands out pools of 500 RIDs at a clip. Each DC can, then, create up to 500 accounts before it has to go back to this one central DC, which then doles out 500 more RIDs. (Actually, DCs don't wait until they're “on empty;” they refill their pool once they've used only 100 or 250 of them—100 if they're Windows 2000 Servers running SP3 or 250 if running 2000 and SP4 or Server 2003.) The computer that hands out the 500-RID bunches is called the RID operations master or the RID FSMO. By default, it is the first DC installed in a domain. Note that there is a RID FSMO for each domain, not just one per forest.

You move the RID FSMO function from one DC to another with Active Directory Users and Computers. Open up ADUC, right-click the object representing the domain, and choose Connect to

Domain Controller, then choose a DC as you did for the domain-naming FSMO. Then return to the icon representing the domain, right-click it again and choose Operations Masters to see a dialog box like the one in Figure 8.51.

**FIGURE 8.51**

Transferring  
RID, PDC, or  
infrastructure  
operations masters

Notice that there are three tabs on that dialog—RID, PDC, and Infrastructure. Those three FSMO roles are domain specific, not forest specific, and you use this dialog box to transfer any of those roles to another DC. By default, AD assigns those roles to the first DC created in a domain.

As you saw in transferring the domain name FSMO role, just click Change and confirm the change, and ADUC will transfer the FSMO role to the DC that you've indicated.

You must be a Domain Admin for a given domain to transfer the RID FSMO role for that domain.

### INFRASTRUCTURE AND PDC FSMOS

In a multidomain network, it is, according to the Microsoft folks, difficult to quickly reflect changes to group and user accounts across domains. So you might rename a user, or put a user in a group in the domain that you administer, but that change might not show up in other domains for a while. Something called the *infrastructure operations master* speeds this process up. You change its role in the same way that you'd change the RID FSMO. There is one infrastructure FSMO per domain.

**WARNING** *There's one oddity about the infrastructure operations master role: Don't make a DC that is a global catalog server into an infrastructure FSMO, unless every DC in your domain happens to be a global catalog server. The very first DC that you set up assumes all five operations master roles, which means that initially your infrastructure master is on a global catalog server. That's OK so long as all of your DCs are GCs, and of course that's true if you only have one DC.*

You must be a Domain Admin for a given domain in order to transfer the infrastructure FSMO role for that domain. You also use the infrastructure FSMO to prepare to shift an existing Windows 2000–based AD to a 2003–based AD, as you’ll learn in the “Migration Strategies” section later.

Finally, there’s the PDC emulator FSMO. It’s a very important one.

In many cases, computers running a pre–Windows 2000 operating system need to find the PDC of the domain that they’re a member of. Some of those cases will be obvious: For example, clearly an NT 4 BDC will look for its PDC when the BDC needs to update the information in its SAM. But there are many other cases where only the PDC will do; here are a few significant ones:

- ◆ The Network Neighborhood/My Network Places is populated by a computer acting as the “master browser” that collects the names of local computers. By default, the PDC acts in that role.
- ◆ When Windows 95 systems log in, they look for a file of system policies called `config.pol`—but they’ll only look to the PDC for that file; BDCs are no good, as far as they’re concerned.
- ◆ If an NT 4 domain is trying to establish a trust relationship with an AD domain, then the NT 4 domain will need to contact the PDC for that AD domain. That’s because NT 4 doesn’t understand multimaster replication and therefore thinks that it *must* do its negotiation with the one writeable version of the domain—the PDC.

Arbitrarily dubbing one of an AD domain’s DCs as the “primary” DC, then, makes sense. And while an AD domain is in Mixed mode, the PDC emulator FSMO is more than just an emulator; it’s the only DC that can accept account changes.

But does that mean that a PDC emulator becomes irrelevant once you’re in Native mode and have no pre-2000 boxes around? Not at all. The PDC emulator still serves in two extremely important functions. Although we haven’t covered replication yet, you probably know that replicating AD changes can take time—sometimes a significant amount of time. So suppose the following happens: I’m working in St. Louis and need my password changed. So I call the company help desk, which is, unknown to me, in Ottawa. The help-desk person changes my password, and it seems that all will be well.

But consider: What DC did the help-desk person change my password on? Well, she probably did it on a DC that was physically close to her, a DC in Ottawa. So an Ottawa DC knows my new password. But how long will it be before my local St. Louis DCs know my new password? Well, it could be hours. So does that mean that I’ll have to just twiddle my thumbs for a few hours waiting for my new password to find its way to Missouri? Well, if we were talking about any other attribute besides a password, then the answer would be yes—but passwords are special.

When an admin changes a password on some DC somewhere, that DC immediately contacts the system acting as the PDC emulator FSMO for that domain. So the PDC FSMO almost always knows the most up-to-date passwords. When I try to log in to the domain, it is a local DC that tries to log me in. As I tell that DC my new password, the local DC is inclined at first to decline my logon, as the password that I offer doesn’t match what the DC has. But before declining my logon, the DC connects to the PDC emulator FSMO for its domain and double-checks—and if the password that I gave my local DC matches the new one that the PDC has, then I’m logged in. This “high-priority replication” also occurs for one other user attribute—account unlocks. Thus, when a user forgets his password and retries to log on with the wrong password over and over, then not only does

he need a new password, he probably also locked himself out of his account. So when the administrator resets the user's password, the admin probably also has to unlock the account. Immediately replicating the new password without replicating the account unlock wouldn't be very helpful.

That's one important job for the PDC FSMO—what's the other one? We'll cover that in an upcoming section, "Forestwide Time Synchronization."

You can change the PDC FSMO from Active Directory Users and Computers, as you did with the infrastructure or RID FSMOs. You must be a Domain Admin for a given domain in order to transfer the PDC FSMO role for that domain.

## Transferring FSMO Roles the Hard Way

Transferring FSMO roles is very simple via the GUI, as I've shown you. But there's a catch: You can only use the GUI to transfer a FSMO role *if the present FSMO is up and running*. If you FDISK-ed the computer that was acting as your PDC FSMO, then there's no one around to "approve" transferring the PDC FSMO role to another computer. In that case, you don't just *transfer* the operations master role—you "seize the master."

If your PDC FSMO or infrastructure FSMO will be temporarily offline, then it's perfectly safe to transfer those FSMO/operations master roles to another computer, and you can actually do it through the GUI. It'll tell you that the operations master is offline and that you can't transfer the role, but ignore it and click Change anyway. You'll get the usual confirmation request and then *another* dialog box, like this:

After a bit more thought, you'll get a *final* confirmation dialog box:

And notice the "FSMO" reference—see, even Microsoft doesn't want to get rid of the term! But to transfer the RID, domain naming, or schema FSMO, you'll need to use a command-line tool, NTDSUTIL. You start it from the command line by typing **ntdsutil**. Then do this:

1. Type **roles**; NTDSUTIL will respond by changing the prompt to **fsmo maintenance:**.
2. Type **connections** to point to the computer that you are going to transfer the FSMO role to. NTDSUTIL will respond by changing the prompt to **server connections:**.

3. Type **connect to server *servername***, where *servername* is the server that you want to transfer the FSMO role to.
4. Type **quit** to return to FSMO maintenance.
5. Type **transfer *fsmotype master***. You'll get a request for confirmation if NTDSUTIL finds that it cannot contact the current FSMO to get its approval. Confirm that you want to force a transfer.
6. If that works—if there are no error messages—then you're done. But if the transfer fails, then type **seize *fsmotype master***. A bit more drastic, but it always works.
7. Type **quit** twice and you should be done.

For example, here is a session where I seized the RID master role from a computer called dc2.bigfirm.biz to a computer named bigdog.bigfirm.biz (what I typed is in bold; the computer's responses are not bold):

```
C:\>ntdsutil
ntdsutil: roles
fsmo maintenance: connections
server connections: connect to server bigdog.bigfirm.biz
Binding to bigdog.bigfirm.biz ...
Connected to bigdog.bigfirm.biz using credentials of locally logged on user.
server connections: quit
fsmo maintenance: transfer rid master
ldap_modify_sW error 0x34(52 (Unavailable)).
Ldap extended error message is 000020AF: SvcErr: DSID-032108D3, problem 5002
(UNAVAILABLE), data 1722
```

```
Win32 error returned is 0x20af(The requested FSMO operation failed. The current
FSMO holder could not be contacted.)
Depending on the error code this may indicate a connection, ldap, or role transfer
error. Server "bigdog.bigfirm.biz" knows about 5 roles
Schema - CN=NTDS Settings,CN=BIGDOG,CN=Servers,CN=Default-First-Site-Name,
CN=Sites,CN=Configuration,DC=bigfirm,DC=biz
Domain - CN=NTDS Settings,CN=BIGDOG,CN=Servers,CN=Default-First-Site-Name,
CN=Sites,CN=Configuration,DC=bigfirm,DC=biz
PDC - CN=NTDS Settings,CN=BIGDOG,CN=Servers,CN=Default-First-Site-Name,

Infrastructure - CN=NTDS Settings,CN=BIGDOG,CN=Servers,CN=Default-First-Site-Name, CN=Sites,CN=Configuration,DC=bigfirm,DC=biz

fsmo maintenance:

To transfer or seize the RID FSMO, type **transfer rid master**, or **seize rid master** as you see above. For domain-naming operations master, use **domain naming master**; for the schema operations master, use **schema master**.

**WARNING** *If you seize a RID, domain-naming, or schema master, make sure that the old master never comes online again, or AD havoc will result! If need be, boot it from a DOS/Win 9x floppy and FDISK it.*

## Forestwide Time Synchronization

As you'll read in the upcoming sections on replication, the AD needs all of its domain controllers to pretty much agree about the current time and date. They don't have to be *exactly* the same, but they need to be close—Kerberos fails if a domain controller and the system trying to use that DC to authenticate it disagree about what time it is by more than five minutes. Under NT 4 and earlier, establishing time synchronization across a domain was difficult to accomplish. But Windows 2000, XP, and 2003 include a service called the Windows Time service that keeps all of your Windows 2000, XP, and 2003 workstations and servers in good time sync.

Machines in an AD stay in sync this way. The PDC emulator FSMO of the forest root—the first created domain's first domain controller, recall—is the Master Time Server Dude. All other servers automatically create a hierarchy, sort of like a "telephone tree," to distribute time synchronization information. Everyone below that top dog automatically gets time synced from someone above it in the hierarchy. Specifically,

- ◆ Member servers and workstations synchronize to the DC that logged them in.
- ◆ DCs in a domain all look to the DC in their domain that holds the PDC emulator operations master role.

- ◆ If there is more than one domain in the forest, then there will be more than one PDC emulator, as each domain has a PDC emulator. The PDC emulators must agree on the time, so they choose one of their number to be “the source”—the PDC emulator for the *first* domain in the forest, the forest root. So, again, it’s the PDC emulator FSMO for the forest root domain that is the ultimate time authority.

But who syncs that top dog, the forest root domain’s PDC FSMO?

First of all, odd as this sounds, you *needn’t* sync the FSMO. All that matters in AD is that all of the servers think it’s the same time. Sure, it’d be nice if it was the *actual* time, but that’s not necessary. If your whole enterprise was ten minutes early, that would constitute no problem for AD, as long as all of the servers are ten minutes early.

**WARNING** *But it’s very important that you set the time zones correctly on all of your systems! AD stores and syncs time in “universal time,” so in its heart of hearts AD is always working on London, England time. 2K, XP, and 2003 use the time zones to understand the system clock’s time and to display time that you’ll understand. So if you were to leave everyone’s time zone to Pacific and then just set the system clocks to whatever the local time was, each of those systems would think that the time in universal time was hours different. . . and synchronization would fail. Such a situation will drive you crazy, as you’ll be looking at a DC and a workstation whose time looks identical—but unknown to you, their time zones are set differently—so it’s a mystery why they won’t talk to one another. It wouldn’t be if you could see their beliefs about what the universal time was! You can quickly check a system’s time zone by opening a command prompt and typing **w32tm /tz**.*

But as long as we’ve got this hierarchy, let’s do it right and sync that root domain PDC somewhere reliable. You could use an atomic clock, one of those roughly \$100 things that read the official time off some A.M. signals out of Colorado or other places. Or you could save a buck or two and just let the Internet set your time.

The suite of Internet standards includes a way of sharing time information called the Simple Network Time Protocol (SNTP), RFC 1769. Many, many machines on the Internet serve as SNTP servers and will provide up-to-date time information to any machine running an SNTP client. Fortunately, Windows 2000 and later systems include an SNTP client—in fact, it is *the* protocol that AD uses to synchronize its member systems. You can tell a Windows 2000 or later machine to synchronize its clock from a given Internet time server with this command:

```
net time /setsntp:DNSNAME
```

For example, if a machine named clock.atomictime.org were an SNTP server, you could tell your system to use it to synchronize with this command:

```
net time /setsntp:clock.atomictime.org
```

You can specify multiple time servers by separating them with spaces and surrounding them with double quotes, like so:

```
net time /setsntp:"clock1.bigfirm.biz clock2.bigfirm.biz clock3.bigfirm.biz"
```

If you forget what server you told the clock to sync with, you can find out by typing this:

```
net time /querysnTP
```

By default, the forest root's PDC FSMO will try to synchronize with its time source once every 45 minutes until it successfully connects with the time source. Then it does it again in 45 minutes, and again 45 minutes later. It keeps resynchronizing every 45 minutes until it has successfully synchronized three times in a row. Then it reduces its frequency to once every eight hours. You can change this with a Registry entry, although I'm not sure why you'd need to. (All Time Service parameters are in `HKLM\System\CurrentControlSet\Services\W32Time\Parameters`.)

But where to find an SNTP server? Oddly enough, there are many around. Most ISPs' big DNS servers seem to act as SNTP servers. You can find out if a particular machine is an SNTP server with a neat little free tool called `ntpquery.exe` from <http://www.bytefusion.com/ntpquery.html>. You just point it at a DNS name or IP address and if that machine is a time server, you get a screen full of incomprehensible long numbers.

There doesn't seem to be a way to enable success/failure logging to the Event Log. But there is a diagnostic program that you can use to figure out if you're connected to a useful time server. Shipped on all 2000, XP and 2003 machines, the program is called `w32tm`. Although it's not as pretty as `ntpquery.exe`, it's free and integrates with the time service.

To find out if a system's time server is working, open a command prompt and type `w32tm /resync`. It'd look like

```
c:\>w32tm /resync
Sending resync command to local computer...
The command completed successfully.
```

Or, if it *didn't* work, you'll see

```
The computer did not resync because no time data was available.
```

This service requires that port 123 be open to the outside world, so set your firewalls appropriately.

**TIP** You can even use this if you don't have an Active Directory running. If, for example, your home machine were a Windows 2000 Professional or XP machine, then you could use `net time /setsntp` to give your workstation the name of a time server, and the workstation would periodically resynchronize with that server. But only do this if you're connected to the Internet via cable modem or DSL. . . it might be quite unsettling to have your workstation dial up Earthlink at 3:30 in the morning just to get the time! And if you're running XP or 2003 then you can set the time server from the GUI—just double-click the time in the system notification area (most of us call it the “system tray”) and you'll see a tab Internet Time where you can set a server. You won't see it on an AD member system, as AD selects time servers in an AD.

## Local AD Replication

You've already read that AD uses a multimaster replication scheme, which means that any change to an AD object—a new machine account, a modification to a machine account, a new user account, and so on—can happen on any domain controller. As replication takes time, that means that at any given second it could be possible that every single DC in a domain might have a slightly different copy of the AD database for that domain. But if left alone for long enough (that is, if no one changed anything about the AD), then every copy of the AD database sitting on all of the DCs would eventually be identical.

**WARNING** Note that this is only true if your Active Directory is in Native mode or Windows Server 2003 functional level. Mixed-mode ADs or Windows Server 2003 Interim-mode domains will employ single-master replication.

How does this work—how can we have many different sources of changes to a database and not end up with a hopelessly garbled database? Let's start off by understanding local AD replication, the way that AD replicates at a single site. (Recall that a site is a collection of networks connected at high speed—say, for example, a bunch of Ethernets. Any device in a site should be able to communicate with any other device in a site at millions of bits per second.) We'll add WAN considerations later.

### AD Local Replication Starts as a Loop

If you set up a site containing more than one domain controller, then those domain controllers will discover each other (not a terribly hard thing to do, as they're all publicized via DNS and the AD) and then they'll automatically work out a replication sequence. So as to avoid chaos, every DC doesn't replicate to every other DC. As to how it does that, here's a simplified version.

Suppose the bigfirm.biz domain exists in a single site that contains four DCs named BIGDOG, DC2, DC3 and (unoriginally) DC4. AD replication sort of works like this: BIGDOG replicates its info to DC2, which takes BIGDOG's news, adds it to DC2's news, and passes all of that news to DC3. DC3 then takes the things that it learned from DC2 (which included BIGDOG's changes), adds them to its (DC3's) changes and then sends all of *that* to DC4. DC4 then takes everything that it's learned from DC3, as well as any changes that DC4 knows of, and sends them to BIGDOG, closing the loop.

I said that was the *simplified* version. Now let's fill in a few details and complicate things a bit.

### WELL, ACTUALLY, IT'S TWO LOOPS

First of all, there isn't just one loop, there are two—you might say that AD replicates in both a clockwise and counterclockwise direction. bigfirm.biz's DCs might replicate as you see in Figure 8.52.

**FIGURE 8.52**

AD replication loops on a small site

In that picture, notice that every domain controller replicates with *two* other DCs. BIGDOG replicates any changes that it receives to both DC4 and DC2. And notice that this points out one way in which my simple text example above was inaccurate: If replication actually worked as I suggested,

then when BIGDOG received a bit of news, it would pass that news to DC2, who'd pass it on to DC3, who'd pass it on to DC4, who'd end up telling it again to BIGDOG. But that *won't* happen. Suppose we modify the user account for a user named Tom to reflect the fact that he has a new manager. Instead, BIGDOG will tell its news ("Tom has a new manager!") to both DC2 and DC3. DC2 will soon tell DC4 about Tom's new manager, and at about the same time, DC3 will also tell DC4 about Tom's new boss. There's no way to know beforehand who'll get to DC4 first, but no matter which one it is, when the other DC tries to tell DC4 something that it already knows, then DC4 just says, "Thanks, but I already knew that." Result? The news has made its way around the AD fairly quickly.

And by the way, I've been writing things like "BIGDOG tells its news to DC2," and that's a little incomplete. More specifically, AD replication is always "pull" replication. More correctly, I should say, "BIGDOG notifies DC2 that it's got some news and eventually DC2 asks BIGDOG to communicate any changes that BIGDOG has seen" but that's a bit cumbersome to write. (The techie phrase that the AD uses is "pull replication with notification"—BIGDOG notifies, DC2 pulls.)

### LOCAL REPLICATION HAPPENS EVERY FIVE MINUTES

Domain controllers within a site replicate to their two replication partners—what you might call their "clockwise" and "counterclockwise" partners—every five minutes. As far as I know, that's a hard-wired value; you can't change it. If there's nothing to say, then a DC says nothing at those five-minute intervals. But if a DC doesn't hear from either of its replication partners for an hour, it nudges that partner anyway, saying, "Are you *sure* you don't have anything new to tell me—that is, are you still alive?"

### THE KCC MAKES THE LOOPS

Who forms this loop? Who decides which DC will be the two replication partners for a given DC? A program that runs on every DC called the Knowledge Consistency Checker (KCC). It pops up every 15 minutes, looks around, and asks, "Have we lost any DCs or gotten any new ones since the last time I looked?" If the DC population has changed since the last time, then the KCC—or rather KCCs, as there's one running on every DC—adjusts the loops.

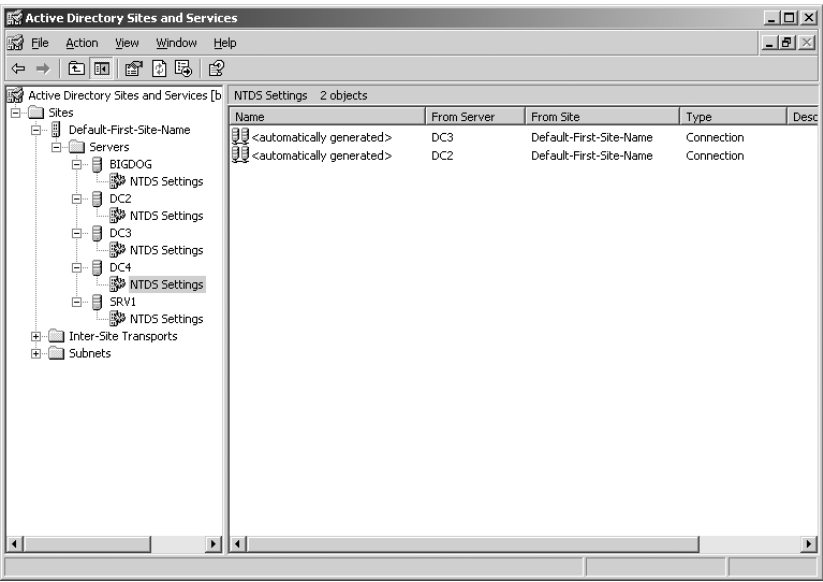

You can't see the KCC in Task Manager because it's part of LSASS.EXE. But watching LSASS.EXE can be a great way to figure out whether you need another DC. Using Performance Monitor, log the Process object and look at LSASS.EXE's percentage of CPU use over time. If it grows considerably—or if you find that when LSASS.EXE is busy then the total CPU utilization is usually 100 percent—then you know that it's time for an extra domain controller.

By the way, you may see DCs with more than two partners, even in a small network. That happens for several reasons. First, if you've just brought a DC up, then the KCC may not have had time to re-adjust the replication to an optimal loop configuration. Second, I'm talking here about replication within a domain, but there is other replication going on as well—I'll get to that in the upcoming "There Is More Than One Replication Topology" section—and so a DC might have other partners because it's part of replicating things other than just the domain's data. Finally, as you'll see in the next section, a KCC will assign more than two partners if there are a lot of DCs.

How can you find out the names of the replication partners for a given DC? With Active Directory Sites and Services. Open it (it's in Administrative Tools, recall) and you'll see icons that look a bit like a tall building with windows in it. You may have more than one of those icons, as you get one

for each site. Open one of the site icons and you'll see a folder named **Servers** and, inside that, icons representing each DC. If I first actually create enough DCs for bigfirm.biz so that we've got DC2, DC3 and DC4 in addition to BIGDOG, then I can start AD Sites and Services to see the four DCs. If I open any server icon I'll see a folder named **NTDS Settings**; I open *that* and I get Figure 8.53.

**FIGURE 8.53**  
Viewing DC4's  
replication partners

Here, I've created extra DCs for bigfirm.biz—BIGDOG, DC2, DC3, and the unoriginally-named DC4—as well as SRV1, the DC from the ecoast.bigfirm.biz domain. You can see that DC4 replicates with both DC2 and DC3—two separate rings. Notice that you are seeing the *pull* partners here. DC4 pulls data from DC2 and from DC3.

If you *really* want to, you can lay out the entire replication scheme in an AD. Just right-click in the right pane and choose **New/Connection**, and you can specify which DCs replicate to what DCs. I recommend against it, *but* you might do it when in a troubleshooting situation.

You can force the KCC to run by installing a program called **repadmin.exe** and then typing **repadmin /kcc**. REPADMIN is one of the Resource Kit tools that you get free with Server—look in the `\Support\Tools` folder and install the tools by double-clicking the file named **SUPPTOOLS.MSI**.

**BUT SOMETIMES IT'S NOT A LOOP, IT'S A MESH**

This sounds pretty good, until you start thinking about what might happen in a company with *lots* of domain controllers. Suppose you had 200 DCs. That'd mean that if one DC started replicating some change to the Active Directory, the change could take up to 100 replications to get to all other DCs. Let's see: 100 replications, each of which happens at roughly five-minute intervals—500 minutes—that's *more than eight hours*. Would you call *that* an acceptable interval for replication within a site? Well, no, of course you wouldn't, and Microsoft didn't think so, either. So the KCC looks around and asks,

“Are any DCs more than three hops apart?” If so, the KCC just adds more links, converting the loop into a mesh. I’ve seen ADs with several dozen DCs—unusually large domains, to be sure—where some DCs had eight replication partners apiece.

I’ve been calling the process of moving an AD change through a set of domain controllers a “loop,” but as you see, it might not *be* a loop; it might be a mesh. That’s why Microsoft has a different term to describe the path that an AD change might take through a set of DCs: the *replication topology*.

### THERE IS MORE THAN ONE REPLICATION TOPOLOGY

Even a simple network, however, is a bit more complex than I’ve described. I’ve described a single loop—oops, I mean replication topology—but every forest will have more than that. Every forest has at least three replication topologies.

To see why, recall that a forest is a collection of domains. Each domain has its own “private” information that it (mostly) only replicates among the DCs for that domain. (For example, the information in your user account, such as your name and password, stays in your domain’s replication topology. If you were to create a new user account in one domain, then the other domains would know nothing of that, so it wouldn’t generate replication in the *other* domains, save for a bit of activity on the global catalog servers.) That domain-specific data is one replication topology: the pathway for updates from one DC to another within a domain. But recall that there is some data that is specific to the *forest*, not the domain; that data needs to be seen by *every* DC, no matter what domain that DC is a member of. The forestwide data is called the *schema and configuration naming contexts*, and it replicates among all DCs in the enterprise, not just the DCs in one domain, so the KCC creates a replication topology for that data that is distinct from the replication topology that any single domain uses.

**NOTE** Just a word on that phrase naming context. It’s an LDAP term that Microsoft adopted, unfortunately in my opinion. It just means “a database that must be replicated amongst a bunch of computers.” So when you read a high falutin’-sounding phrase such as, “The KCC creates a replication topology for the bigfirm.biz domain-naming context,” you can translate it to this: “The KCC figures out which DCs replicate to which DCs so that they can replicate bigfirm.biz’s domain info, such as usernames, attributes, passwords, and the like.”

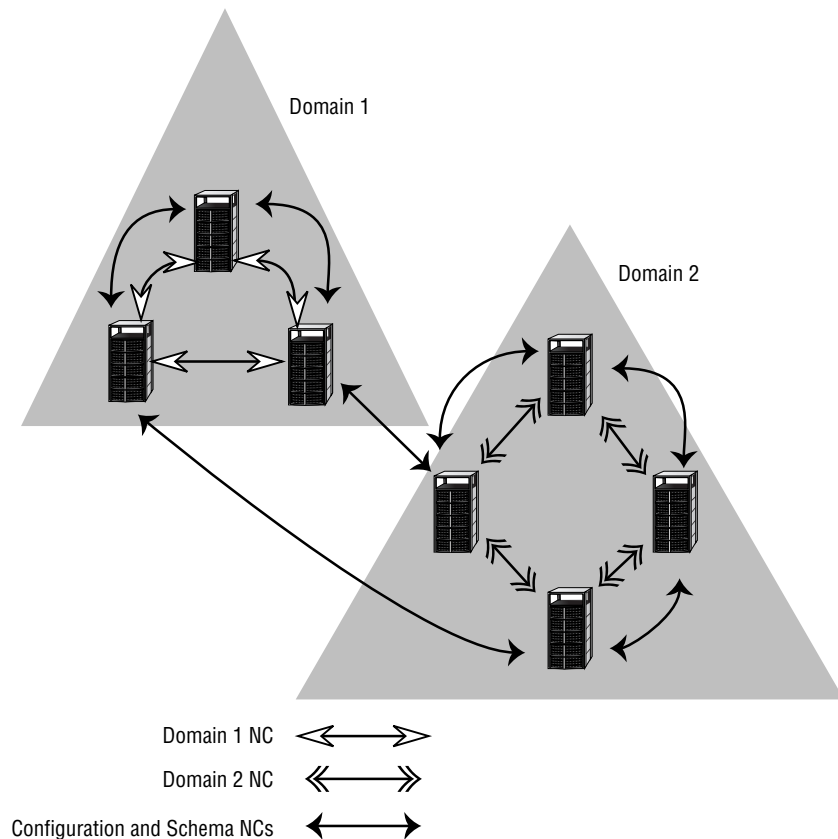

There is also, recall, a database that consists of a subset of data from all of the domains: the global catalog. The KCC creates a replication topology that global catalog servers use to replicate the GC as well.

This all means that you could have *quite a few* replication topologies running. For example, a four-domain forest would have one replication topology for each domain, then one for the forestwide data, and then finally one for the global catalog—six, in all. You can see a simpler example—replication in an imaginary two-domain forest—in Figure 8.54.

In this example, you see the two triangles labeled Domain1 and Domain2—recall that Active Directory diagrams always use triangles to represent AD domains. Domain1 has three DCs that have formed a two-way loop to replicate their domain information amongst themselves, and Domain2 has four DCs that have created a similar loop. There is also a third loop that incorporates all of the DCs, which replicates the schema and configuration naming contexts. (For simplicity’s sake, I left out one replication path, the global catalogs.)

**FIGURE 8.54**

Two domains,  
three replication  
topologies

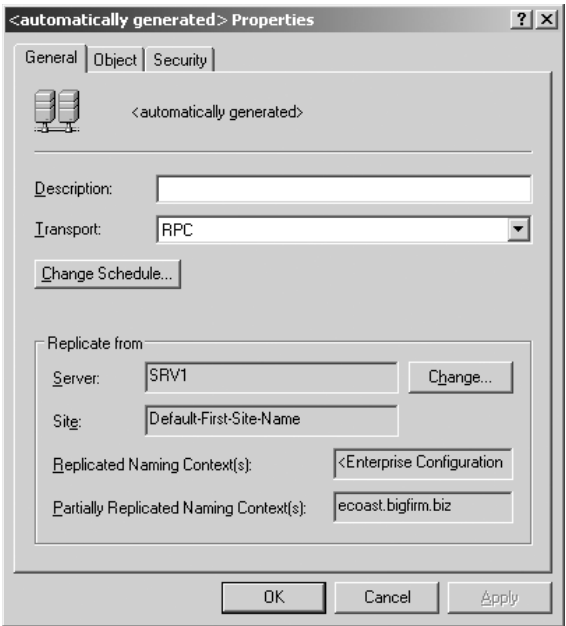

You can figure out what kind of replication each connection does by double-clicking the connection object between any two DCs. For example, I just looked into the **NTDS Settings** folder for my BIGDOG domain controller in my bigfirm.biz domain, and I see that it replicates with three DCs—DC2, DC3, and SRV1. SRV1 is, you may recall, the sole DC for ecoast.bigfirm.biz. Why do BIGDOG and SRV1 replicate if they're not in the same domain? Two reasons. First, BIGDOG is a global catalog server and therefore needs to gather information from every domain, and, second, because all they share the forest-wide naming contexts Configuration and Schema, and they have to be replicated. If I double-click the BIGDOG-SRV1 connection object, it has a properties page like Figure 8.55.

Notice the fields Replicated Naming Context(s) and Partially Replicated Naming Context(s)—these tell the tale. <Enterprise Configuration> says that this connection replicates the Configuration and Schema naming contexts. Then, ecoast.bigfirm.biz tells that SRV1 tells BIGDOG about the ecoast.bigfirm.biz domain, but not *everything* about the domain. Why would one DC give only partial information about its domain to another DC? Again, because BIGDOG is a global catalog server. In contrast, click most of the other connection objects in a domain like this and you will see nothing in the Partially Replicated Naming Context(s) field and the domain's name in the Replicated Naming Context(s) field.

**FIGURE 8.55**

Properties for a connection object between domains

### **BUT WHAT ABOUT “REPLICATION CRASHES”?**

Recall that back in my picture with the four bigfirm.biz domain controllers, I said that if we changed Tom’s manager then the information would replicate its way both clockwise and counterclockwise until the news hit DC4 roughly simultaneously from both sides. But we don’t want DC4 recording the fact of Tom’s manager change over and over again, so I said that AD has a way of making DC4 smart enough to say, “Thanks, but I already know about it” the second time that it hears of Tom’s new manager. I’ll show you exactly *how* in a few pages, but for now I’ll ask you to trust me that AD knows how to keep a piece of news from going ’round and ’round and ’round the network forever. But there’s another kind of potential replication problem: collisions. Suppose an administrator connected to BIGDOG changes Tom’s manager to one value. At about the same time, an administrator connected to DC4 changes Tom’s manager also but to a different name.

Who wins?

To see, let’s look a bit under the hood at replication. Back when we created Tom’s user record, someone probably filled the Manager field with the name of Tom’s manager—as in the song on Paul Simon’s old *Graceland* album, let’s call him Al. Let’s suppose that our bigfirm.biz domain initially contained information looking something like this:

Object	Tom’s user account
Attribute	Manager
Value	Al Jones
Version number	1
Modified	1 December 2000 1:01 P.M.

A couple of months later, the admin attached to BIGDOG updates Tom's user record to reflect the fact that his new manager is named Beth Meadows. BIGDOG then stores (and replicates) this database information:

Object	Tom's user account
Attribute	Manager
Value	Beth Meadows
Version number	2
Modified	5 February 2001 4:22 P.M.

Notice that in addition to the new value, there's a new timestamp and a new version number. Version numbers are simple: a DC is just supposed to increment them when it changes an attribute. As the previous value had version number 1, the change gets version number 2. If we changed it again, it'd be version number 3, and so on.

Now, over at DC4, another administrator thinks that he's supposed to update Tom's record with Beth's name, but he figures that Beth must *really* be Elizabeth, so he enters that, resulting in DC4 storing and replicating this data:

Object	Tom's user account
Attribute	Manager
Value	Elizabeth Meadows
Version number	2
Modified	5 February 2001 4:25 P.M.

Notice that the version number here is 2, not 3. That's because from the point of view of the domain controller DC4, this *is* the second version. It doesn't yet know that BIGDOG has changed the record.

BIGDOG then tells DC2 about Beth, and DC4 tells DC3 about Elizabeth. Soon thereafter, either DC2 tries to replicate to DC3 or vice versa—it's just a matter of chance. It's then clear that there's a conflict: two different items are trying to update the same attribute of the same record. Time for conflict resolution. How does AD do that? Fairly simply:

If one candidate has a later version number, then it wins. If they have the same version number, then the later modification wins.

See why time synchronization is so important? In both cases, the version number is 2, so that's irrelevant. But Elizabeth appeared three minutes after Beth, so she wins.

It's just a might sleazy, but I should mention that there is, therefore, a way that the admin at BIGDOG could have improved the chances that his changes would be more collision-proof. If he'd changed the manager to Beth, then Elizabeth, then back to Beth, then his replicated record would have had a version number of 4, because by AD's lights, the attribute had changed three times in just a few moments. The Beth record would have a higher version number than the Elizabeth record, and it would have won, even if it were an older record.

## AD REPLICATION NUTS AND BOLTS

I hope you will never have to worry about how the AD gets its data from one DC to another. But just in case you need to troubleshoot replication, here's how it works under the hood.

A note on this explanation, though: Recall that Active Directory is a database. It stores a lot of information about the objects in its database. Recall also that some examples of those objects are user and machine accounts, but there are many other kinds of things stored in AD. For the purposes of explaining AD replication, however, I'm going to simplify just a bit and use only user account creations and modifications in my examples.

### AD in a One-Domain Controller World

Let's consider what happens when you connect to a DC and create a user account. Again for purposes of readability, I'll simplify the structure of a user account record and say that user accounts only keep track of these things:

- ◆ The user's name
- ◆ The user's UPN (logon name)
- ◆ The user's password
- ◆ The name of the user's manager

Suppose I create a user named Dawn, with a UPN of dawn@bigfirm.biz. Let's say that her password is "swordfish" and her manager's name is Wally. Suppose when I create Dawn's account, Bigfirm has only one DC—BIGDOG—and so that's the DC that creates the account.

Now, you'd think that all that AD would store would be something like "created a user account; name=Dawn, UPN=dawn@bigfirm.biz, password=swordfish, manager=Wally, time and date of creation=10:00 A.M. 28 February 2001." But it's a bit more complex than that. I only mentioned this in passing, but AD does not replicate entire *records*; instead, it replicates *single attributes*. So if I change Dawn's manager to Jane in a few months, then AD won't replicate "name=Dawn, UPN=dawn@bigfirm.biz, password=swordfish, manager=Jane;" instead, it'll only say something like "for Dawn's record, manager now equals Jane." That's important because it implies that we must keep track of updates to each attribute, not each record.

### Introducing Update Sequence Numbers (USNs)

The AD keeps a running total of changes that it has seen in its history called an *update sequence number* or USN. Every DC has its own set of USNs, as you'll see, but for now let's just stick with the one DC that I'm creating Dawn on. (Recall that for the moment we're assuming a one-DC world. And let me add here that this is a really bad idea in the real world—always have at least two DCs for each domain!) BIGDOG might have seen 5000 changes since I first created its Active Directory, so it would associate Dawn's name with USN=5001. You may recall also that AD keeps version numbers on each attribute, so it'd store a version=1 for that attribute. Creating Dawn's user record, then, would cause the DC to think the following:

- ◆ "Got a new object in the database. It's a user account that I'll give a SID of 1-5-21-43-534-83-1188."
- ◆ "Got a new username for 1-5-21-43-534-83-1188, Dawn. It's the 5001st thing that I (the DC) have learned, so I'll associate her name with USN=5001. Version number is 1."

- ◆ “Got a UPN for 1-5-21-43-534-83-1188, value=dawn@bigfirm.biz. It’s the 5002nd thing I have learned, so I’ll give it USN=5002. Version number is 1.”
- ◆ “Got a password for 1-5-21-43-534-83-1188, value=swordfish. It’s the 5003rd thing I have learned, so I’ll give it USN=5003. Version number is 1.”
- ◆ “Got a manager for 1-5-21-43-534-83-1188, value=Wally, USN=5004, version number is 1.”

So now we’ve created a user account for Dawn. She logs in the first time, and her workstation asks her to change her password, so she changes it to “secret.” AD stores that new password like so:

- ◆ First, it computes a USN for the new password. We’ve probably created other user accounts and done maintenance on other accounts between the time that we first created Dawn’s account and now, so it’s likely that the latest USN is higher than 5004. Let’s just say that this DC’s USNs are up to 5716.
- ◆ Next look at the previous version number for the password attribute for Dawn. It was version=1, so the new password will have version=2.
- ◆ AD then stores something like “got a password for 1-5-21-43-534-83-1188, value=secret, USN=5716, version number is 2.”

The following table summarizes what BIGDOG knows about Dawn.

Attribute	Value	USN	Version
Name	Dawn	5001	1
UPN	dawn@bigfirm.biz	5002	1
Password	secret	5716	2
Manager	Wally	5004	1

But if an AD increments its USN number every single time there’s a change, won’t it run out of USNs? Then what happens? Well, the USN is a 64-bit number, so you could have 18,446,744,073,709,551,616—that’s more than 18 quintillion—changes before it becomes a problem. Remember that I said earlier that someone at Compaq had created an AD with 100 million members? Well, if you created an AD that large, then you could apply on average more than 18 billion changes apiece to each of those accounts before you maxed the USNs out. Or, in other words, if you made 1000 changes a second, then it would take about 18 quadrillion seconds to cause the USNs to roll over. Eighteen quadrillion seconds is (if I’ve done the calculation right) more than 500 million years.

And you just *know* that Microsoft will come out with a radically different update to the Active Directory by then...so we’ll have to reset our USNs at that time anyway, and the count will start all over again!

### **Adding a Second Domain Controller**

Well, thus far, we haven’t done anything with replication, inasmuch as there’s only been one DC. Let’s add one named (you guessed it) DC2. It’s got a brand-new, basically empty AD database file. It connects to BIGDOG and gets the current state of the domain’s AD. Let’s suppose that the very

first account that it gets from BIGDOG is Dawn's account. Dawn's name, UPN, password, and manager will then get USNs 0–3, as you see in the following table:

Attribute	Value	USN	Version
Name	Dawn	0	1
UPN	dawn@bigfirm.biz	1	1
Password	secret	2	2
Manager	Wally	3	1

Notice something *very* important here. USNs from one domain controller do not have to match USNs from another domain controller. If we had a third domain controller that also held a copy of Dawn's user account information, then that DC's Dawn records would almost certainly have a different set of USNs.

### **Limiting Replication: Using USNs and Introducing “High-Water Marks”**

What, then, does a USN do? Basically this: It helps replication partners know how much replication they have to do. BIGDOG replicated everything that it knew to DC2, item by item, and there were plenty more records than just Dawn's to pass along. As BIGDOG told things to DC2, it also told DC2 the USNs—that's BIGDOG's USNs—for each piece of data. Let's suppose that the highest USN in BIGDOG's AD database at the time was 6729. In general, DC2 doesn't care all that much about BIGDOG's USNs. But as BIGDOG finished replicating to DC2, then DC2 made a note to itself, saying, “The last time that I replicated from BIGDOG, BIGDOG's highest USN was 6729.” That is DC2's *high-water mark* value for BIGDOG.

Five minutes later, DC2 wants to replicate again from BIGDOG. But how much of BIGDOG's database does DC2 need in order to be up to date? We certainly don't want to replicate all of BIGDOG's AD database to DC2 every five minutes! To avoid that, DC2 starts out the replication process by asking BIGDOG, “What's your currently highest USN?” The replication conversation could, then, go something like this:

DC2: What's your currently highest USN?

BIGDOG: It's 6729.

DC2: Hmmm, let's see—my high-water mark value for you is also 6729. As that was the last USN that you replicated to me, I already *have* that change, so I guess I'm up to date. Thanks, I guess we're done!

Alternatively, if BIGDOG had said, “My currently highest USN is 6800,” then DC2 would know that it had missed 71 changes to AD and so could ask BIGDOG to send along the changes associated with BIGDOG's USNs 6730 through 6800. That would lead to these events:

- ◆ DC2 would record BIGDOG's changes in its copy of the Active Directory.
- ◆ Those changes would have USNs *on* DC2, and so DC2's highest USN is now higher.
- ◆ DC2 would now know that its high-water mark value for BIGDOG is no longer 6729, but instead now 6800.

**A Problem: Infinite Loops**

Reviewing, then:

- ◆ Each DC maintains a separate copy of the Active Directory on its domain.
- ◆ That AD contains USNs for each item in the AD.
- ◆ USNs in one domain controller's copy of a given AD record will generally not match the USNs in another DC's copy of the AD for the same record—if Mary Smith's password has USN 10030 on one DC, that same password for Mary will be stored on a different DC, but with a different USN.
- ◆ Each DC remembers the highest USN that it has heard from each of its partners. Those highest USNs-so-far are called the *high-water mark* values for each replication partner.
- ◆ DCs use the high-water marks to be able to tell their replication partners, "Only tell me what's new since the last time we spoke."

So far, so good. But so far, there's no way to avoid an infinite loop. To see that, let's suppose that we start off with our two domain controllers, BIGDOG and DC2. Let's say that BIGDOG's highest USN is 5000, and DC2's highest USN is 1000. The system is quiescent, so BIGDOG's high-water mark for DC2 is 1000, and DC2's high-water mark for BIGDOG is 5000.

Now suppose an administrator makes a change on BIGDOG—we change the value for Tom's Manager field, as in the earlier example. BIGDOG gives that AD change—that "update" in AD-ese—a USN of 5001.

DC2 says to BIGDOG, "What's your highest USN?" BIGDOG responds, "5001."

DC2 now knows that it's hopelessly behind and so seeks to get back "in sync" with its buddy BIGDOG. So it says, "Send me all of your updates with USNs higher than 5000." BIGDOG responds with the new information. DC2 records this new manager for Tom dutifully, and that change gets USN 1001 on DC2. DC2 also records that BIGDOG's high-water mark is now 5001.

Eventually BIGDOG says to DC2, "What's new?" Or, in AD-ese, "Do you have any updates after that last one that I got from one, any greater than 1000?"

DC2 says, "Sure, I've got a 1001." (Which is true.) So BIGDOG realizes that now *it* is hopelessly behind the times (which is not true) and asks DC2 for this new information. DC2 responds by telling BIGDOG about Tom's "new" manager. BIGDOG records this information, bumping its highest USN up to 5002 and recording that DC2's latest high-water mark value is 1001.

But now what happens the next time that DC2 says to BIGDOG, "What's your highest USN?" Well, of course BIGDOG replies, "5002," and the whole mess starts all over again. Although this would make for very busy-looking domain controllers, it wouldn't be of much use...so Microsoft included a "propagation dampening" feature to stop the loops. It's got two parts: the originating USN and something called the up-to-date vector.

**Originating USNs: Credit Where Credit Is Due**

I've told you so far that whenever a DC stores an update (update=change, recall) to the Active Directory, then it identifies the update by a USN, and that USN is local to that DC—all other DCs in the domain will eventually know the information included in that update, but those DCs will all end up assigning a different USN to the information.

But what I *didn't* tell you was that DCs also store some more information: the name of the *originating* DC and the USN on that DC. So the table that I showed you a few pages back of how part of DC2's AD might look after replicating from BIGDOG might be more completely represented like so:

Attribute	Value	USN	Version	Originating DC	Originating USN
Name	Dawn	0	1	BIGDOG	5001
UPN	dawn@bigfirm.biz	1	1	BIGDOG	5002
Password	secret	2	2	BIGDOG	5716
Manager	Wally	3	1	BIGDOG	5004

As before, this table shows four attributes and values for a user named Dawn. Each attribute has a USN that is a *local* USN, the USN that DC2 created when copying the records from BIGDOG, and a version number. But now we've got the originating DC, which identifies the DC that *first* made the change, and that DC's USN. Thus, even if we had 100 DCs here, they'd all have their own different USNs on their local copies of Dawn's information—but every one of them would remember that the first DC with this information was BIGDOG and would remember BIGDOG's corresponding USNs.

#### ***Up-to-Date Vectors: Breaking the Loop***

What good are those originating USNs? They're the key to stopping the infinite loops. You've already heard that each DC remembers the highest USN that it's ever heard from each of its partners. Those numbers are, again, called the *high-water mark* table for that DC. Now let me add a bit more information that's kept by each DC: the highest *originating* USN that it's ever heard, *from all DCs*—not just the replication partners. This table of highest originating USNs is called the *up-to-date vector*.

Thus far, I've told you this (incomplete) story about how DCs update each other: One DC remembers the high-water mark that it's seen so far from its partner, and so it asks the partner, "What records do you have in your AD with a higher USN than this high-water mark that I have for you?" In actuality, the more complete request goes, "What records do you have in your AD with a higher USN than this high-water mark that I have for you, *but that do not include any originating USNs less than or equal to my table of up-to-date vectors?*"

#### ***A Replication Example Using High-Water Marks and Up-to-Date Vectors***

Let's revisit my earlier BIGDOG/DC2 replication example. Suppose our story starts as follows:

DC	Highest USN	High-Water Mark for Partner	UTD Vectors	
			BIGDOG	DC2
BIGDOG	5000	1000	4817	388
DC2	1000	5000	4817	388

I'm making this example easier by starting from a quiescent, "everybody knows exactly the same things" state. Things work as well otherwise, but this is clearer. BIGDOG knows DC2's highest USN

accurately, DC2 knows BIGDOG’s accurately, and they each have the same UTD vector. (Note that every DC’s table includes its *own* highest originating USN as well!)

Now, suppose an administrator is connected to BIGDOG and makes a change—again, Tom’s manager works fine. In storing this new item, BIGDOG gives it USN 5001, identifies the originating DC as BIGDOG, and the originating DC’s USN as 5001. BIGDOG also updates its UTD vector to reflect that the latest originating USN that it knows of from BIGDOG—*itself*—is 5001.

Now DC2 asks BIGDOG, “What items do you have in your AD that have a USN greater than 5000 (DC2’s current high-water mark for BIGDOG) *and* whose originating USNs are greater than the ones that I have in this up-to-date vector: BIGDOG=4817, DC2=388?”

BIGDOG now examines everything with a USN higher than 5000. It finds one record, the one that describes Beth’s new manager. BIGDOG examines its originating DC/USN and finds that it originated on BIGDOG with a USN of 5001. BIGDOG then looks at the up-to-date vector that DC2 sent it and sees that as far as DC2’s concerned, any item that originated at BIGDOG after USN 4817 is news...so BIGDOG sends the info about Beth’s manager along to DC2.

DC2 then stores this information as local USN 1001, originating DC=BIGDOG and originating DC’s USN=5001. It also notes that the highest originating USN from BIGDOG is 5001, and a high-water mark for BIGDOG of 5001. The current state of replication then looks like this:

DC	Highest USN	High-Water Mark for Partner	UTD Vectors	
			BIGDOG	DC2
BIGDOG	5001	1000	5001	338
DC2	1001	5001	5001	338

Next, BIGDOG seeks to replicate with DC2. BIGDOG last knew of USN 1000, so it asks DC2 for any updates after 1000, provided that their originating USNs exceed the ones in BIGDOG’s up-to-date vector; BIGDOG includes the contents of its current up-to-date vector.

DC2 notes that it has a USN 1001 and considers sending it to BIGDOG. But then it makes a second check of the originating DC and USN and notes that the record came from BIGDOG. So it then asks, “What is the latest originating USN from BIGDOG that BIGDOG knows about?” and the answer is 5001. DC2 then says to itself, “Well, this record was new to me...but clearly BIGDOG already knows about it, as it knows all of the BIGDOG-originated records up to the one with a BIGDOG USN of 5001.”

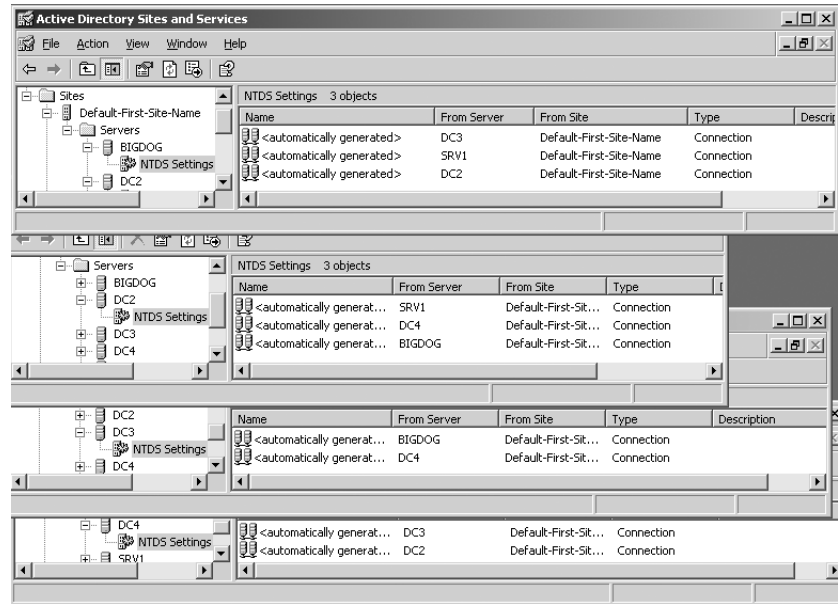

DC2 then replies, “No, I don’t have anything that you don’t know. But my highest USN is now 1001.” BIGDOG makes a note of that, and the replication is done—we’re back to quiescence.

**Adding More Domain Controllers**

Let me wrap up this discussion of replication nuts and bolts with a somewhat more complex example. To demonstrate how all of that works, let’s see how my four bigfirm.biz DCs—BIGDOG, DC2, DC3, and DC4—would replicate. BIGDOG holds all of the FSMO roles, but other than that is indistinguishable from the others. After giving them 15 minutes to run the KCC and settle down into a replication structure, I opened four copies of AD Sites and Services to show the NTDS Settings folders for all four, as you see in Figure 8.56.

**FIGURE 8.56**

Replication partner settings for BIGDOG, DC2, DC3, and DC4

By the way, you can use the NTDS Settings folder to force replication. Just right-click any replication partner and you'll see an option to Replicate Now; that will force the DC to replicate with that replication partner immediately. Sketched out, the bigfirm.biz replication structure looks like Figure 8.52 a few pages back.

Recall that each domain controller has an up-to-date value for every other DC—not just its replication partners. You can see the entire up-to-date vector for any domain controller with a command-line tool called REPADMIN. REPADMIN is part of the mini-Resource Kit that comes with Server that I mentioned earlier. Recall that you can install it by looking in the \Support\Tools folder of the Server CD for a file called SUPPTOOLS.MSI; double-click it and answer the prompts and you'll get several useful and interesting tools.

REPADMIN runs from the command line, and it's as cryptic as most command-line Resource Kit tools. To see the up-to-date vector for a domain controller, make sure that you're sitting at the domain controller and open up a command prompt, then type this:

```
repadmin /showutdvec dcname naming-context
```

where *dcname* is the name of your domain controller and *naming-context* is just the name of your domain, but written strangely. Take each part of the AD DNS-like domain name and write it as **DC=firstpart,DC=secondpart,DC=thirdpart** and so on for as many parts as the domain name includes. For example:

acme.com becomes DC=acme,DC=com

hq.bigfirm.biz becomes DC=hq,DC=bigfirm,DC=com

And so bigfirm.biz is just dc=bigfirm,dc=com. Why REPADMIN wants it this way has to do with the internal representation and storage of the Active Directory. AD is built to use a

database-access language called the Lightweight Directory Access Protocol (LDAP), and that's how LDAP refers to domain names. There's far more to know about LDAP, but I've been trying my hardest to spare you its cryptic nature, so you won't hear any more LDAP stuff than is absolutely necessary. Here's a sample run of `repadmin /showutdvec`, although not on our imaginary network:

```
C:\>repadmin /showutdvec bigdog dc=bigfirm,dc=biz
Caching GUIDs.
..
Default-First-Site-Name\DC3      @ USN      4747 @ Time 2003-01-18 14:45:18
Default-First-Site-Name\DC4      @ USN      4968 @ Time 2003-01-18 13:59:00
Default-First-Site-Name\BIGDOG   @ USN      6454 @ Time 2003-01-18 14:49:34
Default-First-Site-Name\DC2      @ USN      39469 @ Time 2003-01-18 14:45:18
```

You can see that BIGDOG's up-to-date vector even includes an entry for itself. Now, if you try this out on *your* network, then you might come across a confusing but common sight—more lines than you've got DCs! Suppose your domain had five DCs, and you ran a `repadmin /showutdvec` on one of your DCs. You'd expect five UTD entries, and perhaps that's what you'd get. But you'll often see entries in the UTD vector that don't have a name, but instead have a long string of letters and numbers. That string of letters and numbers is called a *globally unique ID*, or GUID. What you're seeing (if you see something like that) is the remnants of old DCs. If, in the five-DC example, you perhaps *used* to have a couple of DCs in your domain that you have demoted (that is, you ran `DCPROMO` on them to convert them back to member servers), then those now-gone DCs will have entries left in the other DC's up-to-date vector tables. The GUID is the only information left about that old DC—the AD recognizes that it no longer exists, but the process of demoting a DC does not direct the other DCs to scrub its up-to-date value from their up-to-date vectors. (Old DCs never really die apparently; they just fade away.)

Now, let's suppose that I change the AD, again by modifying Tom's manager while attached to DC2. Clearly DC2 is going to replicate that account to its partners, BIGDOG and DC4; that part's easy to understand. But it's just as clear that BIGDOG will want to replicate the new account to DC3—and that DC4 will want to replicate the account to DC3. Clearly we don't want DC3 getting any more replication traffic than is necessary, so how does AD keep DC3 from getting the same report twice?

#### **Step One: Create the New User on DC2**

First, let's change Tom's manager at DC2 and review what happens to DC3. When things start out, suppose DC3 has the following up-to-date vector:

DC3	4747
BIGDOG	6454
DC2	39469
DC4	4968

Let's assume that the AD is quiescent when I change Tom's manager, so those are also the current high-water values for those domain controllers. I make the change to Beth's account on DC2 and, as you saw earlier, DC2's highest USN increments. Let's say that the update on DC2 has a USN of 39473. I'll simplify this example and focus mainly on the up-to-date vector, as I hope that the

highest-USN and high-water mark's use is clear by now. (Also, explaining a complete four-DC replication with all the bells and whistles takes pages and pages and pages.) DC2 bumps up its up-to-date vector for itself to 39473.

#### **Step Two: DC2 Replicates the New User to BIGDOG**

After a little while, DC2 says to its two replication partners BIGDOG and DC4, "I've got a new USN; you might want to come replicate with me." Let's say that BIGDOG responds a bit more quickly than DC4, saying, "Send me all the new entries whose originating USNs exceed 4747 if it came from DC3, 6454 if it came from BIGDOG, 39469 if from DC2 or 4968 if from DC4." DC2 sees that the record's originating DC is DC2 but that the originating USN is 39473—which is larger than 39469. So it sends along Tom's new manager. BIGDOG increments its USNs and stores away the information about Tom's new manager, including the fact that the information originated at DC2 with USN of 39473. BIGDOG also changes the value in its up-to-date vector entry for DC2 up to 39473.

#### **Step Three: BIGDOG Replicates to DC3 and DC2**

Armed with this new information, BIGDOG taps both DC3 and DC2 on the shoulder and says, "Hey, check out my new USN." Perhaps DC2 responds first, saying, "Tell me any new stuff as long as it originated with DC3 after 4797, BIGDOG after 6454, DC2 after 39473, or DC4 after 4968." BIGDOG says, "Hmmm, I guess this info about Tom's manager isn't all *that* new...it's from DC2 and has a USN of 39473. Never mind, DC2."

DC3 responds similarly but not identically: "Tell me any new stuff as long as it originated with DC3 after 4797, BIGDOG after 6454, DC2 after 39469, or DC4 after 4968." Notice that DC3's got an older up-to-date vector entry for DC2. BIGDOG sees that the info on Tom's manager is originally from DC2 but has a USN larger than 39469 and replicates the information to DC3. DC3 stores it, noting again that the information originated with DC2—not BIGDOG, even though he's the one that passed the info along—and that DC2's USN for the information was 39473. DC3 updates its value in the up-to-date vector table for DC2 to 39473.

#### **Step Four: DC2 Updates DC4**

While BIGDOG is updating DC3, the chances are good that DC4 finally responded to DC2, saying, "What's new since the last time we talked, DC2? But only tell me things if they originated with DC3 after 4797, BIGDOG after 6454, DC2 after 39469, or DC4 after 4968." (As you can see, DC4 has the same up-to-date vector that DC3 had a moment ago.) DC2 sees that the only new record that it has originated at DC2 and has a USN of 39473, so replicates it to DC4. DC4 stores that information, including the fact that the information originated with DC2 and updates its up-to-date vector table entry for DC2 to 39473.

Note that as of now, all four DCs have the latest information. Additionally, all four DCs have an up-to-date vector table entry for DC2 of 39473. Thus, when any DCs consider sending the information on Tom's new manager to any other DC, they stop, as they see the other DC's up-to-date vector and realize that the other DC already knows!

#### **Peeking at AD Replication**

How can you monitor AD replication? You've already seen how to use REPADMIN to find up-to-date vectors. It'll do other stuff, too.

**Finding Replication Partners** REPAADMIN will also tell you what systems are replication partners with a given DC. Just type **repadmin /showrepl DCname naming-context** where DCname is just the DNS name of a domain controller and naming-context is the LDAP name of the naming context. Here's an excerpt of the output from **repadmin /showrepl bigdog dc=bigfirm,dc=biz**:

```
C:\>repadmin /showrepl bigdog dc=bigfirm,dc=biz
Default-First-Site-Name\BIGDOG
DC Options: IS_GC
Site Options: (none)
DC object GUID: 8ab4d1e6-c1e9-4d4a-ac31-deae028ac046
DC invocationID: 8ab4d1e6-c1e9-4d4a-ac31-deae028ac046

==== INBOUND NEIGHBORS =====

dc=bigfirm,dc=biz
    Default-First-Site-Name\DC3 via RPC
        DC object GUID: 17311f00-9de0-4484-a7cf-2115a4c9a184
        Last attempt @ 2003-01-18 16:13:06 was successful.
    Default-First-Site-Name\DC2 via RPC
        DC object GUID: 2cebe5be-f5e8-4f08-85ef-b4c6123d1600
        Last attempt @ 2003-01-18 16:13:24 was successful.
```

Here's what this is telling you: First, notice the **DSA Options: IS\_GC**; that tells you that this server is a global catalog server. Second, you see that this replicates with DC3, which is in the site named **Default-First-Site-Name**. (I'll cover sites in a moment.) It also replicates to DC2 in the same site. Finally, you see when it last replicated.

**Seeing High-Water Marks** You can see a DC's high-water marks by adding **/verbose** to the **/showrepl** command.

So, for example, to see the high-watermark table for DC2 as seen from BIGDOG's perspective, use REPAADMIN like so:

```
C:\>repadmin /showrepl bigdog dc=bigfirm,dc=biz /verbose
... (skipping output) ...

==== INBOUND NEIGHBORS =====

dc=bigfirm,dc=biz
    Default-First-Site-Name\DC2 via RPC ...
        USNs: 34330/OU, 34330/PU
        Last attempt @ 2003-01-18 16:45:18 was successful.
```

You'll see a line for each replication partner; I've skipped some output to keep the size manageable, as the **/verbose** option tends to be, well, verbose. The high-watermark value is the number followed by the **/OU**—34330, in the case of that example. That's the highest USN from DC2 that BIGDOG has seen.

**Forcing Replication** You can force any two replication partners to replicate a particular naming context with the **/replicate** option:

```
repadmin /replicate destination-DC source-DC namingcontext
```

For example, to force DC2 to pull information from BIGDOG:

```
c:\>repadmin /replicate dc2 bigdog dc=bigfirm,dc=biz
Sync from bigdog to dc2 completed successfully.
```

It would be convenient sometimes to tell AD to get off its butt and replicate every DC with every DC *now*, and it'd be really great if there were one command to do that. Unfortunately there isn't, but you *can* tell a given DC to replicate with all of its partners with REPADMIN via the `repadmin /synca11 destinationDCname namingcontext` command. So, for example, to tell BIGDOG to replicate with all of its replication partners in win2ktest.com, I'd type this:

```
repadmin /synca11 bigdog.win2ktest.com dc=win2ktest,dc=com
```

**Logging Replication Info to the Event Log** Those are the basics of how the AD shuffles information around its various sites and domain controllers without duplicating efforts. Would you like to watch the replication process for yourself? Then look in `HKEY_LOCAL_MACHINE\SYSTEM\CurrentControlSet\Services\NTDS\Diagnostics`. There are about a dozen value entries in there, and they can all accept numeric values between 0 and 5. 0 means “don't tell me anything”; 5 means “fill up the Event log with lots of replication details!” And I *do* mean fill it up. It's interesting stuff, but there's a *lot* there.

## Sites Revisited

Once you've built your TCP/IP infrastructure, you've got to tell the Active Directory about it. There are several reasons for that, but the most important is that the Active Directory is smarter than the old SAM-based NT 4 domain system in the way that it uses bandwidth. When replicating from domain controller to domain controller, it needs to know whether it's communicating via a high-speed link, and thus can be voluble without worrying about choking the link, or if perhaps it's talking to its domain controller sibling over a 56K link and then will take the time to compress the data a bit, becoming a trifle more terse and bandwidth friendly.

But the domain controller can't know the answer to that question unless you help it. A DC knows that it can communicate at high speed with another DC if they're both in the same *site*. But how does it know that?

## How Sites Work

The answer is this: They look to find themselves in the `Servers` container of one of the `Sites` containers of the Active Directory. There is a separate container for each *site*, where a site is defined as “a collection of subnets that communicate with each other at very high data rates.” You define sites and then place domain controllers in sites.

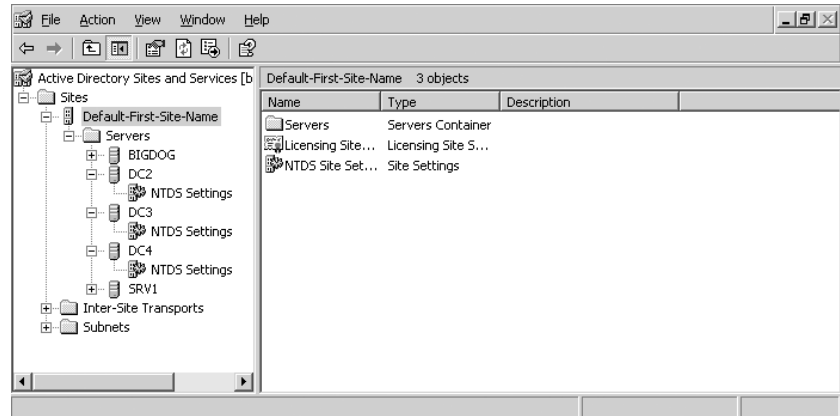

Workstations and servers, however, don't get that help. They've got to choose domain controllers to log them and their users in, and clearly they want to be logged in by a nearby domain controller. They determine who's nearby by examining what subnet *they're* in, then the subnet that each domain controller's in to figure out which DC is nearest. They need to know which subnets are close to one another—in other words, which subnets are in the same sites.

“But,” you might wonder, “how did the Active Directory figure out what sites it had, what subnets it had, and which subnets go into what sites?” *That's* the part that requires a little administrative

elbow grease, so let's see how to apply that elbow grease. Our tool of choice will be a snap-in called Active Directory Sites and Services, located in Administrative Tools. Open it and you'll see a screen like Figure 8.57.

**FIGURE 8.57**

Initial Active Directory Sites and Services screen

Notice that there's only one site, one called `Default-First-Site-Name`. When you create an Active Directory forest, the AD just creates a site by that name and assumes that everything's in it. Open up `Default-First-Site-Name`, and you'll see that your domain controllers are in there. The idea with setting up AD's site topology is that you must:

- ◆ Define each site.
- ◆ Define each subnet.
- ◆ Assign each subnet to a site.

From there, the domain controllers figure out by themselves to which site they belong.

## Renaming Default-First-Site-Name

Let's first rename our first site from that goofy `Default-First-Site-Name` to something simple like `HQ`.

1. Open Active Directory Sites and Services.
2. Open the Sites folder to reveal the folder labeled `Default-First-Site-Name`.
3. Right-click the `Default-First-Site-Name` folder.
4. Choose Rename.
5. The name `Default-First-Site-Name` will be highlighted. Just overtype it with **HQ** and click anywhere else on the screen.

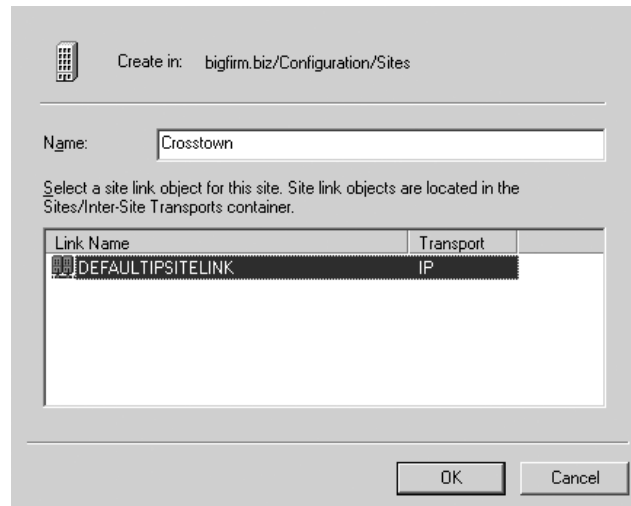

This works best if you do it *early* in your AD creation. In fact, it's really best to rename `Default-First-Site-Name` when you create your first DC. You *may* have to reboot your DCs to make this take effect, although restarting the Netlogon service on them may do the trick.

## Defining a Site

Suppose I set up another site, across town from my first site. The Active Directory needs to know about that site. Right-click the **Sites** folder and choose **New Site**, and you see a screen like Figure 8.58.

**FIGURE 8.58**

Creating a new site

I just fill in a name for the new site (Crosstown), and then click the **DEFAULTIPSITELINK** object and click **OK**. When I do, I get a message box like Figure 8.59.

**FIGURE 8.59**

Checklist for hooking up the new site

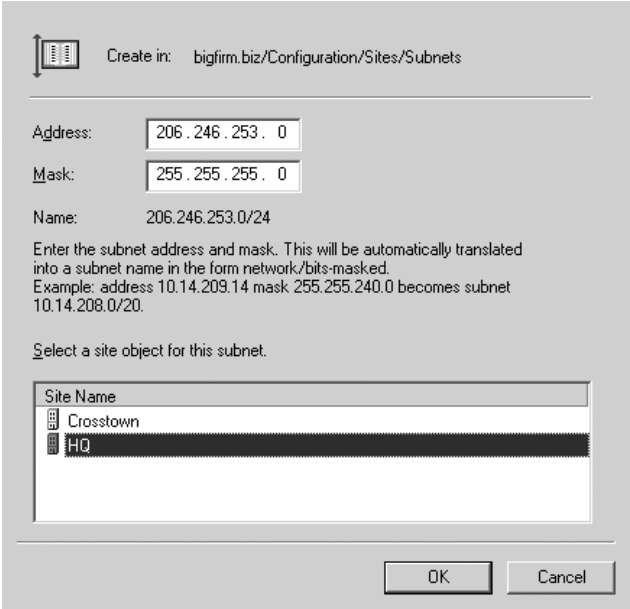

## Defining a Subnet and Placing It in a Site

Next, I'll describe the subnets in my enterprise. Suppose the original site is at 206.246.253.0 and the Crosstown site is at 200.200.200.0. I need to tell Site Manager about these subnets. Right-click the **Subnets** folder and choose **New Folder** and you'll see a dialog like Figure 8.60, where I define the 206 subnet and associate it with HQ.

**FIGURE 8.60**

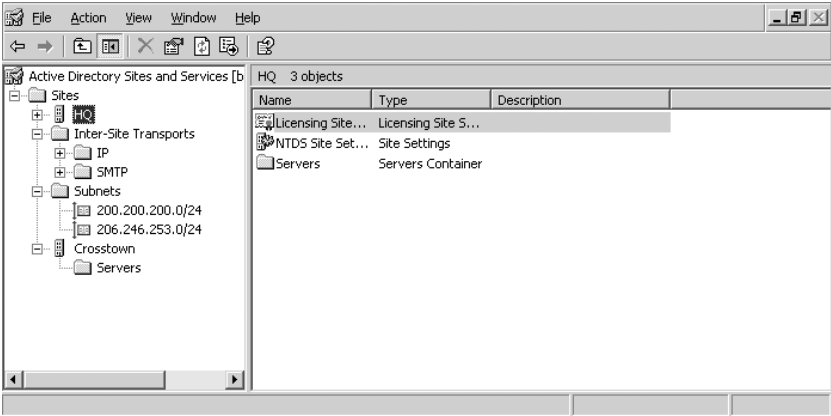

Creating a new subnet

Notice that AD then asks me to associate the subnet with a particular site. I'll define another subnet for the Crosstown site, 200.200.200.0, as well, and now Active Directory Sites and Services will look like Figure 8.61.

**FIGURE 8.61**

Sites and Services after defining sites and subnet

### Placing a Server in a Site

Right now all four of bigfirm.biz's DCs are in HQ. Suppose DC3 belongs in Crosstown. I could tell AD that by finding DC3 in the HQ\Servers folder in Sites, right-clicking it, and choosing Move to see a dialog box like Figure 8.62.

**FIGURE 8.62**  
Moving a server

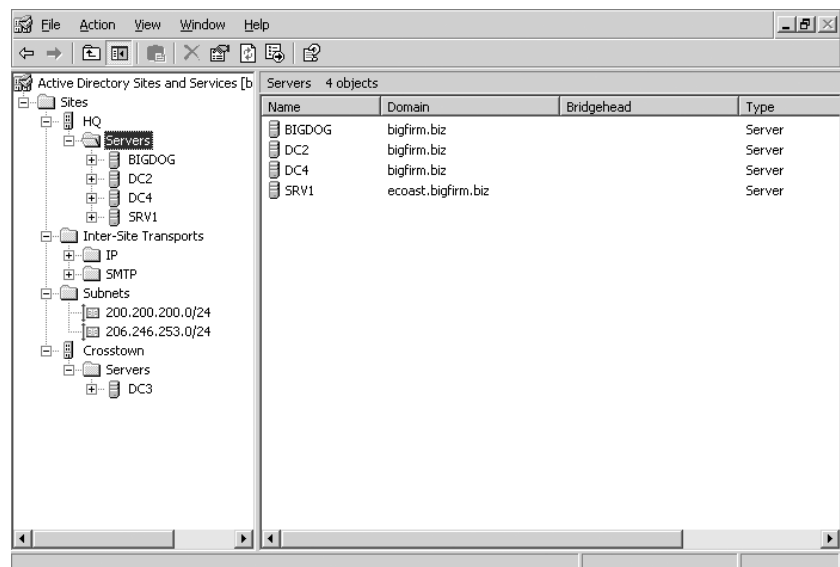

It's a little bit of work, but arranging your servers in Sites and Services Manager pays off if your enterprise spans WAN links.

## Inter-Site Replication

Now that you've seen how to create subnets and a site, let's see how to get them to communicate with one another.

You already know that within a site, AD replicates by building a replication topology that is either a two-way loop (in a site with seven or fewer DCs) or a mesh. But a loop or mesh topology across WAN links would be inefficient, so AD instead creates a minimal spanning tree, meaning that it creates a set of site-to-site replication paths that minimizes the load on your WAN bandwidth. Take a look at the AD Sites and Services snap-in shown in Figure 8.63.

**FIGURE 8.63**  
AD Sites and  
Services for a two-  
subnet, two-site  
enterprise

This is obviously a very simple “enterprise.” But it’ll serve fine to let me explain what you’ve got to worry about in a multisite world. You see, once you set up your sites, then they figure out how to replicate all by themselves, *within the site*. But across sites, they need a little help. You need to define how bits get from (in the example pictured) HQ to Crosstown.

Huh? The AD needs you to tell it how to get from point A to point B? Hasn’t it ever heard of IP? I mean, Ping can figure out how to get from HQ to Crosstown—why can’t the AD?

The AD can easily figure out how to get from one place to another, but it doesn’t know three things:

- ◆ If you have more than one connection from point A to point B, as you might in an intranet or the Internet, is there a connection that you’d prefer that the AD uses over another one?
- ◆ Is the connection available all the time, or only part of the time?
- ◆ Would you like to use real-time RPC connections to replicate, or e-mail-based SMTP connections?

You tell AD about connections between sites by creating *site links*. Right-click either the IP or SMTP folders, choose New/Site Link, and you’ll see a dialog box like the one in Figure 8.64.

**FIGURE 8.64**

Creating a new site link

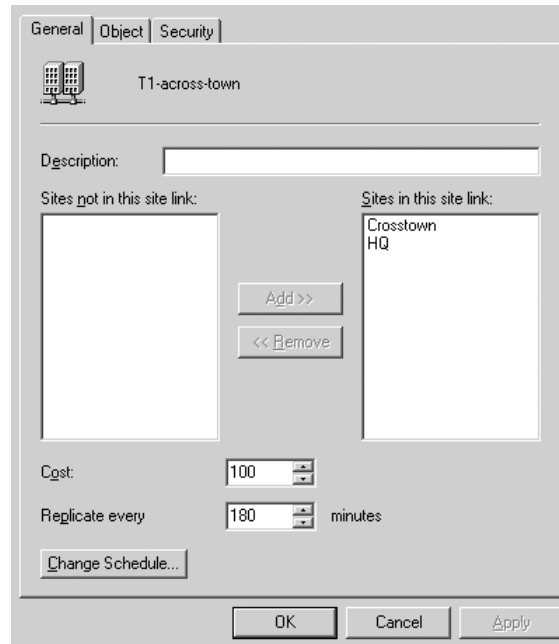

In this dialog box, I tell AD which sites this link will join, name the link, and click OK. An icon will then appear in Active Directory Sites and Services in the IP folder (or the SMTP folder if you created it in there, but the chances are that you’ll almost always create site links with IP, as you’ll see). Double-click the site link object and you’ll see a dialog box (Figure 8.65) that looks just a little different from the one that let you create the site link.

This dialog box is *very* important for three reasons. First of all, notice the spinner box labeled Cost; you’ll use that to nudge the AD to use a link more or less. The AD will choose lower-cost links over higher-cost links. Second, you can control how often the AD tries to replicate over this link. Notice that site-to-site linking is quite different from intrasite links; replicating across a WAN link every

five minutes might not be a low-cost approach for a wide-area based directory service, unless you put up all of those WAN links solely for AD's convenience! The minimum interval that you can specify for a replication across a WAN link is 15 minutes—the maximum intrasite time for replication. Click the Change Schedule button, and you'll see a dialog box like Figure 8.66.

**FIGURE 8.65**

Site link properties

**FIGURE 8.66**

Setting the replication schedule

It could be that the HQ-to-Crosstown link is a dial-up link that's only up from 2 P.M. to 3 P.M. on Tuesdays. In that case, you can tell AD not to bother trying to replicate before then.

**WARNING** *AD sites must replicate at least once every 60 days or less. AD throws away objects that have been inactive for 60 days, so if one site and another didn't talk for a few months, then they'd start deleting objects from their copies of the AD that they weren't using but that other DCs in other sites were still using. Do not reconnect a DC that hasn't replicated to the AD for more than 60 days back to the network.*

Finally, you create a site link either in the IP or SMTP folder to indicate how to replicate. SMTP *sounds* like a great answer: It doesn't need to be running all of the time, the link needn't be up that often—heck—we might even be able to send replication updates via Hotmail!

Unfortunately, it's not that useful. First of all, you can only replicate the forestwide schema and configuration naming contexts, so you could not use only SMTP to, for example, update one domain controller in domain X from another domain controller in domain X that was on a different site. They must replicate with RPC, a real-time connection. And, second, you can't use just any old mail server. You need a public key certificate on that server to ensure secure mail before security-conscious AD will let you use it to replicate. (Oddly enough, you *could* do domain replication in the betas that appeared mid-way through Windows 2000's gestation. But nothing much has changed in Server 2003 on that score, unfortunately.)

Once you tell AD all of these things about sites, a souped-up version of the Knowledge Consistency Checker called the Inter-Site Topology Generator or ISTG (there's one ISTG DC at each site, and they choose themselves, so there's no FSMO seizing to worry about here, it's automatic) talks to the other ISTGs and figures out which links to use so as minimize cost.

## Understanding Functional Levels

Too bad previous versions of NT weren't a flop.

If they *had* been flops, then we wouldn't have to worry about mixing versions of NT. If Microsoft knew that you greeted every new version of NT by throwing out the old stuff and upgrading every single server and workstation—"You! All of the 2000 stuff! Out *now*! And that goes for the NT 4 stuff as well, it's not even supported any more!"—then it'd be easy to add new features. But that doesn't happen, nor should it—the old stuff runs pretty well, in general.

## Mixed and Native Modes in Windows 2000

But that introduces some problems as to what ADs can and can't do—and so we have functional levels. When Microsoft came out with Windows 2000, then they might have said, "You can't use 2000-based AD domains until you FDISK all of your NT 4 DCs," but that would have been a marketing disaster and would have annoyed all of us. (That's what I meant when I said that it was too bad that earlier versions of NT weren't flops; when NT came out, in theory it followed a Microsoft networking OS called LAN Manager, but it had a tiny market share and so very few people worried about "How will I convert my LAN Manager domains to NT 3.1 domains?" That's not the story for Server 2003, however, as NT 4 and Windows 2000 are collectively the most popular server OS.)

So Microsoft said that sure, you could continue to use your NT 4-based BDCs in an Active Directory. You upgraded the primary domain controller to Windows 2000 and that 2000 box created an AD, but it also continued to work with the old NT 4-based BDCs. Clearly the NT 4 boxes don't understand (for example) OUs, and so the NT 4-based BDCs couldn't really be full members of the

DC family if the 2000-based DCs exercised a lot of their new-to-Windows-2000 powers. The result was Mixed mode.

A Mixed-mode AD was one that had a Windows 2000 system acting as a domain controller and holding the PDC role or, rather, the PDC emulator role, and any number of BDCs running NT 4. Windows 2000-based ADs would not exercise a few powers—universal groups and multimaster replication are the most important—until the last NT 4 BDC was shut off. Once all of a 2000-based AD's DCs were running Windows 2000, though, an administrator could click a button in Active Directory Users and Computers that would shift the domain into Native mode, and at that point a 2000-based AD could strut its stuff.

Let me stress that all that you have to upgrade to go to Native mode is the DCs. All other systems could be NT 4 systems for all that a 2000-based AD cares. Native versus Mixed mode is only a matter of the OSES on the DCs. As you'll see, that's the case with 2003's "modes" as well.

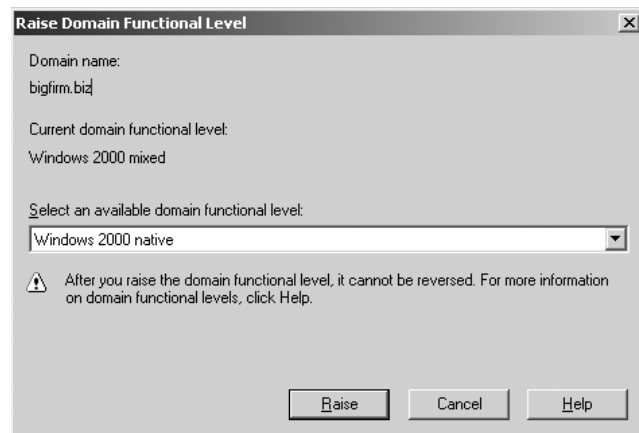

### Domain Functional Levels in Server 2003

In Windows 2000-based ADs, there were only two possible conditions: either a population of DCs that were all 2000-based or a population of DCs that included both 2000 and NT 4—that's why there were only two modes. But ADs that include Server 2003 can have several possible combinations of DCs, each with their own mode or, in 2003's preferred term, *functional level* or, as I sometimes write it "domain functional level" to distinguish it from *forest* functional levels that you'll meet soon.

You change a domain's functional level by opening Active Directory Users and Computers and right-clicking the icon representing the domain. Choose Raise Domain Functional Level and you'll see a dialog box like Figure 8.67.

**FIGURE 8.67**

Raising a domain's functional level

In this case, the domain is at something called Windows 2000 mixed functional level, and you've got the option to change to two other possibilities. Here's what you get from each functional level:

- ◆ **Windows 2000 mixed domain functional level:** a domain that can have some DCs running Windows Server 2003, others Windows 2000 Server, and still others NT 4 Server. This still works if you're running only 2003 and 2000 or just 2003, but in those cases you'll want to raise the

functional level to enable your AD to use as many features as is possible. This is basically just Windows 2000's Mixed mode, but with 2003 servers added. Newly built AD domains, domains upgraded from 2000-based mixed mode ADs, and domains directly upgraded from NT 4 domains start in this functional level. Even if your network consists of a forest composed of one domain which in turn contains just one DC and that DC is running Server 2003, it'll be in Windows 2000 mixed domain functional level. Like 2000's Mixed mode domains, these domains lack multimaster replication and universal groups. They also cannot use something called "SID histories," which we'll cover in the later "Migration Strategies" section, and they cannot convert distribution groups (e-mail lists) to security groups (that is, regular old groups) and vice versa.

- ◆ **Windows 2000 native domain functional level:** a domain with only 2000-based or 2003-based DCs. Like 2000's Native mode, but with Windows Server 2003 DCs added. When you upgrade a 2000-based AD then you get this functional level, or you get it if you raise the functional level yourself. You can't use 2000 native functional level if you have any NT 4-based DCs. Systems in 2000 native domain functional level can use universal groups, multimaster replication, SID histories, and they can convert between distribution and security groups. They really only miss out on one thing: they cannot rename domains, or at least they can't use the new-to-2003 simplified domain renaming feature.
- ◆ **Windows Server 2003 interim domain functional level:** I honestly don't know much about this because I've not found much of a use for it. You can raise your domain to this level only if none of your domain's DCs are running Windows 2000. NT 4 BDCs are OK and of course Windows Server 2003-based DCs are fine. You can only get to this functional level with a separate tool from Microsoft and as far as I can see you get nothing out of an interim functional level that you don't get from a regular old 2000 mixed domain functional level. (Well, there are a few small things, but nothing of any significance.)
- ◆ **Windows Server 2003 domain functional level:** the Big Enchilada. To get here you've got to have all of your DCs in the domain running Windows Server 2003. And once you've reached that lofty level, are you ready for what new functionality you get? Well, here it comes: you can easily rename domains.

"Whaaaaaat?" you say? Okay, there's another important reason to get to 2003 functional level. You see, you can't upgrade your *forest* functional level until all of the domains in the forest are at 2003 domain functional level. Which brings us to...

## Forest Functional Levels in Server 2003

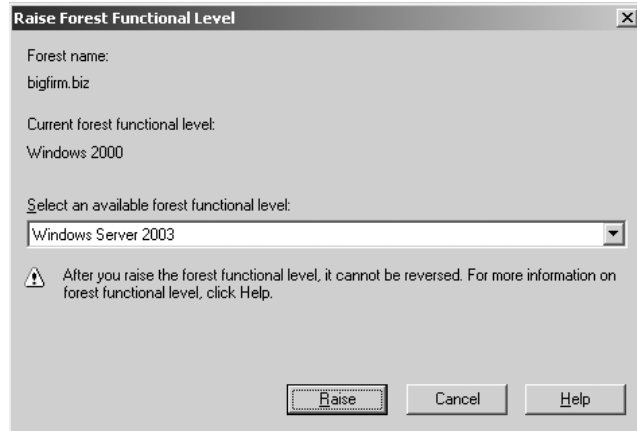

2000 only had different kinds of domains because that's all that NT 4 had—domains. But both Windows 2000-based ADs and 2003-based ADs have forests, leading inevitably to different functional levels for forests.

When you upgrade DCs or domains in an existing forest, or if you create a new forest, then 2003 assumes for safety's sake that not all DCs and domains are entirely 2003-based, and so it will not stretch its wings to use all of the new capabilities that 2003 offers. To get all of those abilities, you must shift the forest from its default level, which is called Windows 2000 forest functional level, to the all-2003 setting, Windows Server 2003 forest functional level.

You raise a forest's functional level with Active Directory Domains and Trusts—Start/Administrative Tools/Active Directory Domains and Trusts. Right-click the icon in the left pane labeled Active Directory Domains and Trusts and you'll see Figure 8.68.

**FIGURE 8.68**

Raising a forest's functional level

You can't go to Windows Server 2003 forest functional level unless every single DC in every single domain in the forest is running Windows 2003. But think about that—doesn't that mean that all of your domains must be in 2003 domain functional level before Domains and Trusts lets you raise the forest functional level? No, it doesn't, as it turns out. When you open the dialog in Figure 8.68, then you'll either get the screen that you see in that figure, or you'll get a message that says, "You can't go to 2003 level," and tells you (or, rather, offers to generate a text file telling you) exactly which DCs must be upgraded before you can go to 2003 forest functional level. When you right-click AD Domains and Trusts, then, the forest does a quick census of its list of DCs. If they're all 2003-based DCs, then you get the option to raise the forest functional level, and, if not, you get the option to see which ones must be upgraded. That leads to what seemed, to me anyway, an odd thing: you can raise your forest's functional level even *if* the domains are all set at Windows 2000 native domain functional level—they needn't be at Windows Server 2003 domain functional level. As it turns out, this is something of a convenience. Provided that all of your DCs are running 2003 and you raise your forest's functional level, then AD Domains and Trusts also automatically raises the functional level of all of your domains to 2003 domain functional level.

So what do you get from this improved functional level? Several items that I've discussed elsewhere, but that I'll summarize here:

- ◆ **Transitive forest trusts.** One trust makes every domain in each of two forests trust each other... but only if both forests are at 2003 forest functional level.
- ◆ **More flexible group membership replication.** 2000's old problem about "if you change a group's membership and I change that same group membership at about the same time, then one of our changes will be lost" goes away in a 2003-level forest.
- ◆ **Better inter-site routing.** 2003 saw a completely massive rewrite of the code that handles site-to-site replication, with the result that where 2000-based forests would fall apart at about 200 sites, 2003-based forests can handle up to 5000 sites.

- ◆ **GC fixes.** Any change to the structure of the global catalog, such as the type that usually happens when you install an AD-aware application, causes GCs on a 2000-level forest to completely panic; they dump their entire databases and rebuild them from scratch, causing massive replication loads over the network. 2003-level forests are much smarter, as their GCs focus only on the changes to the database, rather than restarting from square one.
- ◆ **Schema redefines.** AD's somewhat inflexible schema structure loosens up a bit on a 2003-level forest. You still can't delete or undo schema changes, but the schema manages itself to ensure that you'll never have one AD-aware app accidentally step on another AD-aware app's schema changes.

As anyone who lived through an initial AD rollout under 2000 knows, the road to native mode was sometimes long, and I'm sure that'll be the case when moving a forest to Windows Server 2003 forest functional level. But once there, it's worth it. As I've observed elsewhere, you *paid* for this stuff...you may as well get what you paid for.

## AD's Long Arm: Group Policy Overview

I've talked so far in mildly vague terms about how you can accomplish different kinds of control in an Active Directory. The specific tool for exerting much of that control is group policies, something that first appeared in Windows 2000 but that many people don't know much about even today because it seems too complex—but it isn't, once you understand a few things. Here's an overview of what they do and how they work but, again, it's just an overview—I'll cover it in more detail in the next chapter.

### Differences in System Policy and Group Policy Implementation

With Windows 9x, Me, and NT 4's system policies, you could control a wide variety of things—you could give a user a particular Start/Programs menu, give him a particular look to a desktop, restrict the user from running many programs, and the like. All of these restrictions would be collected into a single file called `NTCONFIG.POL` (for NT 4, 2000, XP, or Server 2003) or `CONFIG.POL` (for Windows 9x and Me), which you'd then place on each of the domain controller's `NETLOGON` shares. When a Windows 9x, Me, NT 4, Windows 2000, XP, or Server 2003 system starts up and logs onto an NT 4 or AD domain, then that system downloads `CONFIG.POL` or `NTCONFIG.POL` and performs whatever instructions are encoded in the `POL` file—again, to modify the Start Programs menu, change the desktop, or whatever. That's an important point—system policies work because the client operating systems request the policy files and follow their orders, not because the DC that logs them on forces the files and settings upon the client (and remember here “client” can mean *any* machine logging onto a domain, whether it's a workstation, member server, or DC—DCs must log on also).

You can have only one `NTCONFIG.POL` or `CONFIG.POL` policy file. And you did read that right in the previous paragraph—you can use `NTCONFIG.POL/CONFIG.POL`-type system policies on *either* NT 4-based domains or AD domains. Why can you still use system policies on ADs when ADs have the more powerful *group* policies available to them? Because systems prior to Windows 2000 are completely deaf to group policies. Recall that I said that policies work because the client knows to download and execute them; Windows 9x, Me, and NT 4 systems don't know to go get group policies,

and so system policies make sense on AD domains that have these older systems connected to them. Again, Windows 2000 and later systems will *also* look for, download, and execute system policies—but *only* if there are no group policies present on the domain and, of course, NT 4–type domains will never contain any group policies.

So system policies are contained in a file, stored on the NETLOGON share of DCs in an NT 4 or AD domain, and work because many Microsoft OSes know to download and use them. How are group policies different?

- ◆ First, group policies can only exist on an Active Directory domain—you can't put them on an NT 4 domain.
- ◆ Second, group policies do a lot more than system policies do. For example, you can use group policies to deploy software to a desktop automatically.
- ◆ Third, group policies clean up after themselves when removed, unlike system policies.
- ◆ Fourth, group policies get applied more often than do system policies. System policies only get applied when you log on. Group policies get applied when you turn the computer on, when you log on, and automatically at random times throughout the day.
- ◆ Fifth, you have a lot finer control over who gets—or *doesn't* get—a policy.
- ◆ Sixth, group policies are neat, but they only apply to Windows 2000, XP, and Server 2003 systems.

That's the overview; here are few more details.

### **Group Policies Apply to Sites, Domains, and OUs—Not Groups (Mostly)**

System policies applied to domains only. But as you've seen, AD has the notions of sites and OUs. Group policies are OU-aware and site-aware; you can create a GPO—group policy object, recall, a record on the AD that contains one or more group policy instructions—and apply it to domains, OUs, or sites.

But what about groups? Why did I mention OUs rather than groups? Because oddly enough, “group” policy objects don't apply to groups—only sites, domains, or OUs. You can't directly say, “Everyone in the ACCOUNTANTS group gets QuickBooks Pro 2002 deployed to their desktop.” Now, if ACCOUNTANTS were an OU rather than a group, then you *could* deploy QuickBooks Pro 2005 to all of the accountants. (As I write this, there isn't a QuickBooks Pro 2005, but I'm guessing that there will be.)

Is it *completely* impossible to apply a policy to a group, then? Well, not exactly.

### **Policy Filtering and Group Policies**

What I said in the preceding section wasn't completely true—you *can* deploy an application to a group. But how you do it is a bit sneaky.

As you've read, AD lets you apply group policies to sites, domains, and/or organizational units. Microsoft even has an acronym for those three—SDOU. But you can use someone's group membership to influence whether or not he gets the effect of a particular policy.

I've already said that GPOs are not files, but they share one thing with files: they have permissions associated with them. And you can apply permissions to groups. One of the permissions

associated with GPOs is Apply Group Policy; if this permission isn't granted, then the policy doesn't apply.

To apply a policy to just the ACCOUNTANTS group, then, you'd apply a policy to the entire domain, but then you'd set permissions for the Domain Users group so that Apply Group Policy was not allowed, and then you'd add a separate permission for just the Accountants group, allowing them to apply the group policy.

Policy filtering is a bit troublesome for two reasons. First, it can greatly complicate trying to figure out what someone else did when setting up policies: If you were to walk into an already-configured enterprise without any documentation and try to figure out what policies are supposed to do for that enterprise, you'd have your work cut out for you. As a matter of fact, there's an acronym relevant to that: RSOP, which stands for Resultant Set of Policy. To see what it means, consider the following question. I've got a new user, Bob, in a given organizational unit, which is in a particular domain, and Bob's machine is in a particular site. That means that the site may have policies that apply to Bob, the domain may have policies that apply to Bob, and the OU may have policies that apply to Bob. And don't forget that OUs can live inside OUs, so there might be an entire hierarchy of OUs that Bob lives in—each of *those* OUs could have policies attached to them. And on top of it all, policy filtering may affect whether or not all of those policies apply to Bob. The question is, which policies apply to Bob? It's not an easy question—you have to thread through which policies apply, the order in which they apply—a later policy generally overrides an earlier policy, although it can be configured differently—and then policy filtering must be taken into account. Determining the set of policies that actually affect Bob—his RSOP—is a difficult computational task, and you'll see a class of applications called *RSOP modelers* whose job is to do that very thing.

The second concern about policy filtering is that it slows down the process of applying GPOs to a user when logging in, which slows down the login process.

## Group Policies Undo Themselves When Removed

One of the troublesome things about NT 4's system policies is that once a system policy is applied to a user account or a machine, the policy remains in place even if it is removed from the domain controllers. So, for example, if for some reason you create a system policy to set everyone's background color to green, then the Registry of every computer that logs in from that point on will be changed to set the background to green. If enough users scream about this and you remove the policy, their screens will remain green. They could certainly *change* the color themselves, but it'd be nice if the policy had undone itself on the way out. With Windows 2000, XP, or Server 2003 clients, that happens: Remove a policy and its effects are reversed. This can be quite powerful: For example, if you used a group policy to deploy an application and then remove the policy, the application uninstalls itself!

## You Needn't Log In to Get a Group Policy

NT 4 only applied system policies at startup (for machine policies) and logon (for user policies). In contrast, Windows 2000, XP, and Server 2003 systems apply group policies every 90 minutes or so for workstations and member servers and every five minutes for domain controllers.

## What You Can Do with Group Policies

You can do basically anything with group policies that you could do with system policies, and lots more. Here are a few examples:

**Deploy software** You can gather all of the files necessary to install a piece of software into a *package*, put that package on a server somewhere, and then use group policies to point a user's desktop at that package. The user sees that the application is available, and again, you accomplish all that from a central location rather than having to visit every desktop. The first time the user tries to start the application, it installs without any intervention from the user.

**Set user rights** You may know from NT 3.x and 4.x that NT had the notion of "rights," the ability to do a particular function. One such example is the one I've already used about a standard user not being able to change his workstation's time and date. Under NT 4, you had to visit a machine to modify user rights; now it's controllable via a GPO, meaning again that you needn't wear out any shoe leather to change a distant machine's rights.

**Restrict the applications that users can run** You can control a user's desktop to the point where that user could only run a few applications—perhaps Outlook, Word, and Internet Explorer, for example.

**Control system settings** The easiest way to control disk space quotas is with group policies. Many Windows 2000 systems are most easily controlled with policies; with some systems, policies are the *only* method to enable and control those systems.

**Set logon, logoff, startup, and shutdown scripts** Where NT 4 only supported logon scripts, Windows 2000 allows any or all of these four events to trigger a script, and you use GPOs to control which scripts run.

**Simplify and restrict programs** You can use GPOs to remove many of the features from Internet Explorer, Windows Explorer, and other programs using GPOs.

**General desktop restriction** You can remove most or all of the items on a user's Start button, keep her from adding printers, or disallow her from logging out or modifying her desktop configuration at all. With all of the policies turned on, you can really lock down a user's desktop. (Too much locking down may lead to unlocking the automatic rifles, however, so be careful.)

There's lots more to work with in policies, but that was a basic introduction to get you started. (You can read more in the next chapter, and you'll see references to group policies throughout the rest of the book.) Let's return now to the larger issues of AD—namely, how best to get it on your system.

## Watching the Network: Auditing with the Active Directory

You *know* they're out there, don't you?

You know—the bad guys. The ones who are trying to Take Down Your Network.

Okay, that's a big exaggeration. There really aren't all that many people attacking networks, and, truthfully, most networks face more threats from *inside* people than outsiders. So my pathetic scare tactic in the first three sentences wasn't all that effective. Hmmm, let's see if I *can* find a scenario sufficiently frightening to the average administrator to get your attention. Ah, got it! How about this

one: Something goes wrong, or it seems that something went wrong, and so the boss asks: “What kind of network activity have we had recently? Are there any clues to who’s logged on recently, or tried to?”

And you have look at her and say, “Ummm, I really don’t know.”

Now, *that’s* scary. So let’s see how to answer that question with verve and aplomb, or at least some of how to answer that question with verve and aplomb—through audits.

## What You Can Audit

AD will optionally track a number of activities and save what it finds about those activities in event log entries, in the Security log. (And let me warn you, some of those entries are somewhat less than totally useful—but this is still worth doing.) Windows 2000 and every subsequent version of NT support several kinds of audits:

- ◆ Audit account logon events
- ◆ Audit logon events
- ◆ Audit account management
- ◆ Audit directory service access
- ◆ Audit policy change
- ◆ Audit system events
- ◆ Audit process tracking
- ◆ Audit object access
- ◆ Audit privilege

### LOGON EVENTS

Audit logon events and audit account logon events are two slightly different items that are both quite valuable in tracking who did what where to whom. As you know, domain-based networks rely on a small number of computers to validate—log on—users. So a user Ray might try to access a member server \\SV1, and \\SV1 might try to authenticate that user at a domain controller \\DC2. Here’s what these two settings would track:

- ◆ Audit account logon events would tell \\DC2 to log the fact that it was asked to validate Ray and did. That would appear in \\DC2’s log.
- ◆ Audit logon events would tell \\SV1 to log the fact that it needed to check to see that Ray was a recognized user prior to letting him access something on that machine. The log entry would appear on \\SV1’s log.

Did you notice the point about where the entries live? That’s important: *There is no central domain repository of logs.* Part of your job as an administrator is to collect and manage the logs of all of your systems. Fortunately, the only logs you typically need are the ones for the domain controllers and members servers...although workstation logs can be sometimes useful as well.

### OBJECT ACCESS

Audit object access is possibly the most important, or at least shares the most important spot, in my opinion, with the logon events audits. Why? Because you can ask your systems to keep track of who reads, writes, deletes, or creates any file or any group of files on themselves. Wondering if the user

deleted his e-mail PST file or it disappeared all by itself? With object access auditing, you're able to look at the user's workstation's logs and tell exactly when the file met its maker.

Tracking files and directories on a given machine—or tracking any other object, for that matter, as printers count as objects as well—requires *two* steps: First, enable object access auditing on the computer that stores the object and, second, tell the computer to audit that particular object. You see, by default simply turning object access on at a particular computer won't result in a single entry in the Security event log. You've got to then say, "Watch this directory" or, "Watch this file" or even, "Watch this file, but only when Joe is working with it." You'll see more about how to do that in Chapter 11.

### **ACCOUNT MANAGEMENT**

As its name implies, this is also a good item to audit. Any changes to user or group accounts get logged here. Create a user, create a group, modify a group's membership, change a password, and you're logged.

### **POLICY CHANGE**

Think of this as an audit of the auditors: Turn off logging to do something sneaky, and you will have left behind an entry that tells when you turned logging off. It also logs changes in user rights—why exactly did that administrator let that user log on locally to the domain controller between 9:50 and 10:10, anyway—and changes in trust policies.

### **PRIVILEGE USE**

This is a potentially useful tool but, boy, does it generate output. Every single time that you exercise a right—not a permission—then it's logged here. You'd be surprised how often you exercise rights—logging on, shutting down a system, changing the system time, taking ownership, and so on—so be prepared for larger logs if you turn this on. It'd be great if you could just turn on one or two particular privileges, but I've not found a way to do that.

### **SYSTEM EVENTS**

System events doesn't generate all that many entries and is probably worth running. It logs whenever you restart the computer or shut down the computer and also logs whenever you do something that "affects the system security or Security log," in the documentation's words. My experience is that it tracks the Security log—when you cleared it, resized it, and so on.

### **DIRECTORY SERVICE ACCESS**

This is a kind of catch-all that logs any activity that trips a permission on the Active Directory. Think of the Active Directory as a container and users, machines, policies, organization units, and the like as just objects in that container, such as files in a directory. Just as NTFS permissions on a directory tell you when someone's been creating or deleting files, this setting tells you who's been doing things that modify the AD. I have not found much use for this. It *seems* as if anything that causes an Account Management logging entry also causes a Directory Service Access entry.

### **PROCESS TRACKING**

It's a programmer thing...we admins wouldn't understand. This tracks activity between a program and the operating system—creating handles, starting execution, calling other programs, and the like. You probably won't find this useful...

...Or *would* you? I've used this now and then to find out why something didn't work. A well locked-down system is a good thing, but it can be frustrating sometimes. When I first tried to learn Indexing Services, I played with Indexing Services on my Web server for a week but got nothing to work. Nada, niente, zip. Very frustrating. Then I set up an out-of-the-box system and tried Indexing Services...and it worked. The problem? My Web server was—doh!—locked down, like all good Web servers. Unfortunately, I'd locked it down so tightly that I locked Indexing Services out of being able to access anything. So it was working, all right; it was just coming up snake eyes whenever I asked it a question.

At times like this, I'd love a "Security Monitor"—a little window on my desktop that says, "Yup, you just tried to run XYZ program and you used all the right commands, but nothing happened, because you lack the permissions to do what XYZ was trying to do. You need to be a Domain Admin to do *that* kind of thing, dodo." The next best thing can be process tracking—just flip it on and try to do whatever's not working. (Do not leave it running unnecessarily; it will fill up your Security log in no time flat.) When the app fails, go back and shut off process tracking, then look in the log to see what right you needed but didn't have. I don't want to oversell this—you run a *lot* of processes, and the output's not necessarily crystal-clear—but you can often get just the clue you need to make something work.

## How to Audit

You audit network activity by enabling one or more kinds of auditing on the computer in question. Let me stress that: If you've got 1000 machines in your network, then you may need all 1000 machines to have auditing turned on, depending on what you want to audit. For example, tracking file and directory changes requires having object auditing enabled, so if you wanted to track files on every workstation, then you'd need auditing enabled on every workstation. Which, in the worst-case scenario, would mean visiting every one of those machines. But that's only the worst case; if you have a domain, then it's easier.

You turn auditing on for a particular machine via a policy, either a local policy or a domain-based group policy. I'll discuss local versus domain policies in the next chapter, but here's the short version of the differences: You've already read about the kinds of things that you can do with domain-based group policies, and you can probably see that domain-based group policies are pretty powerful. Ideally in a network with an Active Directory domain then, you'd use the power of domain-based group policies to centralize the process of enabling auditing, and I'll show you how in a minute.

You don't always *have* an Active Directory domain, however, and in case you've not yet built yours but want to start auditing immediately, then here's how to enable auditing: with a tool called the Local Security Policy snap-in. Start it up by clicking Start/Administrative Tools, then Local Security Policy. (You may recognize it from our work with IPSec in Chapter 6.) You'll see an icon in the left pane called Security Settings and, underneath it, folders labeled Account Policies, Local Policies, Public Key Policies, and IP Security Policies. Open up the Local Policies folder, and you'll see three folders inside: Audit Policy, User Rights Assignment, and Security Options. (Aren't they *all* security options? And aren't the Account Policies referred to in the top-level folder by that name referring to the *local* system? The names for this tool perplex me.) Open up Audit Policy and you'll see something like Figure 8.69 in the right window.

**FIGURE 8.69**  
Auditing Options

But you probably don't want to have to go visit every single computer to turn this stuff on. That's where a group policy can make life easier. To enable auditing using domain-based group policies, then create a group policy object and look in the Computer Configure/Windows Settings/Local Policies/Audit Policy. Apply that object to the particular machines for which you want to enable auditing. So, for example, if it's something generic that you want to apply to every machine, then create the group policy object on the domain. But if it only applies to the domain controllers, then apply the policy to their OU. Or, if there's a different group, then use policy filtering—it's covered in the next chapter. (And to see what you actually *see* when you look at a log in the Event Viewer, look to Chapter 18.)

### MANAGING LOGS

What, then, should you audit? I can't tell you what's right for you—there's no good answer because you must trade off log management versus coverage level. Look at it this way: If you turn on all logging on every single machine, then in theory you'd have a wealth of knowledge...but you'd need terabytes of storage space to store it all, and in practical terms you'd never get a chance to review it.

At minimum, I'd log logon failures. Logging all logons is potentially interesting, but so many successful logons occur in a day that you end up filling the log with the information. Policy change and system events aren't too numerous—they won't cost much in terms of numbers of events. Privilege use can be valuable but creates more log clutter.

You should also consider how to manage log size with the log settings. Open up any event log in Manage Computer, right-click the log's icon, and choose Properties, and you'll see a dialog box like the one in Figure 8.70.

Notice how the system manages the amount of space that a log takes: You set an amount of disk space for the system to set aside for that log file. The log can't exceed that space. This is actually a security measure; otherwise, an attacker could bring your system down by doing things that the system would log, such as a failed logon attempt. Merely by deliberately trying and failing to log on, the attacker could make the log grow if it weren't set to a maximum size to actually fill your hard disk—crashing your system.

**FIGURE 8.70**  
Configuring the  
Security log

So fixed log sizes protecting you from fill-the-hard-disk attacks are the *good* news; the bad news is that a fixed-size log can be filled up. So you're faced with some more tough choices: What to do to keep that from happening? The system will, at your request, do one of three things when the log fills:

**Just overwrite the oldest events.** Not a terrible low-maintenance answer, particularly if you provide enough space for the logs. (I recommend that you set the size of each log to 10MB—it's fairly hard to fill up that much space for logging.) But it leaves you open to an attacker doing something bad and then deliberately causing some series of innocuous events to happen over and over again so as to fill up the log with those innocuous events. So let's say that I'm a bad-guy administrator who's just created an administrative account that I will then use for fell purposes. I don't want you to know that I created the account, so I write a little batch file that does something like open a file over and over and over again... "Oops, I guess there was a bug in my batch file," I'll just say. As I know that you're auditing object access to the opened file, then every time that the batch file opens the file, an event gets added to the log. If I let the batch file run long enough, then soon there will be nothing in the log but reports that a batch file opened a file over and over again.

**Overwrite events after  $x$  days.** The default behavior; the system erases events after seven days. For complete coverage, you'd have to back up the logs, although with hope you'd know about intrusions within seven days. Old logs are mainly useful for assessment of how long the bad guy's been around.

**Clear logs manually.** This never erases anything. It's the most secure approach, but again requires you to "touch" every system periodically to back up, archive, and clear the logs. There's also the issue of, "What happens if the log fills?"

By the way, what happens if the log *does* fill up, as in the case that you've told it to keep all events for  $x$  days or you've told it to never delete events? That's up to you. In that case the system would by default just stop logging new events but keep running. There is a policy that you can set with group policies, however, that causes the server to stop altogether. I don't generally recommend this setting, as it could be clearly used to crash a server—fill the log and the system freezes. And, again, I'd set the logs to 10MB in size. You have to work *really* hard to fill up 10MB in an evening, so it'd be tough for an attacker to use a full log to cover his tracks.

That leads me to another point: What we've talked about so far is not, by far, the hardest part of auditing. The hardest part is managing the darn logs. Ten thousand machines means 10,000 logs. They get larger every day, they fill up, and they've got to be regularly stored somewhere and cleared to make space for more logs. I have not come across an automated way to do that, so we're talking about creating a nontrivial amount of administrative work. Given the size of modern hard disks you certainly could let the event log grow to gigabytes in size, so you wouldn't have to back it up and clear it very often, but then what happens when the bad guy clears the log? All you've got—as you've not backed it up often—is a record of the seemingly suspicious activity that someone cleared the log. Sure, you can look 'em in the eye and ask why they did it, but they can always say it was a mistake.

Logs are only useful if they're respected. Harsh as it sounds, to make them useful you must protect them. There should be a specific procedure for clearing logs, perhaps something that requires two administrators' sign-off. Anyone clearing a log otherwise should face disciplinary review and if security is important enough then you might make clearing a log without authorization an “instant termination” offense. Sound harsh? I don't know—what would you do to a bookkeeper who'd deliberately thrown out a few week's receipt and disbursement records?

## Managing Logs: EventComb

Let me leave the issue of auditing and logs with a splash of cold water:

**It may well make good sense for you not to bother with auditing and managing event logs.**

In the perfect world, you turn logging on for every server and workstation. You also collect the logs on all of those machines to some central place regularly—certainly every day or two—and archive them. You additionally peruse those logs before archiving them, looking for traces of wrongdoing or just incipient system failures.

You've got time for that, right?

Unfortunately, most admins don't. There are third-party tools—NetIQ's got one called Operations Manager that it sold to Microsoft, who's now renamed it Microsoft Operations Manager—but they are expensive, costing you per-user (all users, not just administrators) fees that mount quickly. So here's my final advice on logs: Do the math. Figure out how much in terms of personnel time, equipment, media, and the like that a decent auditing process will cost. And try to assess your downside—what *would* it cost you not to be able to answer the kinds of questions that logs can answer? Present these numbers to the boss and if she still wants you to audit, then tell her how many more people and servers you're going to need.

I live about three quarters of a mile from the Atlantic Ocean in a hurricane-prone area. In the perfect world, I'd have a cool 100-foot-high seawall buried in the ground with a set of huge motors that would spring that seawall up into a deployed position at a few minutes' notice. Gargantuan pumps would stand ready to pump floodwaters away from my house. Massive generators would, at my command, spring to life and power the whole process while driving motors that shutter my house's

windows. But in the real world that stuff costs money, and so I've just got insurance, some good water-proof containers for my important documents, and I back up my servers daily. I had to accept a practical level of disaster preparedness...and so does your firm. But *make* the boss examine this trade-off, and do it now—she won't want to hear about this on the morning that you discover that you've been hacked, while you're trying to explain why the logs have been cleared. In practice, you'll come up with some compromise between fully backed up and monitored logs and no logging at all—but get everyone's agreement on it.

Having said all that, you really need a way to look at your logs that doesn't break the bank, and thankfully Microsoft's got a free tool to do that called EventComb.

EventComb is part of a Microsoft document called "Security Operations Guide for Windows 2000 Server." You can download it at [www.microsoft.com/downloads/release.asp?releaseid=36834](http://www.microsoft.com/downloads/release.asp?releaseid=36834). (And if it's not there when you read this, please don't e-mail me asking where it is. Microsoft likes to rearrange their Web site hourly and I'll just tell you to do the same thing that I'd do—just search the Microsoft Web site for "eventcomb.") That link downloads a program called `secops.exe` which, when run, uncompresses to create a folder called SecurityOps that then contains a folder named EventComb, which contains a compiled HTML help file and the program itself. Start EventComb by just executing `eventcomb.exe`.

When it starts, you'll see why EventComb is free; the user interface, well, kind of leaves something to be desired, as you see in Figure 8.71.

**FIGURE 8.71**

Typical EventComb opening screen

But don't let that scare you away; this comes with a pretty good Help file and once you get over the "interface overload," it starts to make sense. Here's a walk-through of a simple event log search. You'll look for an event on your computer that you almost certainly have—540. That indicates successful logons or logoffs. Again, you'll just be looking on the computer that you

happen to be sitting at, but you can tell EventComb to simultaneously search the logs of as many computers as you like.

1. In Select to Search/Right-Click to Add, right-click inside the empty area.
2. In the options that appear, click Add Server.
3. In the resulting server name, fill in **localhost** and then click Add Server and Close.
4. In Event IDs, fill in **540**.
5. Under Choose Log Files to Search, check Security.
6. Under Event Types, check Success Audit and Failure Audit.
7. Back under Select to Search/Right-Click to Add, you'll see that localhost is in the list but is not highlighted—click it once to highlight it.
8. Click the Search button.
9. When finished, EventComb will open a window showing C:\TEMP—inside it will be a file named **localhost-Security\_LOG.txt**. Open it.

Inside you'll see the events that met your search criteria.

As you can see from a look at EventComb, you can create and prestore searches as well as construct far more complex searches than the one you created here. Again, let me stress—this is not the greatest tool in the world, but the price is right.

## Migration Strategies

I've been talking as if you were creating a brand-new network where there was none before, but that's not likely these days. Instead, it's more likely that you've already got an NT 4 domain or a Windows 2000–based Active Directory domain and you want to move to a Server 2003–based Active Directory domain. Or you might have two ADs that you want to make into just one AD. Either way, that kind of work falls under the topic heading of “migration.”

Before I start talking about migration, however, let me offer a bit of advice that quite frankly you would be crazy not to take. If you're migrating, then that means that you probably already have a domain that currently works. You intend to convert this domain to a Server 2003–based AD domain that works. The scary part is in getting from the “before” to the “after.” You'll really make people unhappy if you mess up partway, as an NT 4 domain is better than no domain at all...and messing up partway leaves you with no domain at all. So here's the advice: don't even think about starting your migration until you've tried the process out on a test network. No book, video, magazine article, or instructor can give you the level of understanding that a little hands-on can. So *please* set up a few systems and try this out before doing surgery on your company's network!

There are two basic philosophies about migrating to an AD domain: “in-place” upgrades versus “clean and pristine” migration.

### In-Place Upgrade

In the in-place upgrade approach, you let Server 2003's Setup program convert your domain's from its current SAM file (if it's NT 4) or Active Directory (if it's Windows 2000) to a Server 2003–based Active Directory.

### GETTING READY FOR THE UPGRADE

Before you do this, make absolutely sure you've got your DNS infrastructure in place—do all of those `nslookup` checks that I covered earlier in this chapter. And just to be certain that you've got something of a fallback position, go to one of your NT 4 backup domain controllers or Windows 2000 AD domain controllers and synchronize it, and then take it offline. Then, if worst comes to worst, you can always just shut down the new AD domain controller, turn the BDC back on, promote it to PDC, and then walk around to the other BDCs and force them to synchronize with the newly anointed PDC. If you've gone from 2000-based AD to 2003-based AD then you can do something similar: shut down the new 2003-based DC, start up an old 2000-based DC and, if necessary, seize any FSMO roles to that system. (But let's hope it doesn't come to that.)

### HOW TO DO AN IN-PLACE UPGRADE FROM NT

You must do this at the primary domain controller; if you try to upgrade a backup domain controller then Server 2003's Setup program will simply stop and refuse to go any further.

But before you do it, you need to make a change to your PDC's Registry (and the Registry of any NT 4 domain controller that you intend to upgrade in place to Server 2003). Navigate to `HKEY_Local_Machine\System\CurrentControlSet\Services\Netlogon\Parameters` and add a new value entry called `NT4Emulator` of type `REG_DWORD`. Set its value to 1. (I'll talk about what it does later.)

**TIP** *I've gotten a fair amount of mail asking me something like, "I want to do an in-place upgrade, but I want my new Pentium 4 system to be the PDC. How do I do this?" Simple. First, install NT 4 on the Pentium 4, and tell it that you want the new computer to be a backup domain controller on the existing NT domain. Then, once it's installed, use the NT 4 Server Manager to promote that new BDC to the PDC. Then put the Windows Server 2003 Server CD into the new PDC's CD-ROM drive and do an in-place upgrade.*

When you do an in-place upgrade on an NT 4 domain controller, then the normal Server 2003 Setup runs as usual. But the first time that you boot the machine after Setup, it immediately starts up `DCPROMO` and goes directly to the screen asking whether you want to create a new tree or a child domain in an existing tree. `DCPROMO` runs as you've seen it run before, with one important difference: You don't get to choose the NetBIOS name for the domain. The new AD domain will have the old NetBIOS name of the old NT 4 domain, whether you like it or not. You can, however, give the new AD domain any AD name that you like. So, for example, if you're upgrading the PDC on an NT 4 domain named `AUTOSERVICE`, then your new AD domain—which you can make part of an existing tree or forest, or create your own new forest—could be named `bigfirm.biz`. But its NetBIOS name would continue to be `AUTOSERVICE`, so that the old NT and Windows systems would still be able to find it, as they know it by the `AUTOSERVICE` name.

**NOTE** *Let me stress that, as I get a lot of letters on it—the "downlevel" NetBIOS name needn't be connected at all to the Active Directory domain name. If your domain was called ABC under NT 4 and you upgrade it, then its NetBIOS name is still ABC. You can give it any AD domain name that you like—mycoolnewdomain.org, for example. Then the DC responds to old-style NT 4 (or any NetBIOS) request to the domain ABC, and any AD requests for mycoolnewdomain.org.*

You'll also see one other new thing when upgrading an NT 4 domain, as you see in Figure 8.72.

**FIGURE 8.72**  
2003 interim  
functional level?

I haven't found a lot of use for this, but you can choose to move your new AD domain (and forest) to Windows Server 2003 Interim Functional Level. You should only choose it if there won't be any 2000-based DCs. Then finish running DCPROMO as always.

### **Old DCs Still Work**

At this point, you've now got an Active Directory with only one of your DCs actually running Server 2003, and the others are still running NT 4. As I've said before, this is why there's a Mixed mode or, as 2003 calls it, Windows 2000 mixed functional level—the lone AD DC knows that it *could* do a lot of cool things, but that then its domain data would be incomprehensible to the NT 4 BDCs. So it denies itself a few features—multimaster replication and universal groups are the most important ones—and continues to work fine with the NT 4 BDCs.

As soon as you can, you'll want to get those BDCs upgraded. Once the last one's done, then you can move up to either Windows 2000 native functional level or all the way to Windows Server 2003 functional level, and then you'll finally get all of the features for which you paid. That's worth stressing.

And remember—it's only the state of your DCs that determines what domain functional level you can shift to:

- ◆ All of a domain's DCs must be running Windows 2000 or Server 2003 for the domain to shift to Windows 2000 native functional level.
- ◆ All of a domain's DCs must be running Server 2003 for the domain to shift to Windows Server 2003 functional level.

It does not matter at *all* about the other systems—they could all be NT 4 workstations and member servers and you could still be at 2003 functional level, so long as all of the DCs run 2003.

### **Avoiding Trouble with the Windows 2000 Machines**

There is one quirk about in-place upgrades that you should be aware of.

Suppose, as is the case for many people, that you've introduced a bunch of Windows 2000 member servers and workstations into your NT 4 domain, and then you upgrade a single DC to AD. You'll see a curious effect. Once you have a single AD domain controller in a Mixed mode environment, all of the 2000 Professional machines will only go to *that* machine to log in. (I do not know of a similar problem for XP Pro, but I've never heard otherwise, either.) When those 2000 Pro machines saw only NT 4 domain controllers, then they'd log in to any one of them. But if there is at least one 2000- or 2003-based DC in the domain, then the 2000 Pro boxes will only log in with that one (and any other AD DCs in the domain).

So if you have an NT 4 domain with a lot of 2000 Professional systems in it, then you'll probably want to upgrade those BDCs quickly. Or you can make the Registry change that I suggested at the beginning of the section. That keeps the 2000 boxes from becoming fixated on one DC. But you *must* make that Registry change before upgrading. If you make the Registry fix *after* you upgrade, then any 2000 boxes who have logged onto the domain since the upgrade will remain fixed on that one DC. The only fix is to run around to all of those 2000 boxes and unjoin them from the domain, then rejoin them. Not pleasant.

### HOW TO DO AN IN-PLACE UPGRADE FROM 2000-BASED ADS

As you'd guess, an in-place upgrade from a Windows 2000-based AD to a Server 2003-based AD isn't as drastic as is an upgrade from an NT 4 domain. But it does require a few things: you must expand your forest's schema to make room for 2003's new AD items, and you've got to rearrange your existing domain's AD database likewise. You do this with a tool on the Server 2003 CD called `adprep.exe`. It's in I386.

#### ***Prep the Forest/Schema and Domain***

Even if you're only going to upgrade one domain in your 2000-based forest to Server 2003, you've got to change your domain's schema before 2003 can install its AD machinery. But, as you know, there isn't any such thing as a *domain* schema—all domains in a forest share the same schema. So you've got to change your entire forest's schema. You'll do that on the forest's schema operations master/FSMO. Pop the Server 2003 Setup CD into the computer's CD drive, open a command prompt and navigate to the I386 directory on whatever drive holds the CD. So, for example, if your CD drive were drive D:, you'd open a command prompt, type **D:** and press Enter, and then type **cd \I386** and then press Enter.

Now run `adprep` by typing **adprep /forestprep** and press Enter. You'll see something like this:

```
D:\I386>adprep /forestprep
```

ADPREP WARNING:

Before running `adprep`, all Windows 2000 domain controllers in the forest should be upgraded to Windows 2000 Service Pack 1 (SP1) with QFE 265089, or to Windows 2000 SP2 (or later).

QFE 265089 (included in Windows 2000 SP2 and later) is required to prevent potential domain controller corruption.

For more information about preparing your forest and domain see KB article Q331161 at <http://support.microsoft.com>.

[User Action]

If ALL your existing Windows 2000 domain controllers meet this requirement, type C and then press ENTER to continue. Otherwise, type any other key and press ENTER to quit.

Now, `adprep` is not screwing around here—make sure your DC is up to SP2 or SP3 before going further. If you're at that level, then just type `c` and press Enter to see the `adprep` in action:

```
Opened Connection to W2KSV
SSPI Bind succeeded
Current Schema Version is 13
Upgrading schema to version 30
Connecting to "W2KSV"
Logging in as current user using SSPI
Importing directory from file "C:\WINNT\System32\sch14.ldf"
Loading entries.....
111 entries modified successfully...
```

This goes on for a while, as AD imports and installs a bunch of schema changes. Finally, it says

```
Adprep successfully updated the forest-wide information.
D:\I386>
```

Now you're ready to prep your domain—yes, that's right, you've got to run `adprep` at least twice to upgrade a 2000-based AD domain. Go to the infrastructure operations master/FSMO, insert the CD and get ready as before to run `adprep`. Type `adprep /domainprep` and it'll look like

```
D:\I386>adprep /domainprep

Adprep successfully updated the domain-wide information.
D:\I386>
```

Much less chatty, and quicker, too. Reviewing, then, before you can upgrade a Windows 2000–based AD domain to a Server 2003-based AD domain, you must

1. Upgrade the forest by running `adprep /forestprep` on the schema FSMO computer for your forest, even if that machine is not in the domain that you're going to upgrade.
2. Upgrade the domain structure by running `adprep /domainprep` on the infrastructure FSMO for the domain that you are going to upgrade.

### **Run Setup**

Now you're ready to run Setup. Just do an in-place Setup as described in Chapter 5—put the CD in, double-click it in My Computer if it doesn't auto-start and select the Upgrade option. It will ask you for a product key, and then warn you about anything that will change in this upgrade. It will also check that you've forestprepped and domainprepped properly. (A nice touch—Microsoft makes you type in that irritating product key, only to immediately say, “Oh, golly, Setup can't run, you haven't prepped right.” Grumble grumble grumble...) From there, Setup runs hands-off and there's nothing to do until it's done and you log onto your newly upgraded Server 2003 DC for the first time. If you're

domain was previously in Mixed mode, it'll now be in Windows 2000 mixed domain functional level, and if it was in Native mode before, it'll be in Windows 2000 native domain functional level. If this is the first domain in the forest that you've upgraded, then DCPROMO will set the forest's functional level to Windows 2000 forest functional level. At this point, you're upgraded!

#### IN-PLACE UPGRADES: PRO

To summarize, then, the things in favor of in-place upgrades are the following:

- ◆ They don't require new machines.
- ◆ Your users keep their old SIDs and the domain keeps its old trust relationships, so any servers in other domains—resource domains containing perhaps file and print servers or e-mail servers, for example—will still recognize those users without trouble.
- ◆ The users keep their old passwords.
- ◆ It's simple, just a quick upgrade.
- ◆ If you're going from 2000-based ADs to 2003-based ADs then the upgrade seems pretty trouble-free.

#### IN-PLACE UPGRADES: CON

Although in-place upgrades have a lot going for them, I recommend that many people *not* do them; here's why:

- ◆ You cannot make your former NT 4 PDC into a domain controller on an existing AD domain; upgrading a PDC will always result in the creation of a new AD domain.
- ◆ You cannot set the new domain's NetBIOS name, as it's automatically set equal to the old NT 4 domain's name.
- ◆ You cannot merge your old NT 4 domain into an existing AD domain.
- ◆ You upgrade *all* of the accounts, and it's a one-way trip—there's no AD Rollback Wizard. (Although you can, as I've suggested, keep an old DC “on ice” as an emergency measure.) I prefer more gradual approaches.
- ◆ Any leftover junk in your old NT 4 domain SAM remains in your new Active Directory database.

### Clean and Pristine Migration

The other approach is called *clean and pristine* (C&P). In this approach, you leave your existing domains (NT 4, 2000-based AD, or even 2003-based AD domains) alone and create a new, empty AD domain. Then you use a program called a *migration tool* to copy user and machine accounts from the old domain (or domains) into the new AD domain.

#### C&P IS GRADUAL

In many cases, I prefer the C&P approach. For one thing, it's gradual. With an in-place upgrade, you walk your domain through a one-way door. If you find later that Server 2003-based ADs just aren't the thing for you, then too bad; you're stuck. But if you have a new domain and you copy some subset of your users over to that domain, then you just tell those users to log in to this new domain. If they start using the new domain and you find after a week or two that the AD's just not the tool for you, then you can always just tell the users to go back to their old domain accounts.

Another thing that troubles me about an in-place upgrade is born of a bit of caution. Most operating system Setup programs offer two modes: a clean wipe-and-build-from-scratch mode, and an upgrade-without-disturbing-existing-settings-and-programs mode. Clearly the upgrade option sounds like less work, but stop and think about it—which mode is more likely to be buggy? My guess is that the upgrade would be much harder to write than the wipe-and-install, and more complex means greater chances for error.

On the other hand, that could just be paranoia growing out of spending 30 years in the computer business. I've never seen a 2000 upgrade “blow up” an NT 4 domain, and all of the 2000-to-2003 upgrades I've seen haven't showed any troubles. No, the main thing that I really like about a clean and pristine upgrade is that it lets me migrate small groups of users rather than all of them at once.

### HANDLING PERMISSIONS WITH THE NEW DOMAIN

Suppose you decide to go that C&P route. It might look like this will cause you a bunch of extra work. Suppose your premigration environment includes a bunch of NT 4 domains that trust each other, perhaps the standard admin domain/resource domain model. A user named Joe in the NT 4 admin domain has permissions to access some server in another NT 4 domain, the resource domain. Can he still? After all, the permissions allow Joe-at-the-old-domain to access the server; Joe-at-the-new-domain is a completely different user account. How can you get that server to let Joe's *new* account access that server? There are two approaches: re-ACLing and SID histories.

#### **Re-ACL the Server**

One approach is the obvious (and somewhat laborious) way: Just walk over to all of those old servers and add Joe's new account to the permissions lists on those servers. This is called *re-ACLing* because the other name for a list of permissions on a network service is the access control list. It can be a real pain, but some migration tools will do that for you automatically.

#### **Use SID Histories**

You know that every user has a SID; that's been true since NT 3.1. But under Windows 2000 native and Windows Server 2003 domain functional levels, Active Directory lets users keep more than one SID. As migration tools create the new AD user accounts, those accounts of course get new SIDs. But the migration tools can tack the user's old SIDs onto the new user account as well, exploiting a feature called *SID history*.

**What SID Histories Do** Then, when a user tries to access some resource that he had access to under his old account, his workstation tries to log him in to that resource, using his new Active Directory account. As with all domain logons, AD builds a *token* for the user which contains both his user SID as well as the SIDs of any global and universal groups that he belongs to. Here's the trick to SID histories: AD says, “He's a member of a group with *this* SID”—and sends along his old SID from the old domain! Even though it's a user account's SID, the AD domain controller passes the SID along as if it were a global group SID, and apparently this is acceptable. The resource says, “Hmmm...do I know any of these guys? Well, there's this user SID...nope, I don't know that guy...but wait, look, he's a member of the ‘Joe from the old domain’ group. Dang, I always thought that Joe was a *user*, not a group. Well, in any case, I've got an ACL for that ‘group,’ so I guess he's in.” Thus, even though Joe is logged in as a person from the new group with a new SID, he's dragging the old SID around, and it gets him access to his old stuff.

**What You Need to Create SID Histories** Several notes about SID histories are important:

- ◆ You need a migration tool that knows how to create SID histories. Microsoft’s free Active Directory Migration Tool, which I’ll cover a bit later in this chapter, can do that.
- ◆ Migration tools create SID histories as they copy user accounts from older NT or AD-based domains to your new 2000 native/2003 functional level domain. Before a migration tool can work, you must create a trust relationship between the old and new domains. But no matter which migration tool you’ve got, your migration tool cannot create SID histories unless you have created that trust relationship with NETDOM or with ADMT’s Trust Wizard. I’ll cover how to do this in a few pages in the “Trust Relationships in More Detail” section.
- ◆ You can only create SID histories in a domain whose functional level is either Windows 2000 native or Windows 2003. So when you create that new clean-and-pristine AD domain, then make sure that it’s already shifted into Windows Server 2003 functional level—after all, you’re building a fresh new domain, you may as well get the most out of it—before creating the trust relationship and running the migration tool.

**Getting Rid of Old SID Histories** You can keep SID histories for quite a while—systems running Windows 2000 Service Pack 3 or Windows Server 2003 can store up to 120 old SIDs. But SID histories are really just temporary measures, as you really only need your old SIDs as long as your old domains are around. That probably won’t be for long. Once you’ve moved all of your servers and workstations out of the old domain, then the old SID is of no value. So it’d be convenient to be able to trim those old SID histories off of your user accounts. You can do that with a short VBScript that Microsoft describes in their Knowledge Base article 295758.

#### DISADVANTAGES OF CLEAN AND PRISTINE

Although I’ve said that C&P has the advantage of reversibility, thus helping you to manage your risk, it’s not without costs.

- ◆ First of all, you need more machines than you would if you were just upgrading. You’ll need machines to act as domain controllers in the new domain.
- ◆ Most migration tools cannot copy passwords. The users will then have to create new passwords the first time that they log in to the new AD domain. This isn’t terrible, but it’s annoying to some.
- ◆ You’ve got to buy a migration tool. There *is* ADMT, but it’s really intended for small-scale migrations of a thousand users at best. These tools aren’t cheap, costing somewhere in the neighborhood of \$10 per user. That’s *per user*, not per administrator, so those pictures of Alexander Hamilton start adding up.
- ◆ You cannot create an Active Directory domain with the same NetBIOS name as the old NT 4 domain, because that would require you being able to create two domains with the same NetBIOS name (since you don’t decommission the old NT 4 domains when you do a clean and pristine migration).
- ◆ It’s more work. You’ve got to worry about when to move any given set of users, you may have to re-ACL, and so on.

### CLEAN AND PRISTINE ADVANTAGES

To summarize its advantages:

- ◆ C&P lets you do gradual upgrades.
- ◆ C&P *copies* user accounts, it doesn't *move* them. The old accounts are still there if something goes wrong.
- ◆ C&P lets you create your DCs from clean installs, avoiding the extra complexity and potential bugs of an in-place upgrade.
- ◆ C&P lets you consolidate domains, collapsing a morass of many domains into just one, or just a few.

### Trust Relationships in More Detail

If you want to connect an old and a new domain to do a clean and pristine migration, or if you want domains in one forest to trust domains in another forest, or even if you want a workstation or a server to accept authentications from your domain—that is, if you want to join that workstation or server to the domain—then in every case you must create a trust relationship. As you've read before, to “trust” is to accept authentications from a domain's DCs. When a workstation joins a domain, that workstation is essentially saying to the DCs, “Before, I was only willing to accept authentications that *I* did, from the data in my local SAM. But now I'm willing to believe that if you tell me that such-and-such person is indeed who she says she is, then I'll accept that as reliable information”—again, the workstation now *trusts* the DCs. When a domain trusts another domain, then the first domain is saying that it once was only willing to accept authentications from its own DCs, but now it'll accept authentications from the second domain's DCs as well.

But how to build one of those trusts? In the case of domain-to-domain trusts (which is what people usually mean when they speak of trust relationships—most people don't understand that joining a domain means to establish a trust), I know of three ways: through the GUI, with a command-line tool named NETDOM, and with ADMT.

### TRUSTS HAVE DIRECTION

To understand trusts in depth, the first thing to grasp is that trusts have direction. That shows up particularly clearly in trusts with NT 4 domains, as NT 4 trusts are all one-way only. AD trusts are all two-way, and of course you can simulate a two-way trust with NT 4 by building two trusts—one in each direction. But let's take a moment to discuss trust directions.

Any trust between two domains has a trusting and a trusted domain. The trusting domain is willing to accept login information and authentications from the trusted domain. For example, suppose I have two domains—an NT 4 domain named FACTORY and an AD domain named bigfirm.biz. Suppose also that FACTORY is a domain that contains very few user accounts; instead, it contains the machine accounts for several hundred servers. People with user accounts in bigfirm.biz need to get access to data in FACTORY's servers.

This is an example of a fairly common NT 3.x and 4 domain model called a *master/resource model* or *administrative/resource model*. The idea was to build at least two domains, a “master” domain and then one or more “resource” domains. You'd put all of the company's user accounts into the master domain (bigfirm.biz, in this case) and then put the servers into a resource domain or, in most cases, you'd have several resource domains, and each server would have an account in the resource domain that made the most sense.

So in the master/resource scenario, you'd have servers in the resource domain and users in the master domain. The users would want to access data on the servers, so the servers needed to be able to recognize and accept login data not from their own (resource domain) domain controllers, but rather from the DCs in the user's (master) domain. So I need FACTORY's servers to accept logins from bigfirm.biz's domain controllers.

Or, in other words, I need the FACTORY domain to *trust* the bigfirm.biz domain.

If you've not messed around with trust relationships in the past, then go back and read that again so you're clear on it. The primary goal is to allow bigfirm.biz people access to FACTORY's data. But FACTORY's servers will not, of course, let any users get to that data unless they can authenticate those users. But FACTORY can't authenticate the users, only their home domain's DCs can. Therefore, FACTORY must begin accepting authentication from bigfirm.biz. That's the definition of "to trust" here: to accept authentications, to trust another domain's DCs when they provide authentication. So bigfirm.biz folks get to use FACTORY's data because bigfirm.biz is *trusted*, and FACTORY lets them because it is *trusting*.

This notion of one-way trusts is largely irrelevant in networks that have no NT 4 DCs, but not entirely. There are actually *many* one-way trusts in an Active Directory...*between the DCs and the domain member machines*. The workstations and member servers accept authentications from the DCs, but no DC would accept an authentication from a workstation—you'd be completely out of luck if you tried to log on to a domain using a local account.

#### **TRUSTS DO NOT REMOVE ALL SECURITY**

People sometimes fear creating trusts between two domains, thinking that if domain A and domain B trust one another then anyone with a user account in A can make mischief in B and vice versa. That's not true at all. Establishing trusts between two domains just means that a system in the A domain can recognize a user in B and B in A. To see why this isn't the end of the world, consider: can a user in domain A do anything that he wants on any system in domain A? Of course not—group policies, user rights, and permissions control all of those things.

I think people get that idea because they're used to working in networks running older versions of NT that have been configured with default permissions and rights. As earlier versions of NT's permissions were something like "everyone in the world is welcome here," hooking up domain A and domain B meant that yes, anyone from A could do anything to any machine in B (and the other way around as well). But modern networks are tighter for two reasons. First, the default permissions and rights that a user has in a network running XP Professional and Windows Server 2003–based domains are a lot more restrictive than the ones for a network running NT 4 workstations and domain controllers, and second, administrators are just plain more aware of security, and so more likely to take a close look at how they secure their servers. Once a server in domain A is well-protected from the users in domain A, then it'll be pretty much automatically protected from users in any other trusting domain.

#### **TRUSTS INVOLVE ADMINISTRATORS FROM BOTH SIDES**

The decision to let domain A accept authentications from domain B (to use a one-way trust example) isn't one that A can make unilaterally, nor is it one that B can foist onto A. Creating a trust relationship is sort of like creating a treaty between countries—you need signatures from both sides to make it legal. Now, I realize that in many cases one person—probably you—will be the domain admin on both sides, but you will nevertheless have to establish credentials on both domains before you'll be able to create that domain.

#### FOUR KINDS OF TRUSTS

In a Windows Server 2003 world, there are four kinds of trusts: external, shortcut, forest, and realm. You will probably only work with the external and, on rare occasions, forest trusts, but let's take a quick look at what they are.

- ◆ **External** trusts are basically the kinds of trusts that I've been mostly talking about when I talk about domain-to-domain trusts. If you want a domain in a forest to trust a domain *outside* the forest or, in Microsoft terms, an *external* domain, then you build an *external* trust. You'll use these for migration. For example, if you're migrating from an NT 4 domain to a new empty Windows Server 2003–based AD domain, then you must first create an external trust between the two domains so that you can copy the user accounts and other things to the new domain.
- ◆ **Shortcut** trusts help speed up authentication in large forests. As you know, every domain in a forest trusts every other domain in the forest, and so any DC in any domain in a forest can authenticate a user from any other domain in the forest. But this can take time, particularly if a DC has to ask one domain to authenticate the user in question, and *that* domain needs to ask another domain, and so on. Shortcut trusts allow you to essentially “introduce” two different domains in the forest, saying “if domain A ever needs to authenticate someone from domain B quickly, then don't search around the forest to find a DC for domain B—just come right over and ask.” I have never seen a forest so large that it needs this. . .but I'm sure that the few forests that *are* large enough to need this spend enough with Microsoft to have made it worth Redmond's time to add this kind of trust!
- ◆ **Forest** trusts are the neat new-to-2003 trust that lets you build one trust relationship between two forests. Once done, every domain in the first forest trusts every domain in the second forest.
- ◆ **Realm** trusts allow trust relationships with Unix systems that use Kerberos for authentication. (What we call domains, Unix Kerberos users call realms.)

We'll mostly use external trusts, but I'll show you how to build a forest trust also.

#### THE SWISS ARMY KNIFE OF TRUST TOOLS: NETDOM

As I've said, the true under-the-hood meaning of “trust relationship” extends beyond domain-to-domain trusts; it includes the connection between domain members and their DCs, meaning that even someone operating a one-domain enterprise deals with trusts. But there's a tendency for administrative tools to either handle domain-to-domain trusts or domain membership trusts; there's only one tool that I know of that envisages trusts in their entirety. It's called NETDOM. First introduced in the NT 4 days, NETDOM has become more powerful and useful with every version—and 2003's version is no exception. To get NETDOM on your system, pop your Server CD into your CD-ROM drive and take a look in `support.cab`, a file that you'll find in the `\Support\Tools` folder. Among other things, you'll see a program called `netdom.exe`. (Or double-click the MSI file and install all of the support tools—there are many useful ones.)

#### NETDOM and Domain Members: Add, Join, Move

Most of NETDOM's options affect domain membership trusts. I don't want to devote too much space to this, as I'm mainly interested in discussing domain-to-domain trusts, but it's worth listing some of the NETDOM options.

`netdom add` adds a machine account to a domain. It doesn't join the machine to the domain, it only creates the machine account on the target domain and, if the domain is an AD domain, you can even

tell NETDOM what OU to put the machine account in. This is useful because a machine's local administrator can join that machine to a domain, *if* a domain administrator has already created a machine account for that machine on the domain. Here's what its syntax looks like:

```
netdom add machine /domain:domainname /userd:destination-domain-admin-account
/passwordd:destination-domain-admin-password /server:dcname /ou:destination-OU /DC
```

That looks like a mouthful; let's pick it apart to make it easier to understand. If I wanted to create a machine account in a domain, then I'd need to know:

- ◆ The name of the machine that I wanted to create a domain account for. That's what the *machine* parameter supplies.
- ◆ Next, I'd need to know what domain I was joining that machine to. That's what the */domain:domainname* parameter supplies. If I don't specify this, then the machine account gets created in my current domain.
- ◆ That domain's only going to let me add a machine account if I'm someone with the permissions to do that on the domain. That's what the */userd* and */passwordd* parameters supply. Of course, if I'm already logged on as someone with those permissions, then I needn't resupply them.
- ◆ I might want to force this operation to occur on a particular DC. The */server* option lets me do that.
- ◆ I might want to place this new machine account in a particular OU; the */ou* option accomplishes that. Unfortunately, you've got to specify the OU in LDAP terminology.
- ◆ Finally, machine accounts for domain controllers are a bit different than the rest of the machine accounts, so NETDOM includes the */DC* option for that eventuality.

So if I wanted to create a machine account named Matterhorn in a domain named apex.com and place its account in an OU named Workstations, I'd type

```
netdom add Matterhorn /domain:apex.com /ou:"ou=Workstations,dc=apex,dc=com"
```

Again, that does *not* join Matterhorn—there needn't even *be* a system named Matterhorn for this to work. But now it'd be possible for a local administrator at Matterhorn to join apex.com, and she would not have to fill in a domain account/password to satisfy her workstation OS. But what if you wanted to both create the machine account *and* join the machine to the domain? For that, there's *netdom join*. It looks like

```
netdom join machine /domain:domainname /userd:destination-domain-admin-account
/passwordd:destination-domain-admin-password /ou:ou /usero:local-machine-admin-
account /passwordo:/local-machine-admin-password /reboot
```

Most of those options will seem pretty familiar. As before, I need to tell NETDOM what machine to join, what domain to join it to, and perhaps what OU in that domain to place the machine account in. As this creates a machine account on the domain, I'll need to present domain-level administrative credentials. But now because I'm also joining the machine to the domain, I'll need the *machine's* permission as well, so I'll need to show that I've got an account that the machine recognizes as a local administrator account—that's what *passwordo* and *usero* do. Think of the "o" at the end as "object," as in "we're joining this object to the domain." The same for *userd* and *passwordd*—they're the user account with admin privileges on the *destination* domain. Finally the *"/reboot"* tells the workstation or

member server to reboot to make the changes take effect. Interestingly enough, you needn't be anywhere near the target machine to do this—it'll work remotely without a problem! So, for example, suppose I wanted to move a system named Saturn into a domain named planets.com. The administrator account on the Saturn machine is named satadmin with password "hi," and planets.com has a domain administrator named planadmin with password "so." The command would look like

```
netdom join Saturn /domain:planets.com /reboot /usero:satadmin /passwordo:hi
/userd:planadmin /passwordd:so
```

I told you that NETDOM could help with migration by letting you move a machine from one domain to another—that's the NETDOM `move` command. It'll need *three* sets of account names and passwords, because to move a machine from domain A to domain B, then you'll need to demonstrate administrator credentials on domain A, domain B, and on the machine that you're moving. As before, you specify `userd`, `passwordd`, `usero`, and `passwordo`. But now you'll need to specify `userf` and `passwordf`—an account name and password on the *former* domain. By now, all of the options should be familiar:

```
netdom move machine /domain:destination-domainname /ou:ou /reboot /userd:destination-
domain-admin-account /passwordd:destination-domain-admin-password
/usero:local-machine-admin-account /passwordo:/local-machine-admin-password
/userf:former-domain-admin-account /passwordf:former-domainadmin-password
```

So suppose I wanted to move a machine named saturn.planets.com from a domain named planets.com to one named cars.org. Say that I've got an admin account on Saturn named satadmin, a domain admin account on planets.com called planadmin, and a domain account on cars.org called caradmin. Finally, let's suppose that each of those admin accounts have the password "hi." The command would look like

```
netdom move saturn.planets.com /domain:cars.org /usero:satadmin /passwordo:hi
/userf:planadmin /passwordf:hi /userd:caradmin /passwordd:hi /reboot
```

Before moving to Netdom's domain-to-domain trust abilities, let me mention that it can help out in other ways in maintaining domain member trusts:

- ◆ `netdom reset` resets a machine's account. Sometimes you'll sit down at a system and be unable to log onto the domain because the machine has lost its domain account, or so it says. Sometimes just resetting it does the job.
- ◆ `netdom resetpwd` resets a machine's domain password. You must be sitting at the machine for this to run. Sometimes if a machine has not connected to the domain for several weeks then its account password expires; this can fix that.
- ◆ `netdom remove` removes a system from a domain.
- ◆ `netdom renamecomputer` renames a computer and its machine account. Be careful about doing this with Certificate servers; they are installed to be name-dependent.

### **Building Domain Trusts with NETDOM**

Now let's see how to build a trust with NETDOM. Recall that we'll work with two kinds of trusts: external (domain-to-domain nontransitive) and forest (forest-to-forest transitive) trusts. Let's first take up external trusts. By now, it'll be easy to guess how NETDOM does it. You need to specify who will trust whom and present domain admin credentials for each domain.

Here's the syntax:

```
netdom trust trustingdomainname /uo:trusting-admin /po:trusting-admin-password
/d:trusteddomainname /ud:trusted-admin /pd:trusted-admin-password /add /twoway
/enablesidhistory
```

Remember that in the most basic trusts, there is a *trusting* and a *trusted* domain. The trusting domain accepts authentications from the trusted domain. You can choose to make it two-way, but even if you do, NETDOM insists that you call one domain the trusting and one the trusted. (Of course, if you're building a two-way trust, then it doesn't matter which you make the trusted and which you make the trusting.) As before, you present credentials, but this time you use the /uo and /po parameters to specify the username and password for a domain admin from the trusting domain, and /ud and /pd to specify the username and password for a domain admin from the trusted domain. The /add parameter says to create the trust, the /twoway parameter says to build it in both directions. That's optional—if you *do* want a one-way trust, then don't include /twoway. As you can guess, /enablesidhistory makes a trust that can support migration tools that create SID histories.

So, for example, to make apex.com and bigfirm.biz trust each other, let's suppose that apex.com has a domain admin named apeadmin with password "ook" and bigfirm.biz has a domain admin named bigadmin with password "hithere"; we could make them trust one another with this command:

```
netdom trust apex.com /uo:apeadmin /up:ook /d:bigfirm.biz /ud:bigadmin /pd:hithere
/add /twoway /enablesidhistory
```

Trust relationships can fall apart for a variety of reasons, so if you create a trust and leave it for a few months, and then try to use it to migrate then you might find that it doesn't work. NETDOM can "refresh" a trust with the /reset option:

```
netdom trust trustingdomainname /uo:trusting-admin /po:trusting-admin-password
/d:trusteddomainname /ud:trusted-admin /pd:trusted-admin-password /reset
```

It's the same as the command that creates the trust, but instead of ending with /add /twoway /enablesidhistory, you just type /reset. Or, instead of /reset, use /verify to just check that the trust is working; if not, then try /reset. I *strongly* recommend that you verify a trust before trying a migration tool! You can also verify *all* of the domains that a domain trusts like this:

```
netdom query /d:domainname /ud:adminacct /pd:password trust /verify
```

Then, once the trust isn't needed any more, you can break it with this syntax:

```
netdom trust trustingdomainname /uo:trusting-admin /po:trusting-admin-password
/d:trusteddomainname /ud:trusted-admin /pd:trusted-admin-password /remove /twoway
```

Once you've got that trust in place, you're ready to start migrating. But before you do, let's look at one more kind of trust...

### **When It Doesn't Work: LMHOSTS to the Rescue**

Once in a while, I can't make NETDOM or, for that matter, any trust-making tool, work. No matter what I do, NT's User Manager for Domains (often) or AD Domains and Trusts (less frequently) complains that it cannot contact a domain controller for the other domain.

That could be because of something very simple. If one system can't ping the other system, then you can't establish a trust. Trust also could fail if one system cannot resolve the other system's name—the NetBIOS names, if it's an NT-4-to-AD trust, or DNS names, if it's an AD-to-AD trust. So check basic connectivity, WINS, and DNS if you can't get one domain to acknowledge another's existence.

But once in a while, there's simply nothing that you can do to make an NT 4 system see an AD domain controller. So in that case, you need to employ the “emergency measures”—a file called LMHOSTS. As you read in the previous chapter, LMHOSTS is an ASCII file that you place in `system32\drivers\etc`. You can use it to help one domain find another domain's primary domain controller—which NT needs to find if it's to create a trust. In each domain controller, create an LMHOSTS entry that points to the other domain controller by entering a line like this in LMHOSTS:

```
IPaddress-of-other-DC "name-of-other-domain <spaces to fill to 15 chars> \0x1B"
```

That should be typed as just one line, even if it broke on the printed page. The idea here is that you're creating an LMHOSTS entry that points to a DC whose ID is “1B” hex, which designates the primary domain controller. For example, if the domain controller for `bigfirm.biz` that is acting as the PDC FSMO had the IP address 25.7.4.11, then you'd enter this line into the LMHOSTS on the primary DC on APEX:

```
25.7.4.11 "BIGFIRM          \0x1B"
```

Notice that the name in the entry is the *domain's* name, not the PDCs. As BIGFIRM is seven characters long, you add eight spaces after its name, before the `\0x1B`. And you must use the double quotes. That entry goes into the LMHOSTS file on the PDC for APEX so that it can find the PDC for `bigfirm.biz`. In all likelihood, that'll work; but if the `bigfirm.biz` system still claims to be unable to find the PDC for APEX, then find out the IP address for APEX's PDC—let's say that it's 25.10.10.19—and put *this* entry in the LMHOSTS file on `bigfirm.biz's` PDC FSMO:

```
25.10.10.19 "APEX          \0x1B"
```

This time, pad the name with eleven spaces because APEX is four characters long. Those entries identify the PDC of a domain, but there's another designation that you may need—a simple declaration that the PDC also happens to be a regular old domain controller. You do that with a 1C entry—it looks identical to the 1B except for the “C”:

```
25.7.4.11 "BIGFIRM          \0x1C"
```

Again, you name the *domain*, not the domain controller, with this trick.

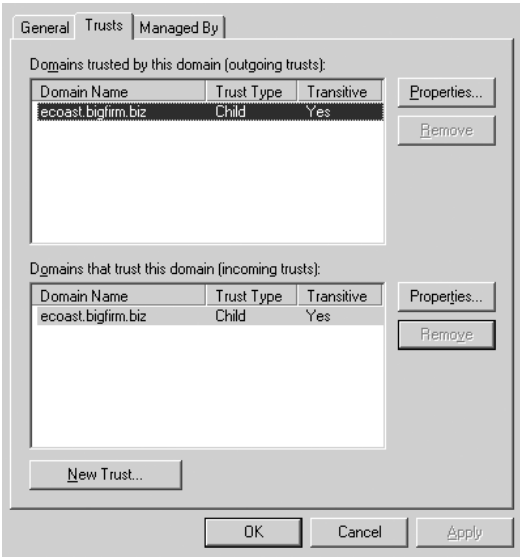

## BUILDING TRANSITIVE FOREST TRUSTS

Before I move along to ADMT from forests, let's cover forest trusts. As far as I can see, you can't get NETDOM to create the really cool new-to-Server-2003 transitive trusts between forests. For that, you'll need a GUI tool—Active Directory Domains and Trusts.

Before starting ADDT, however, let's make sure that you've got a few things ready. First, as always, check DNS with a few `nslookups` to see that the folks in each forest will be able to find domain controllers in the other forest. Then, make sure that both of the forests are at Windows Server 2003 forest functional level. Finally, make sure that you have the name and password of an account that is either in Enterprise Admins or in Domain Admins for the forest root domain—and you'll need one of those accounts from each forest.

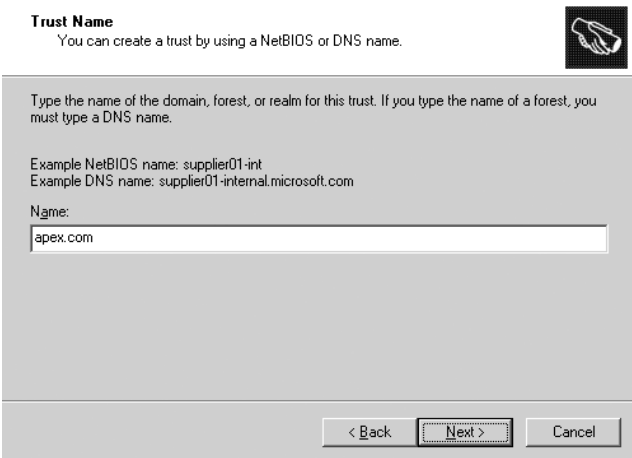

Start up Active Directory Domains and Trusts (Start/Administrative Tools/Active Directory Domains and Trusts) and right-click the icon representing the forest root domain (you can't create a forest trust from any other domain), choose Properties, and in the resulting page click the Trusts tab. It'll look like Figure 8.73.

**FIGURE 8.73**  
Viewing a domain's trusts

My screen shots show how to create a forest trust between bigfirm.biz (which is, recall, a forest root domain) and apex.com, the forest root of another forest. Notice that the screen shows that I've already got a trust from bigfirm.biz to ecoast.bigfirm.biz. That shouldn't be a big surprise, as ecoast is a child domain. You cannot use ADDT to delete a trust between domains in a forest, but you can use ADDT to build just about any other kind of trust. Click New Trust... and a Welcome to the New Trust Wizard screen appears; click Next and you'll see something like Figure 8.74.

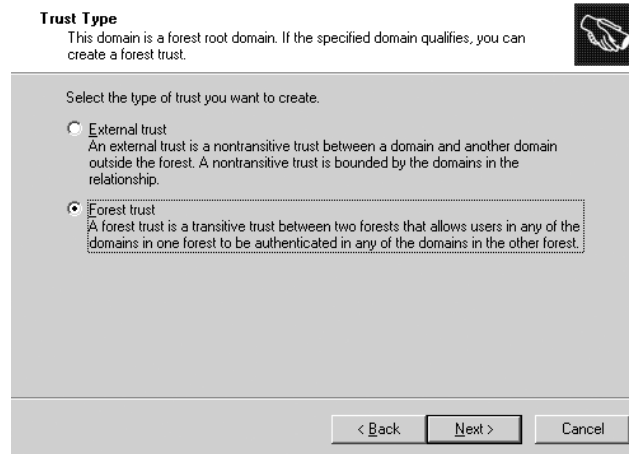

**FIGURE 8.74**  
Who will you trust?

I've filled in apex.com. Click Next to see the *important* question, as you see in Figure 8.75.

**FIGURE 8.75**

What kind of trust?

**Trust Type**  
This domain is a forest root domain. If the specified domain qualifies, you can create a forest trust.

Select the type of trust you want to create.

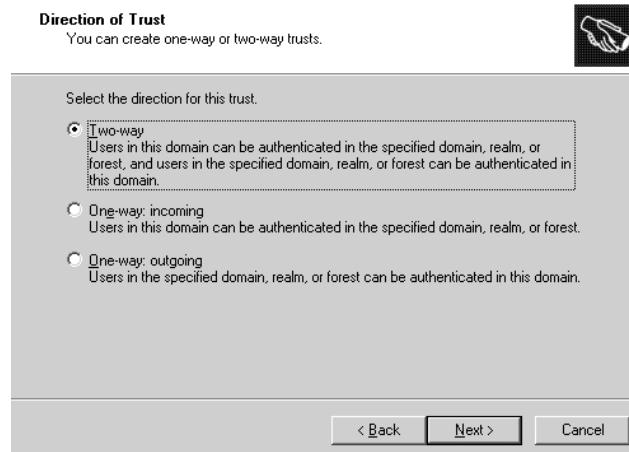

- ☐ External trust  
An external trust is a nontransitive trust between a domain and another domain outside the forest. A nontransitive trust is bounded by the domains in the relationship.
- ☒ Forest trust  
A forest trust is a transitive trust between two forests that allows users in any of the domains in one forest to be authenticated in any of the domains in the other forest.

< Back   Next >   Cancel

Recall that an external trust is a simple domain-to-domain trust, and a forest trust is the transitive trust that we want. Choose Forest Trust and click Next to see Figure 8.76.

**FIGURE 8.76**

Which way should the trust go?

**Direction of Trust**  
You can create one-way or two-way trusts.

Select the direction for this trust.

- ☒ Two-way  
Users in this domain can be authenticated in the specified domain, realm, or forest, and users in the specified domain, realm, or forest can be authenticated in this domain.
- ☐ One-way: incoming  
Users in this domain can be authenticated in the specified domain, realm, or forest.
- ☐ One-way: outgoing  
Users in the specified domain, realm, or forest can be authenticated in this domain.

< Back   Next >   Cancel

As you've seen, at its heart a trust has two sides—the domain that trusts and the one that is trusted. This page lets you choose who trusts whom, and whether or not trusts should just run bidirectionally. Choose Two-way and click Next to see Figure 8.77.

This is a real time-saver. As I said before, one administrator can't create a trust for two domains; it takes admins from both sides. That used to mean that you'd first set up one side of the trust on one domain, then run over to a DC for the other domain and finish setting up the trust at the other domain. This, however, saves you the trouble. If you click Both This Domain and the Specified Domain, and Next, then the wizard will ask you for an administrator account

and password on the other domain. Fill in the administrative account and password, click Next, and you'll see Figure 8.78.

**FIGURE 8.77**

Set up both sides or just this one?

**FIGURE 8.78**

How friendly are we?

Here's another example of Server 2003's better attention to security detail. In most cases, you create a forest trust because you want all of the domains in one forest to trust all of the domains in the other forest. If that's the case, then choose Forest-wide Authentication. If, on the other hand, you want to more finely tune the kind of authentication info that passes between the forests, then choose Selective Authentication. But if you do, you'll have a lot more work ahead of you! Then click Next and the wizard will ask you the same question from the point of view of the other forest; select whatever you prefer and click Next again. You'll get two more information panels confirming what you've selected; click Next to get past them. Then you'll be asked if you want to confirm the link between forests. This sounds like a good idea, but it's not—it'll only work if you built the two halves of the trust by hand. Click No to get past those pages and you'll end up at a final "this is what you did" page. Click Finish and it's done—Apex and Bigfirm are working as one.

## Microsoft's Free Migration Tool: ADMT

If you're thinking about a clean and pristine migration, then you need a migration tool...and if you've priced migration tools, then you might be reconsidering a C&P. But you needn't, as Server 2003 includes a migration tool called the Active Directory Migration Tool or ADMT. Originally written for Microsoft by NetIQ, ADMT 2 maintains the ease of use of the first version and adds some nice features as well.

### AN EXAMPLE MIGRATION SETUP

To show how ADMT works, I'll demonstrate how to do a simple but fairly complete migration from an NT 4 domain named NT4HOLDOUT to our Active Directory bigfirm.biz. (Let me stress that the process is the same to go from an Active Directory domain—it just seems that more people migrate from NT 4, and simply upgrade in-place from 2000-based ADs, so I chose NT 4 for my example.) I'll explain this step-by-step so that you can duplicate this if you like. (But you needn't do that—you'll understand basically what ADMT does whether you try it or just read along. Additionally, I refer here to file shares and NTFS ACLs, which we've not covered yet but we will in three chapters—skip ahead to the file shares chapter if you don't know that stuff yet. I'm using them in a very basic way in any case.) You'll see:

- ◆ How to migrate a user account to an AD domain from an NT 4 domain with ADMT
- ◆ How SID histories allow the migrated user to access resources on the old domain whose ACLs have not been changed
- ◆ How ADMT can re-ACL a member server in the old resource domain
- ◆ How ADMT can migrate member servers from the old domain to the new AD domain

To make this work, I'll set up four systems—two in NT4DOMAIN, two in bigfirm.biz. The two in NT4DOMAIN are:

- ◆ A PDC for NT4DOMAIN, an NT 4 system named NT4HOLDOUT. On NT4HOLDOUT, I create:
  - ◆ A domain user account named Jane, password “jane.”
  - ◆ A global group named Accountants and make Jane a member.
- ◆ A member server for NT4DOMAIN named NT4MEM. On NT4MEM, I create:
  - ◆ A share named \\nt4mem\janepersonal, with both share and NTFS permissions allowing only Jane access; I then put a few files in \\nt4mem\janepersonal.
  - ◆ A share named \\nt4mem\taxes that only the Accountants group can access, and put a few files in that.

The Active Directory domain contains two machines as well:

- ◆ A DC for bigfirm.biz, our old friend bigdog.bigfirm.biz set up as we've done it in this chapter and the previous one.
- ◆ An XP Pro workstation named vxp2.bigfirm.biz. It could as easily be a 2000 Pro workstation or an NT 4 workstation. Whatever the OS, it should be a member of the bigfirm.biz AD.

**WARNING** *The target domain must be a Windows 2000 native or Windows Server 2003 functional level domain for ADMT to work.*

My goals here are to:

- ◆ Get Jane an account in bigfirm.biz without interrupting her ability to access the shares on NT4MEM while NT4MEM is still part of the NT4DOMAIN domain.
- ◆ Eventually migrate NT4MEM to bigfirm.biz so that I can shut down the NT4DOMAIN domain altogether.

Before we go any further, check that we won't have any name resolution problems—either point all of the systems to the same WINS and DNS servers or ensure that each system's DNS servers and WINS servers talk to one another. And yes, WINS is important here because we've got NT 4 systems still running.

### ESTABLISH THE TRUST

Next, establish the trust between the two domains. As you've already read, I'd recommend using NETDOM to do this. And always be sure to use the latest NETDOM (which in this case is the one on the Server 2003 CD). As we'll want a two-way trust, it doesn't matter which we call the trusting and which the trusted. Assuming that NT4DOMAIN has an admin account nt4admin with password "swordfish" and bigfirm.biz has an admin account bigadmin with password "bigguy", then the following NETDOM command would do the trick:

```
netdom trust nt4domain /uo:nt4admin /po:swordfish /d:bigfirm.biz /ud:bigadmin
/pd:bigguy /add /twoway /enablesidhistory
```

I like to stop and test things at this point—is the trust working, are the permissions correct on NT4MEM? To try that, I'd log onto VXP2, the XP box that is a member of bigfirm.biz, and try to log on as Jane. (You know, sort of to get in touch with my feminine side—some people cross-dress, I cross-logon.) First of all, if Jane can log on, then the two domains do indeed trust one another. And, of course, Jane should be able to access both the \\nt4mem\janestuff and \\nt4mem\taxes shares. So in a sense a trust relationship is kind of a mini-migration tool of its own, as Jane can now log onto a bigfirm.biz member machine and access her stuff.

But that's not what we *really* want. We want to get rid of NT4DOMAIN and all of its members eventually. Eventually Jane will have a bigfirm.biz account, and NT4MEM will be a member of bigfirm.biz, and NT4HOLDOUT (the PDC of the NT 4 domain) will be shut off and given to charity or reformatted as a member of bigfirm.biz. But, again, we want to do all of this gradually, and that's where ADMT comes in. So it's time to...

### GET BOTH SIDES ADMT-FRIENDLY

ADMT can be an absolutely frustrating nightmare of a program because of its needs. It's a program that takes information that is fairly private and internal to a domain—user accounts and passwords—and reveals them to a completely different domain. Before ADMT can do that, we'll have to open up a number of locked doors. Here's what we've got to do.

### ***Put Domain Admins in Each Other's Administrators Groups***

We'll work from a machine in the NT4DOMAIN domain—the PDC, named NT4HOLDOUT—and a machine in the bigfirm.biz domain, bigdog.bigfirm.biz. Each system's local Administrators group must contain the Domain Admins global group from the *other* domain. To do this, go to NT4HOLDOUT and open User Manager For Domains. Then double-click the Administrators group and add the Domain Admins group from bigfirm.biz. Of course, User Manager won't call the domain bigfirm.biz but rather its old NetBIOS name, BIGFIRM, as you're working on an NT 4 system that doesn't understand AD. Make sure that you're adding the Domain Admins group from BIGFIRM, not NT4DOMAIN.

Over at bigdog.bigfirm.biz, open up Active Directory Users and Computers as we've done before and look in the *Built in* folder to find the Administrators group. Open it up and add the Domain Admins group from the NT4DOMAIN; again, make sure that it's the NT4DOMAIN's Domain Admins that you're adding, not the bigfirm.biz Domain Admins—they're already there.

### ***Turn On Auditing***

ADMT has some specific auditing needs, presumably so that it can monitor how it's doing. The source domain—the one the users are being copied from NT4DOMAIN—needs both success and failure audit enabled for user and group management. Turn that on in User Manager for Domains, clicking Policies/Audit and checking the boxes for Success and Failure next to User and Group Management.

On the target machine (bigdog.bigfirm.biz) on the target domain (bigfirm.biz), enable auditing by modifying a group policy called Default Domain Controller Policies in Active Directory Users and Computers. Right-click the Domain Controllers OU and choose Properties, then the Group Policy tab; the Default Domain Controllers Policy; double-click it and the group policy editor appears. To get to the policy you're looking for, open Computer Configuration, then Windows Settings, then Security Settings, then Local Policies, and finally inside Local Policies you see Audit Policy. Inside Audit Policy, double-click Audit Account Management and make sure that Define These Policy Settings is checked, as is Success and Failure. Then click Close...but don't close the GP editor; your work's not nearly done yet.

### ***Enable Anonymous Access***

While in the GP Editor for the Default Domain Controllers Policy at bigdog.bigfirm.biz, go next from the Audit Policy folder to another just two folders down on the same level, Security Options. We've got to loosen up an item in here. Set Network Access: Let Everyone Permissions Apply to Anonymous Users to Define This Policy Setting and Enabled.

That's all you need from that policy, so you can close up the Group Policy Editor, the properties page for the Domain Controllers OU, and ADUC.

### ***Put Everyone in the "Pre-Windows 2000 Compatible Access"***

Remember when DCPROMO asked about loosening up permissions to make NT 4 RAS servers happy? Well, you've got to do that loosening-up to make ADMT happy. No, you needn't run DCPROMO to do this; instead, you can just open a command prompt (still at bigdog.bigfirm.biz) and type this:

```
net localgroup "Pre-Windows 2000 Compatible Access" Everyone /Add
```

You should get the response “The command completed successfully.”

### ***Install ADMT on bigdog.bigfirm.biz***

Put the 2003 Server CD into bigdog’s CD drive and navigate to I386\ADMT. Double-click the file named ADMIGRATION.MSI. That starts a Setup wizard which asks the usual things—agree to the license, where do I put the files, etc. Tell it to put ADMT in C:\ADMT.

### ***Create a Password Key on the Target***

Now, we want Jane’s password to move over with Jane’s account, and ADMT 2 can do that—ADMT 1 couldn’t—but it’s going to take a little work. Before it’ll migrate passwords, ADMT requires that you create a password encryption file on bigdog and then copy that over to NT4HOLDOUT, and NT4HOLDOUT will use that to be able to send passwords over the wire—but encrypted.

To do this, you’ve got to run ADMT from the command line. Open a command line and change directory to wherever you put ADMT (C:\ADMT in my example), and type

```
admt key NT4DOMAIN c:\
```

This says to prepare a key that NT4DOMAIN can use to transfer passwords to bigfirm.biz. (Bigfirm’s not explicitly mentioned because you’re working on a bigfirm.biz DC.) The C:\ just says where to put the file. If your server has a floppy drive, then A:\ works fine too. It doesn’t matter where you put it—just understand that you’ll have to transport that file to the NT4DOMAIN DC, NT4HOLDOUT, somehow. When it runs properly, ADMT will return a message looking something like

```
The password export server encryption key for domain 'NT4DOMAIN' was successfully
created and saved to 'C:\MDLKDOV.pes.'
```

You’re done on bigdog.bigfirm.biz for the moment. But before you leave bigdog, reboot it. That’s very important! Time to move to NT4HOLDOUT.

### ***Move Over the PES File***

Once logged in at NT4HOLDOUT, you need to get that PES file from bigdog to a local drive; I usually just create a share and copy it over across the network; you can alternatively put it on a floppy, a CD-ROM disc, or whatever you want—but it’s got to get over to NT4HOLDOUT one way or another.

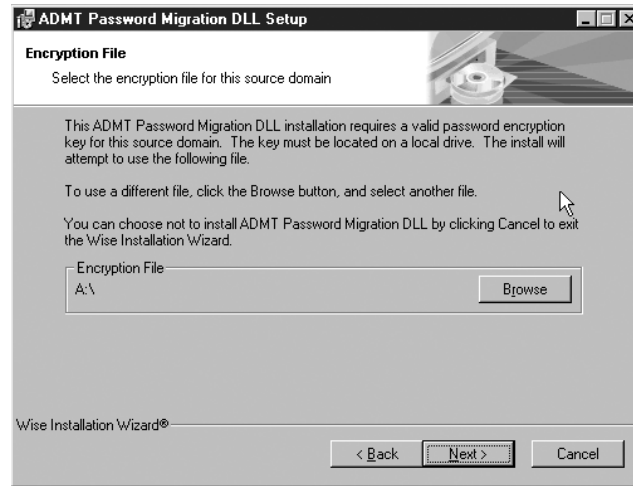

### ***Install the Password Migration DLL on NT4HOLDOUT***

You need just a couple of files from the Server 2003 CD on NT4HOLDOUT, so put the CD in its drive. In \I386\ADMT\PWDMIG, you’ll see PWMIG.EXE; double-click it to start the ADMT Password Migration DLL Installation Wizard, perhaps the world record-holder for wizard name length. After clicking Next, you’ll see something like Figure 8.79.

Here, it thinks that the file is on a floppy, and that’s a perfectly good way to transport it from bigdog.bigfirm.biz to NT4HOLDOUT. In my case, I’ve copied it over the network to C:\, so I’d click Browse to direct the program to the file’s location. Two Nexts and a Finish and the DLL is installed, and you’re prompted to reboot the system. But don’t do that just yet, as you need to do a little Registry fiddling...

**FIGURE 8.79**

Identify the password encryption key

### **Modify Registry Entries for Local Security Authority on NT4HOLDOUT**

Open up Regedit and navigate to HKEY\_LOCAL\_MACHINE\SYSTEM\CurrentControlSet\Control\LSA. There you will see an entry called AllowPasswordExport, with a value of 0. Change that to 1 and create a new REG\_DWORD value entry named TcpipClientSupport, which you also set to 1.

If you're starting to think that maybe it'd be easier to just retype all of the usernames than it would be to get ADMT set up, take heart—you're almost done. Now reboot NT4HOLDOUT.

### **START UP ADMT AND MIGRATE THE ACCOUNTANTS GROUP**

When migrating users from one domain to another, the basic sequence of events is:

1. Set up the trusts, registry entries, etc.
2. Migrate the global groups from the old domain to the new domain. The new global groups get SID histories from the old ones, so anyone in the new BIGFIRM\Accountants group will have access to anything that people in the NT4DOMAIN\Accountants group had access to. This means that as you migrate users from NT4DOMAIN to bigfirm.biz that they can be automatically placed in the Accountants group in bigfirm.biz and they will have immediate access to all of their old stuff.
3. Migrate the users. Once you've got the global groups migrated, you can migrate the users at whatever pace works for you. Users migrated to the new domain will be able to access file shares, shared printers, and other resources from the old domain, because the migrated user accounts have SID histories from the old domain.
4. Migrate the servers to bigfirm.biz. Change the domain membership of the member servers and workstations from NT4DOMAIN to bigfirm.biz. This will require another ACL fix-up, as you want the server to no longer have ACLs that refer to groups in NT4DOMAIN, and instead to replace those ACLs with references to groups in bigfirm.biz.

5. Once all of the member servers are moved over to bigfirm.biz and you've checked that all of the permissions have been correctly changed from NT4DOMAIN references to bigfirm.biz references, you can decommission NT4DOMAIN—break the trust relationship, shut off the NT4DOMAIN DCs, and trim the SID histories from our migrated user accounts.

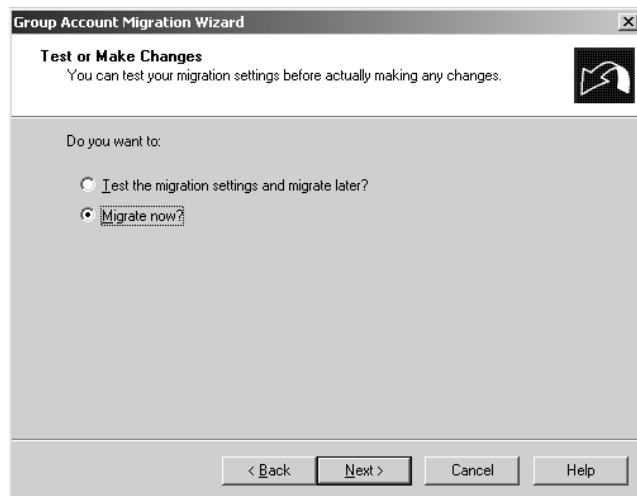

Time to migrate the global groups, so let's do it. Move over to bigdog.bigfirm.biz and start up ADMT (Start/Administrative Tools/Active Directory Migration Tool). It's a kind of sparse-looking UI, but if you right-click the Active Directory Migration Tool icon then you'll see that it can do a lot of things, as in Figure 8.80.

**FIGURE 8.80**  
ADMT functions

ADMT does a *lot* of things, more than I can cover in a short time—I'll just cover the basics here. I *strongly* recommend that you read the Help that comes with it, as ADMT is a powerful and useful tool that can migrate users, groups, machines, and even Exchange setups! On the ADMT menu, choose Group Account Migration Wizard and click Next to see the first panel, as you see in Figure 8.81.

**FIGURE 8.81**  
Is this real or a drill?

I'm running this "for keeps" here because I've done it enough to know how to get it right the first time, but I strongly recommend that you run it in test mode until you've gotten some experience with ADMT. As you've seen, ADMT is *very* demanding in the things that it needs before it'll run correctly, and you really don't want to leave your network half-migrated. Run it in test mode until you're comfortable that you've got all the pieces in place to do the real thing. Click Next and you'll see Figure 8.82.

**FIGURE 8.82**

Choose source and destination domains

This panel is straightforward; you pick the domain that you're moving from and the one that you're moving to. But it's actually quite useful as well, as it serves as a test of connectivity. If NT4HOLDOUT weren't up, your only options on both "from" and "to" would be bigfirm.biz...which wouldn't be a very interesting migration. Once you choose the domains, click Next and you'll notice a pause as the DCs connect and show Figure 8.83.

**FIGURE 8.83**

What group or groups to migrate?

In this panel, you tell ADMT which group or groups to move over. Before I took this shot, I clicked Add and chose Accountants, although I could have chosen any number of groups. Click Next and you're led to Figure 8.84.

**FIGURE 8.84**

Where to put the group?

Like all good AD-aware tools, ADMT lets you choose what OU to place the migrated group into. But don't worry that you have to master that cumbersome LDAPish—you can click the Browse button and ADMT then lets you navigate through the AD structure. Click Next to see Figure 8.85.

**FIGURE 8.85**

Choosing group options

The defaults on most of these panels are fine, but in this one you get an important option—to create a SID history on the group. Check the box labeled Migrate Group SIDs to Target Domain, which is ADMT's way of saying “create a SID history item in bigfirm.biz for the Accountants

group.” Clicking Next to this panel is something of a useful diagnostic—if something isn’t in place to allow the SID history mechanism to work, ADMT emits an error message. Or it issues the warning in Figure 8.86, which is actually a *good* sign.

**FIGURE 8.86**

Creating a “helper group” for SID histories

Whenever you use a SID history, the authenticating system checks with the old domain, NT4DOMAIN in this case. This group has something to do with how ADMT ensures that the SID histories will work right, but the wizard checks anyway to ensure that it’s okay to create the group. Click Yes and you’ll see a login screen, as if you haven’t already presented your credentials frequently enough; Next takes you to Figure 8.87.

**FIGURE 8.87**

Handling conflicts

You’re migrating a group named Accountants, but what if there already is a group named Accountants? This panel answers the question—skip the migration, zap the existing Accountants group, or add a prefix to the name. Once you make these choices—the defaults are usually fine—just a few more Nexts and it’s done.

### TEST THE NEW ACCOUNTANTS GROUP

As the Accountants group in bigfirm.biz has a SID matching the one on the Accountants group in NT4DOMAIN and *that* group has access to `\\nt4mem\taxes`, then anyone in the new Accountants group should be able to get to `\\nt4mem\taxes`. Let’s try it out.

1. In the bigfirm.biz domain, create a user named Tom.

2. Put Tom in the Accountants group.
3. At the workstation that is a member of bigdog.biz, log on as Tom.
4. Open a command prompt.
5. Type `dir \\nt4mem\taxes` and press Enter. You should see the files in `\\nt4mem\taxes`. Then try looking in those files—you (as Tom) should be able to do it. SID histories work!

### MIGRATE JANE TO BIGFIRM.BIZ

Now let's see how to migrate a user account. On the ADMT menu, choose User Account Migration Wizard. It starts out looking just like the Group Account Migration Wizard, asking about the source and destination domains, whom to migrate, and where to place her new account. But then you see a panel different from the Group panels, as you see in Figure 8.88.

**FIGURE 8.88**

What to do with the passwords?

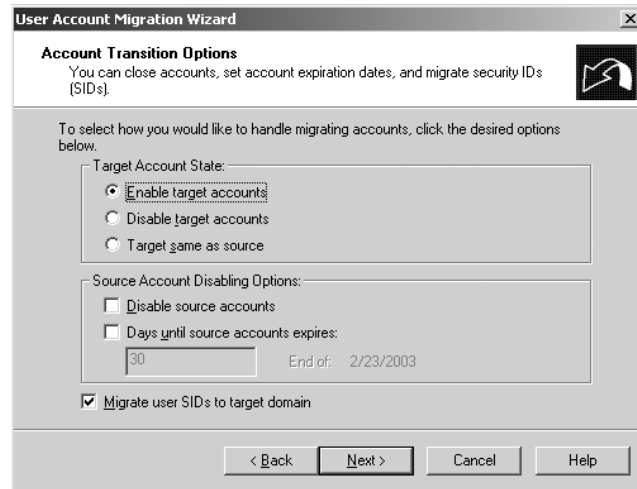

This panel will bring joy to the hearts of ADMT 1 veterans. Under ADMT 1, your newly migrated user accounts could either all have the same password, or they could have passwords equal to their usernames, or you could feed ADMT a cleartext ASCII file of names and passwords—all clumsy answers. But now that you're running ADMT 2 and have done the work of creating a password encryption key and moving it over to NT4HOLDOUT, ADMT 2 offers a new option—to move the passwords over. That's what I picked. Then click Next to see Figure 8.89... *if* the password encryption worked. You *don't* see 8.89 if you didn't dot all the i's and cross all the t's (you get an error message), so that Next is a useful diagnostic tool in its own right.

Migrating a user means that you copy her old account to a new domain. But it's a *copy*, not a *move*, so she's still got the old account. That means that she could start the day by logging on to either account—but you probably don't want that. You'll usually either want her to immediately start logging on with the new account, or to stay with the old account for a little longer, as you get the final arrangements for the new domain in place. That's where this panel is useful. It'll automatically disable the old account, or keep the new one disabled until you enable it, or keep the new account disabled for some number of days.

**FIGURE 8.89**

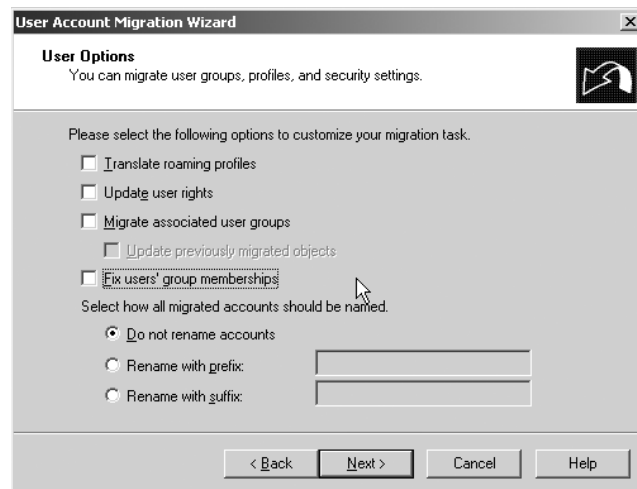

Enable or disable the old and new accounts?

But this panel does something else that's important—it tells ADMT whether or not to create SID histories for the user. Click Next, and you'll get a login screen; fill in your credentials and click Next and you'll see a screen like Figure 8.90.

**FIGURE 8.90**

Making the new user feel at home

This is another powerful panel. In it, you can make ADMT give the new user the same rights as she had before, which isn't a simple matter when moving from NT 4 to AD in any flavor. It'll make sure that whatever groups Jane was a member of follow her over to the new domain. You can also, if you like, "brand" all users with a particular prefix or suffix. This would be useful if you were combining a number of different domains and wanted to avoid name collisions, as more than one domain might have a "Jane" account. You might, for example, say that all accounts from the old MANAGERS domain keep their names, but with "MGR" suffixed to the end of the name, so Jane would become JaneMGR. And speaking of name conflicts, click Next to see how to handle them in Figure 8.91.

**FIGURE 8.91**

Handling name collisions

Assuming that you don't tack a prefix or suffix onto every name in a given domain when assimilating that domain's names, it would again be possible to have two Janes—the new one and one that's been around for a while. This page says that in a case like that, just prefix the new Jane's user account name with "xx." From here, you just click Next to confirm your choices, and the migration happens.

How did it end up? Jane was automatically joined to the Accountants group at bigfirm.biz. I logged Jane onto VXP2, the XP box that is a member of bigfirm.biz. It liked her old password, so the password came across correctly. Then I tried to access her personal shares that only the original Jane could access. She got to them with no trouble, demonstrating that the SID history works. My simple migration was a complete success, and all of your migrations will be, also...so long as you do your homework.

### RE-ACLING WITH ADMT

You've now moved the global group Accountants and a domain user named Jane over to the new bigfirm.biz domain. There's just one holdout... your faithful member server, NT4MEM. (What about the PDC of that domain, NT4HOLDOUT? You can't migrate PDCs over. But when you don't need it any more, you can always wipe it and rebuild it, and then make it a DC in the new domain.) What's involved with moving NT4MEM over? Well, clearly you've got to change NT4MEM's allegiance to NT4DOMAIN, but that's not hard—recall the earlier discussion of NETDOM move and you'll know that you could do this with just one command.

But that wouldn't make the NT4DOMAIN émigrés very happy. For example, consider what happens when someone in the bigfirm.biz Accountants group tries to access `\\NT4MEM\taxes`. NT4MEM looks at the SID for the bigfirm.biz Accountants group and initially says to itself, "Nope, I don't have any ACLs that give *those* guys access, I'll just tell 'im to take a walk and oh...hey...there's this *other* ACL, for the Accountants group right here in NT4DOMAIN. Well, heck, they've got back-stage access here at `\\NT4MEM\taxes`, come on in!"

Thus, if I used NETDOM to move NT4MEM to bigfirm.biz, then everyone who could get to `\\NT4MEM\taxes` could still get to it. But it'd seem sort of a roundabout way—here both NT4MEM and Accountants would be both part of the bigfirm.biz domain at that point, but the only

way that the bigfirm.biz version of Accountants could get to the taxes share would be through an old—and now basically obsolete—connection. That seems inefficient. But it gets worse; you see, whenever NT4MEM wants to use a SID history, NT4MEM must go back to the original domain to authenticate it. Thus, if we shut down NT4HOLDOUT (the PDC of NT4DOMAIN), then the SID histories would stop working and the Accountants group in bigfirm.biz couldn't access shares on NT4MEM—which is also in bigfirm.biz.

What we need is a tool that will not only move NT4MEM over to bigfirm.biz, but also examine all of the shares on NT4MEM and change any of the old ACLs that refer to NT4DOMAIN things to corresponding bigfirm.biz things. This is sometimes called “re-ACLing” and, not surprisingly, ADMT can handle re-ACLing and moving a server. You'll see Computer Account Migration Wizard on the ADMT menu, and it works very much as the Group and User Migration Wizards do, so I'll spare you the screen shots. But there is *one* trick to making ADMT's Computer Account Migration Wizard work: run it from the PDC emulator of the *target* domain (bigfirm.biz, in our example), but log in as the domain administrator for the *source* domain (NT4DOMAIN in my example). Do that, and it'll work. Try it any other way and you'll just receive frustration.

There is a lot more that ADMT can do; all I've done here is to get you started. Again, I strongly recommend that you study the Help files before doing anything drastic with ADMT. But I think you'll like what the tool can do for you.

## AD Maintenance

AD is, as I've said before, a database and, as I've also said, AD's DCs are database servers. So once you have your AD up and running you will almost certainly run into the same kinds of problems that any database administrator runs into. The three most common in the AD world are probably

- ◆ Defragmenting the database: it does it itself, but you can do a better job by taking the DC offline and doing it.
- ◆ Cleaning out improperly deleted objects: what happens if you simply FDISK a domain controller instead of DCPROMOing it to decommission it? (Or, worse, what happens if you FDISK *all* of the DCs in a child domain?) You leave junk in the database. I'll show you how to take that junk out.
- ◆ Renaming a domain: so you say your company used to be called Bigfirm and now it's called Megabucks? Great, congratulations. I'll show you how to rename its AD domain.

### Offline Defragging a DC's Copy of the AD

Defragmenting your hard disk doesn't defrag one of the most important files—the AD database. AD defrags itself online, but it can't do a thorough defragging and compacting while acting as a domain controller. You can clean up your AD and potentially speed up a DC's performance by doing an offline defragmentation; here's how.

#### GET THE DC INTO DIRECTORY SERVICE MODE

Restart your domain controller and, as it's restarting, press F8 to bring up the Recovery menu. One of the many options will be Directory Services Restore Mode; choose that. The system will start up in a kind “safe mode” and may confuse you a bit when you try to log in. You log in as Administrator,

but you do *not* use the normal password of your local Administrator account; rather, you use the Directory Services Restore password. What's that, you ask? Well, if you think back to DCPRMO-ing, you were asked to choose a Directory Services Restore password—well, here's where it gets used.

### RUN NTDSUTIL

Now open a command prompt and start NTDSUTIL. It will compact and defrag the NTDS.DIT, the database file, to an alternative location. You'll then copy that file to its normal spot `\windows\ntds` or `\winnt\ntds`, reboot, and you'll be back in business. Here's what to do in NTDSUTIL:

1. Type **file** and press Enter. You'll get a prompt `file maintenance:`.
2. Type **compact to** followed by some target location like `compact to c:\`. This creates a compressed copy rather than working directly on the actual AD. The output will look like this:

```
Initiating DEFRAGMENTATION mode...
      Database: C:\WINDOWS\NTDS\ntds.dit
Temp. Database: c:\ntds.dit

      Defragmentation Status (% complete)

      0    10   20   30   40   50   60   70   80   90  100
      |----|----|----|----|----|----|----|----|----|----|
      .....

```

#### Note:

It is recommended that you immediately perform a full backup of this database. If you restore a backup made before the defragmentation, the database will be rolled back to the state it was in at the time of that backup.

Operation completed successfully in 7.510 seconds.

Spawned Process Exit code 0x0(0)

If compaction was successful you need to:  
 copy "c:\ntds.dit" "C:\WINDOWS\NTDS\ntds.dit"  
 and delete the old log files:  
 del C:\WINDOWS\NTDS\\*.log

3. Type **quit** and press Enter twice to exit NTDSUTIL.

### COPY THE NEW AD TO %SYSTEMROOT%\NTDS

If all went well, then copy the NTDS.DIT file that you just created to either `\windows\ntds` or `\winnt\ntds`, depending on how your OS is set up. In that same directory, delete any files with the extension `*.log`. Restart the DC and you'll be done!

Note that this only defrags the NTDS.DIT file on that DC...if you have other DCs then you'll need to take them offline and defrag them as well. (Not all at once, of course!)

## Cleaning Out Objects with NTDSUTIL

Active Directory likes orderliness, neatness in all things. When you remove something from the AD database, you're supposed to do it in an orderly manner. For example, suppose you get rid of a DC or, as is most common, you decided to wipe and rebuild the DC...without first DCPROMO-ing. Whenever you decommission a DC, you should first DCPROMO it.

Unfortunately, you can't always have the amount of order that you might like in our domains; DCs may crash and never boot again, making a DCPROMO pretty unlikely. The database objects representing the directory remain, even though there's no corresponding physical objects. Is that terrible, or can you just live with leftover junk in the AD database?

Leftover AD junk is probably undesirable for several reasons. First, it's, well, extra junk. We've all faced software problems that arise in *well-maintained* systems; who knows what kinds of bugs pop up when a database is in an unknown state? Second, as long as AD thinks a DC exists, it'll keep trying to talk to it. That leads to errors in the log files, which can be distracting and irritating. Third, you cannot decommission a *domain* until the last DC is gone. This has tripped me up a couple of times. In one case, I'd created a child domain with just one DC just to play around with it, and then FDISKed the DC. I later needed to decommission the forest's root domain, but found that DCPROMO would not let me do it, as it can't decommission the forest when there are still child domains around! Clearly, I was stuck until I could "get rid of the kids," removing first the DC's object from the database and then the child domain itself.

You can do all those things, with NTDSUTIL. It has a function called "metadata cleanup" that will zap just about anything. The only trouble is that NTDSUTIL's user interface is, well, a bit obtuse. The idea is this: you use a bunch of NTDSUTIL commands to identify some object, like a DC or a domain; that's the cumbersome part. Then, once they're identified, you tell NTDSUTIL to delete them.

I'll walk you through the process by using NTDSUTIL to get rid of ecoast.bigfirm.biz. Recall that ecoast.bigfirm.biz is a child domain of bigfirm.biz and has only one DC. The DC's name is srv1.ecoast.bigfirm.biz. Suppose that system had been destroyed by fire, effectively destroying the domain as well. (That's why you always want at least *two* DCs!) Here's how I'd do an ecoast-ectomy on bigfirm.biz: first, I'd start up NTDSUTIL and tell it to select the last ecoast.bigfirm.biz DC, srv1.ecoast.bigfirm.biz. Then I'd tell NTDSUTIL to delete the DC's object from the AD database. Once that's done, I could then just say to delete the ecoast.bigfirm.biz object as well. I'd do this while sitting at a domain controller, logged in as a domain admin (if the DC is a root domain DC) or an enterprise admin.

1. First, open a command prompt and type **ntdsutil**.
2. Type **metadata cleanup** and press Enter. It's the section that deletes objects, but before it can do that, you've got to log onto a DC (yes, it's dumb, you're *sitting* at a DC, but that's software for you), then you've got to tell NTDSUTIL what you want to delete, and only *then* can you delete the DC and then the domain.
3. At the resulting **metadata cleanup** prompt, type **connections** and press Enter.
4. That changes the prompt to **server connections**; type **connect to server localhost** and press Enter.
5. Back up to metadata cleanup by typing **quit** and pressing Enter; the prompt will return to **metadata cleanup**.
6. Now it's time to select a victim. Type **select operation target** and press Enter.

7. You choose domains, sites, and servers by first asking NTDSUTIL to list them. It lists them, giving them all numbers. So, for example, as you have two domains, select ecoast.bigfirm.biz by asking NTDSUTIL to list the domains, and it will list that and bigfirm.biz, numbering them 1 and 0, respectively. Select domain 1 rather than domain ecoast.bigfirm.biz. Then do the same thing for sites and servers. First, type **list domains** and press Enter. You'll see a list of domains, and ecoast.bigfirm.biz is probably number 1.
8. Type **select domain 1** and press Enter to choose ecoast.bigfirm.biz (unless it comes up as a different number on your system).
9. Next, choose the site that your soon-to-be-deleted DC lives in. But you need to know what number site is HQ, where SRV1 lives. You find out what sites exist and what their numbers are by typing **list sites** and pressing Enter.
10. HQ shows up on my system as site 0. Typing **select site 0** and pressing Enter chooses it.
11. Now that we've got a domain and a site, you're closing in on the server. Find its number by typing **list servers for domain in site** and pressing Enter.
12. As there's only one DC, it's no surprise that SRV1's number is 0. Select it by typing **select server 0** and pressing Enter.
13. You've now got your sights on the target, time to pull the trigger. Type **quit** and press Enter to return to **metadata cleanup**.
14. Now type **remove selected server** and press Enter. You'll get two "are you sure?" dialogs; tell them yes and the server's gone.
15. Finally, type **remove selected domain** and press Enter, then confirm the resulting dialog box and the domain's gone also.
16. Type **quit** and press Enter twice, and you're out of NTDSUTIL.

As your AD gets more and more real use, you'll find yourself using metadata cleanup a few times a year. It's quite useful; I just wish it had a better UI.

## Renaming a Domain

So you say you want to rename your domain from acme.com to apex.com? Well, I've got just one question for you, pardner... *are you sure?*

Server 2003 makes it possible to rename domains, so you could indeed rename an AD named acme.com to one named apex.com. But there's more to it than just renaming, as renames also let you *rearrange* a forest. For example, suppose I have a forest containing three domains:

- ◆ bigfirm.biz
- ◆ ecoast.bigfirm.biz
- ◆ apex.com

This forest contains two trees, bigfirm.biz and apex.com, and one of the trees—bigfirm.biz—has a child domain. Suppose I rename ecoast.bigfirm.biz to acme.com? Then I've got these three domains in the forest:

- ◆ bigfirm.biz

- ◆ acme.com
- ◆ apex.com

See the difference? Still three domains, but now I've got three trees as well, and no child domains. So renaming is more than just cosmetic—it's a forest rearranger. Renaming cannot, unfortunately, merge domains; for example renaming ecoast.bigfirm.biz to apex.com will not result in all of ecoast.bigfirm.biz being melded into the existing apex.com—the outcome of a rename operation must always leave as many domains in the forest as there once were. And you can't use renaming to change which domain is the forest root, although you can rename the forest root domain.

It all sounds good, doesn't it? Well, get ready for the bad news. . .it's a fairly lengthy process. You will need to perform, at minimum, 14 steps to do this. As Microsoft says in their documents on domain renames, they intended for it to be a *possible* but not *frequent* operation. And, having spent a couple of weeks experimenting with domain renames, I'd say that they're right. Domain renaming is sufficiently complex that I can't even cover it in detail here without adding at least another 60 pages to the book; Microsoft has about 100 pages of documentation on it online and trust me, there's not a lot of fluff there. So just take this as an overview of what you'll have to do when renaming a domain, and please get the Microsoft papers and read them through—the object of this section is to give you a feel what a domain rename will entail.

## THE BASICS

You've already read some of the basics—domains can either be renamed without moving them in the forest, or renames can cause forest moves. Here are a few other top-level considerations.

- ◆ This takes your domain out of service for a while. The domain renaming tool, **random.exe**, attempts to convert all of the DCs over at about the same time. That'll keep all of those DCs busy and, to ensure that people don't change things in the domain while the rename is happening, the DCs basically become deaf to normal requests that clients would make of DCs. So plan for a time when it's okay to bring the network down for a few hours.
- ◆ Rendom tries to do all of the DC conversion by remote control, but in case that doesn't work you might want some way of remotely controlling any DCs in a different site, either with Server 2003's new "headless server" feature, terminal services, or a human onsite. DCs that for some reason can't handle renaming must be removed from the domain. It's worth stressing that the domain rename doesn't propagate via normal AD replication; it's a separate bit of remote control on Rendom's part to get all the DCs converted.
- ◆ If you have a group policy in one domain that is linked to a different domain and either of those domains is the domain that will be renamed, then you'll have to break the link and rebuild it by hand after the rename is finished.
- ◆ You cannot rename a domain unless your forest is at Server 2003 forest functional level.

## GET THE TOOLS

You can find two programs you need to do the rename on your Server CD in \VALUEADD\MSFT\MGMT\DOMREN, **random.exe** and **gpfixup.exe**. There's also a document in that directory that briefly discusses domain renaming and includes a URL to a Microsoft site where you'll find the documents on domain renaming. *Please* download and read them before trying to rename one of your domains.

### DOING THE RENAME

In this example, I'll describe how to rename ecoast.bigfirm.biz to acme.com.

1. First, you set up DNS so that there's a dynamic zone ready to receive new SRV records for the new domain name. Create a DNS zone named acme.com and make it dynamic.
2. Next, double-check that your forest is at 2003 functional level. Open Active Directory Domains and Trusts and right-click the Active Directory Domains and Trusts icon, then choose Properties and ensure that the forest functional level is Windows Server 2003 instead of Windows 2000. If it's not 2003-level, then look back in this chapter to see how to raise the functional level.
3. Then build a "shortcut trust" from the domain that you're going to rename to its future parent, if it's going to move in the forest. The idea is that as the move is happening, there's a brief time when the old automatically built trust will be broken and the new one won't yet be in place. So create a two-way shortcut trust between the domain that's being renamed and its parent because the renamed domain will have to communicate with the parent *during* the rename process. For example, suppose you were renaming bld2.se.acme.com to just bld2.com. The old parent domain was se.acme.com, and now the new parent domain will be whatever is the root domain. So you'd create a shortcut trust to that root domain. But what about ecoast.bigfirm.biz? As you're moving from a child domain to a tree of its own, does its parent change? No, not in this case, because ecoast.bigfirm.biz's parent is bigfirm.biz...which happens to be the forest root. Both ecoast.bigfirm.biz and acme.com end up with the same parent. Now, if you're not 100 percent sure whether you need to create a trust or not, go ahead and build one—it doesn't hurt. Use Active Directory Domains and Trusts to create the trust as you saw earlier in our discussion of forest trusts. The wizard's smart enough to keep you from creating unnecessary trusts.
4. After that, look at any Dfs references. We haven't talked about the Distributed File System yet, but you'll learn in three chapters that it's an improvement over the standard file sharing system that lets you create file system connections not to something like \\servername\sharename, but instead to \\domainname\sharename, so your users don't have to know what server a share's on. It's a neat system...but it won't work after a rename. So go to any systems that use drive mappings, shortcuts, etc. that refer to Dfs shares by domain names and rebuild them to refer to server names.
5. Now it's time to get busy, but to do that you'll need to locate a member server in the domain that you're going to rename; you'll run Rendom from there. Yes, you read that right—you can't rename a domain while sitting at a DC. This will be annoying to people in small domains with just two servers, both of which are DCs. (I suppose you could demote one DC, run Rendom and repromote the server back to a DC.)
6. Log on to the member server as an enterprise admin and put Rendom and Gpfixup on the member server. Open a command line and type **rendom /list**. You'll get a response "The operation completed successfully."
7. Rendom created a file called domainlist.xml in whatever directory you ran Rendom in. Open up domainlist.xml with Notepad. Mine looks like this:

```
<?xml version ="1.0"?>
<Forest>
```

```

<Domain>
  <Guid>de18a3e1-225c-4756-962a-944963e30290</Guid>
  <DNSName>ecoast.bigfirm.biz</DNSName>
  <NetBiosName>ECOAST</NetBiosName>
  <DcName></DcName>
</Domain>
<Domain>
  <!-- PartitionType:Application -->
  <Guid>eea9bbe2-de49-4d32-a234-1e605c901e63</Guid>
  <DNSName>DomainDnsZones.bigfirm.biz</DNSName>
  <NetBiosName></NetBiosName>
  <DcName></DcName>
</Domain>
<Domain>
  <!-- PartitionType:Application -->
  <Guid>d6af0d02-b21c-44b2-a409-88de08dc5f59</Guid>
  <DNSName>ForestDnsZones.bigfirm.biz</DNSName>
  <NetBiosName></NetBiosName>
  <DcName></DcName>
</Domain>
<Domain>
  <!-- ForestRoot -->
  <Guid>ca18330e-f33a-48f1-a11c-8878536cf06c</Guid>
  <DNSName>bigfirm.biz</DNSName>
  <NetBiosName>BIGFIRM</NetBiosName>
  <DcName></DcName>
</Domain>
</Forest>

```

In case you’ve never seen an XML file before, it’s a way of storing data in what is intended to be a self-describing way. The things in the angle brackets are called *tags*—`<Domain>`, `<DNSName>`, `<NetBiosName>`, and the like are tags. Notice that every tag has a partner tag with a `/` in the front of its name, like `</Domain>`, `</DNSName>`, and `</NetBiosName>`. Think of these `<tag>` and `</tag>` pairs as being sort of like left and right parentheses that also describe the data between them. For example,

```
<NetBiosName>ECOAST</NetBiosName>
```

Means “this particular object has a NetBIOSName of “ECOAST.” Armed with this info, you can see a few things. First, the whole file describes a forest, as you can see from the fact that the very first line is `<Forest>` and the last is `</Forest>`. Within that are several `<Domain>`-and-`</Domain>` sets. Each domain contains a `Guid`, a `DNSName`, a `NetBiosName`, and a `DcName`—we’ll need to use the `DNSName` and `NetBiosName` sections. Notice that the first domain’s DNS name is `ecoast.bigfirm.biz` and its `NetBiosName` is `ECOAST`—that’s the domain whose name you want to change. Believe it or not, the way that you tell Remond to rename the domain is to directly edit this file—so change `ecoast.bigfirm.biz` to `acme.com` and “ECOAST” to “ACME,” and save the file.

8. Next, check your work by typing **rendom /showforest** to make sure that you didn't mess up the XML file. The output will look something like this:

```
acme.com [FlatName:ACME]
bigfirm.biz [ForestRoot Domain, FlatName:BIGFIRM]
    DomainDnsZones.bigfirm.biz [PartitionType:Application]
    ForestDnsZones.bigfirm.biz [PartitionType:Application]
```

The operation completed successfully.

That looks correct—`ecoast.bigfirm.biz` is gone, and `acme.com` is visible.

9. Now run **rendom /upload**. That creates another XML file, `dc1ist.xml`, that lists the DCs that the domain rename routine will have to find and modify.
10. Then run **rendom /prepare**, which reads the `dc1ist.xml` file and uses it to find DCs and get them ready for the domain rename. You'll see output something like this:

```
C:\domren>rendom /prepare
Waiting for DCs to reply.
Waiting for DCs to reply.
memsv1.ecoast.bigfirm.biz was prepared successfully
srv1.ecoast.bigfirm.biz was prepared successfully
bigdog.bigfirm.biz was prepared successfully
3 servers contacted, 0 servers returned Errors
```

The operation completed successfully.

11. Now you're ready for the big step—**rendom /execute**. My output looks like this:

```
C:\domren>rendom /execute
Waiting for DCs to reply.
Waiting for DCs to reply.
The script was executed successfully on memsv1.ecoast.bigfirm.biz
The script was executed successfully on srv1.ecoast.bigfirm.biz
The script was executed successfully on bigdog.bigfirm.biz
3 servers contacted, 0 servers returned Errors
```

The operation completed successfully.

12. The domain's mostly renamed, but there are a few items left. First, reboot all member servers and workstations in the renamed domain, *twice*. You need both reboots to confirm the membership and change the domain suffix.
13. Unfortunately **Rendom** can't make the DCs change their domain suffixes automatically, as it did with the member servers and workstations. So you've got to do it by hand—go to each DC and change its DNS suffix from the old domain name to the new one. If you're a Windows 2000 veteran and are looking at me strangely when I tell you to go rename your DC, that's a nice new feature of Server 2003—you can now rename DCs just as you rename all

other systems. (Right-click My Computer and choose Properties, then click Computer Name, in case you've forgotten how.)

14. Then the group policies need adjustment. Do that with `gpfixup.exe`, whose syntax looks like

```
gpfixup /olddns:oldname /newdns:newname /oldnb:oldNetBIOSname
/newdb:newNetBIOSname /dc:name-of-PDC-emulator
```

Where `olddns` and `newdns` refer to the old and new DNS-like AD names, and `oldnb` and `newnb` refer to the old and new NetBIOS names. *name-of-PDC-emulator* is, as you'd imagine, the DNS name of the DC in the renamed domain that acts as the PDC FSMO. In this example, you'd type

```
gpfixup /olddns:ecoast.bigfirm.biz /newdns:acme.com /oldnb:ecoast /newnb:acme
/dc:srv1.acme.com
```

And that's it. Congratulations, you're renamed a domain! Again, let me stress that this was an *easy* rename, as we had only a tiny number of DCs and all in a single site. Be sure to read the two Microsoft documents before trying it on a real domain.

## Active Directory Oddities

We're almost done with the Active Directory but, before I forget, I want to alert you to a few "gotchas" in AD. I'll list them briefly.

### If Two Admins Both Modify a Group, One's Changes Get Lost

One of AD's strengths in comparison to NT is its replication model. Instead of a single read-write domain controller backed up by a bunch of read-only domain controllers, every DC is read-write and a complex multimaster replication structure makes sure that each DC knows about the changes that each other DC receives. Replications over slow WAN links compress data 10 to 1 before transmitting, and administrators can schedule when those replications happen. When you changed a single attribute about a user account under NT 4, NT replicated the user's entire record; AD only replicates the changed attribute.

So where's the problem? AD stores a group's membership as one attribute. Group membership as an attribute in combination with multimaster replication creates another potential problem: membership change collisions. The demise of the single-master model makes the following scenario possible: Suppose there's a DC in St. Louis and another in Ottawa, both part of the same domain. A group called `FaxServerOperators` contains, not surprisingly, the names of the users allowed to administer some mythical fax server software. Now suppose that Julie, a domain administrator in Ottawa, adds herself to the `FaxServerOperators` group, and at roughly the same time Steve, an admin in St. Louis, adds himself to that group.

They've each changed the `members` attribute that is part of the record that describes the `FaxServerOperators` object. Ottawa starts replicating Julie's change locally and across the WAN, St. Louis starts replicating Steve's change, and eventually they collide. Who wins? There's a long algorithm that AD uses to figure that out, but basically it's whoever's change happened last.

What to do about this? There are three possible answers.

First, it might be that you don't modify group memberships all that often, and so there's nothing to worry about. But if you want to ensure that changes to group memberships don't collide, then you could return to the days of NT 4, so to speak, by choosing one of your domain's domain controllers as a kind of "administrative clearinghouse," telling all of your administrators around the globe that before they change a group's membership, they should first focus Active Directory Users and Computers on that "clearinghouse" domain controller. You can do that, by the way, by right-clicking the icon representing your domain. Then choose Connect to Domain Controller and fill in the name of the DC that you want to work with.

Second, you could always use the sneaky "version number" trick that I showed you a few pages back (heh, heh).

Third and best, this is fixed in forests at Windows Server 2003 forest functional level. So get to 2003 forest functional level as soon as possible!

### **Make Changes on DCs Near the Target Client**

The group collision discussion leads to some general advice for administrators in geographically scattered domains: Don't assume that AD's replication structure will respond quickly enough to serve your clients' needs. Let's return to St. Louis and Ottawa, but this time let's make Steve in St. Louis a regular user without any administrative powers, and Julie an admin in a centralized, company-wide help desk. Steve needs something changed in his AD account, perhaps because he's in a different department or his phone extension has changed. He contacts Julie and asks her to update his AD record, and she does.

But how long will it be before Steve sees the changes?

Both St. Louis and Ottawa contain DCs. When Steve queries AD about his account, he's probably talking to a DC in St. Louis. When Julie makes an AD change, however, she's likely to be communicating with a DC in Ottawa. If she and Steve worked on the same site, then all of the domain controllers on the site would know of the change that Julie made within a fairly short time—DCs replicate any changes to the other DCs in their site in 15 minutes. But what about replication across WAN links—how fast is that and how quickly would Steve's local DCs know about Julie's changes? That's up to whoever designed your AD replication structure. Frequent updates across WAN links mean that news of account changes travels quickly, but it also sucks up WAN bandwidth, so if Julie and Steve's company is parsimonious in its use of WAN bandwidth for replication then it might be a while before Steve's local DCs see Julie's changes. But Julie can change that by focusing Active Directory Users and Computers on a DC near to Steve. By initiating the AD change in St. Louis rather than Ottawa, Julie ensures that Steve's local DCs will see the account changes more quickly. The cost is that Julie must do account changes through a DC that's communicating with her at WAN speeds rather than LAN speeds—but what price customer service?

You're probably thinking, "What about changes to passwords? Will they suffer from slow replication?" What if Steve asks Julie to give him a new password, as he's forgotten his old one, and so she does—but while she's connected to an Ottawa DC, not a St. Louis DC. Will Steve have to wait for however long it takes for Ottawa to replicate the new password to St. Louis? No: AD treats passwords a bit differently. Suppose Steve tries to log in immediately in St. Louis, before any of the St. Louis DCs know of his new password. His attempted logon fails, but before the St. Louis DC reports that failure, the St. Louis DC communicates with the single DC in the domain, which acts as something called the PDC Flexible Single Master of Operations, even if that PDC FSMO is across a WAN link. That machine always has the most up-to-date password, and can authenticate Steve for St. Louis.

## Choose Your Domain Names Well

Some things never change. Once you've created a domain, you can't change its name. Of course, there are two work-arounds to that.

First, you could always create a new domain with the newly desired name, then use some directory migration tool to copy user and machine accounts over to that new domain, but that's a nontrivial process, no matter how easy our friends at NetIQ, Fastlane, Entevo, and Aelita are trying to make it.

Second, you can use the Domain Rename Wizard... but it only works if your forest is at 2003 functional level.

## Planning Your Active Directory Structure

The idea of this chapter is to give you an overall idea of how AD's pieces work. I strongly suggest that you peruse the rest of this book before starting in on building your AD structure, as the AD *permeates* Windows 2000 and Server 2003. But here are few hints on how to get started on designing your AD structure.

### Examine Your WAN Topology

Domain controllers in a domain must replicate among themselves in order to keep domain information consistent across the domain. DCs need not be connected exactly 24/7—you *could* just dial connections between branch offices and the home office every day or so and then try to force replication to occur, although it's not simple and may lead to problems down the road—but on the whole you'll find that domains work best if they have constant end-to-end connection. If you have an area that's poorly or sporadically served by your WAN connections, perhaps it's best to make it a separate domain.

### Lay Out Your Sites

Once you know where the WAN connections are, list the sites that you'll have, name them, and figure out which machines go in what sites. Also document the nature of their connections—speed and cost—to assist Active Directory in using the inter-site bandwidth wisely.

### Figure Out Which Existing Domains to Merge and Merge Them

You'll probably want to reduce the number of domains in your enterprise. One way to do that would be to merge old resource domains into an old master domain. The idea here would be that you first upgrade the master domain to Server 2003, then merge the old NT 4 resource domains into that master domain as organizational units, using NETDOM, ADMT, or whatever other migration tools you might buy.

### What Needs an OU and What Needs a Domain?

As you read earlier, you can divide up enterprises either by breaking them up into multiple domains or by creating a single domain and using organizational units to parcel out administrative control, or you can do any combination of those.

This is partially a political question, but you can get a head start by looking at the perceived needs of the organization. Is administration centralized or decentralized? Do the company's divisions work together closely, or is there not very much collaboration? And be sure to get corporate sign-off on these matters from the executive suite or be prepared to deal with the bruised egos later.

From a technical point of view, there are really only a few reasons to use more than one domain, as you’ve read. The biggest reason is replication traffic. If you have two large domains connected only by a slow WAN link, then you may find that it makes sense to keep them as separate domains. But think carefully about it—Active Directory is very efficient at using WAN links for domain replication traffic. There’s also the “we don’t trust the branch office” reason, as well as the far less likely reason that you need to grant different account policies to some group.

### **Choose an OU Structure for Delegation, Then for Group Policies**

I haven’t discussed group policies all that much in this chapter—they’ll get more coverage later in Chapters 9 and 12 and other places—but one thing worth noting about group policies is that they’re a tool for controlling users and computers.

As you read earlier, group policies don’t really apply to groups; they apply to OUs. That would seem to mean that you should organize groups of people that you want to control into OUs so that it’s easy to create and apply group policies to them.

On the other hand, recall that the great strength of organizational units under Active Directory is that you can create groups of users, which you can give varying degrees of control (*delegate*) over those OUs. In the end, you’ll find that delegation can affect system performance more than group policies, so when you’re chopping up your domains into OUs, choose OUs that make sense from a delegation point of view. Does Manufacturing want their own local administrators? Put the Manufacturing users into an OU. Does Publicity want to control their own printers? Then put their printers into an OU. In any case, you probably won’t find much conflict between an OU structure that’s group policy-centric over an OU structure that’s delegation-centric: after all, any group that wants to share an administrator probably also wants that administrator to have control over it through group policies.

### **Use Just One Domain if Possible**

Sorry for the repetition, but let me say one more time: minimize the number of domains. In fact, minimize them to just *one* domain, if possible. Active Directory domains can be truly huge, able to contain millions of objects, large enough for almost any enterprise. And AD’s site-awareness allows it to make good use of your low-speed, expensive wide area network bandwidth.

### **Develop Names for Your Domains/Trees**

Active Directory allows a wider variety of domain names than NT 4 allowed, but sometimes you can have too much of a good thing, too *many* options. If you’re going multidomain, how will the domains fit together? Do you divide geographically, by division, by function? Where are the lines of control in the organization now?

### **Get the DNS Infrastructure Ready**

I hope I’ve beaten this one to death enough so far, so I’ll keep this short. Remember:

- ◆ Create a DNS zone whose name matches your AD domain’s and don’t be afraid to use an imaginary top-level domain.
- ◆ Make sure it’s dynamic or do the jiggy-pokery with delegating the subzones.

- ◆ You needn't use a Microsoft DNS server, but it's not a bad idea, particularly with AD-integrated zones.
- ◆ Split-brain DNS is not only a good idea, it's the *right* idea to protect your zones from external prying eyes for 99 percent of the ADs.
- ◆ If you're having trouble creating extra domain controllers, joining machines to the domain, or just plain logging in, use the `nslookup` tool to check the SRV records for global catalog and domain controllers.

## Use the Power of Inheritance

The notion of things existing inside things runs throughout: organizational units can exist inside other OUs, and of course all OUs ultimately exist inside domains, domains exist inside trees, and trees exist inside forests.

When you set a permission or some other security policy on an object (*object* here meaning an OU, domain, forest, or tree), then anything created thereafter inside that object takes on that security policy. This is called *inheritance*. So, for example, if you wanted every user account in a forest to have to change its password every 10 days, it's far easier to set that rule up at the top of the forest before creating other domains, trees, OUs, and the like, because in general, from that point on, any new trees, domains, or OUs created in the forest will have the 10-day-password-change rule. (I said "in general" because it's possible to block inheritance; it's possible for an administrator to configure an object to ignore effects from higher-level objects.)

## Overall AD Design Advice

There's lots to consider in building your AD and only you know what your organization needs and wants—I can't pass along a standard one-size-fits-all design for an AD. But overall, remember these things:

- ◆ Use sites to control bandwidth and replication.
- ◆ Use organizational units to create islands of users and/or computers, which you can then delegate administrative control over.
- ◆ Use domains to solve replication problems and possible political problems.
- ◆ Use forests to create completely separate network systems. If, for example, your enterprise had a subsidiary that wasn't completely trusted (in the human sense, not the NT sense) and you were worried that the automatic trust relationships (in the NT sense) created by common membership in a forest might lead to unwanted security links, then make them separate forests. The value of separate forests is that there is no security relationship at all between two forests unless you explicitly create the relationship using NT trust relationships.

## Understanding and Using Certificates

Before leaving the Active Directory, let's cover a tool that enhances some of the AD's abilities. You've probably heard the terms *digital certificate* or, more likely, simply *certificate* and perhaps *public key* or *public key infrastructure*, or its inevitable TLA, "PKI." You've probably also heard that Microsoft has included

PKI infrastructure components into its NT-based OSes since Windows 2000. So what can it do for you, and how can you make Windows Server 2003 do it?

PKI is a topic so large that I'd need a fair-sized book to do it real justice, so this section is just an overview of Microsoft's implementation of PKI. The two most significant points that you should get out of it, however, are the following:

- ◆ PKI is a standards-based and OS-independent way to authenticate you—to prove who you are.
- ◆ Although it's got a lot of promise, PKI's not yet heavily used in Windows server operating systems, save in a few applications.

So to answer the “what does this do for you” question broadly: A certificate is a kind of ID card, a passport that proves with a high degree of reliability that you are indeed you. But they're not only good for identifying people—they work for servers as well or, for that matter, just about anything that needs to prove its identity.

But there's more to it than just that. Certificates aren't a Microsoft invention; they're based on standards and vendors other than Microsoft support them, and in fact some of Microsoft's competitors have been heavy users of PKI for years before Microsoft noticed the field. Of course, that may not be a bad thing; after all, that means that Microsoft's PKI tools are based on the latest versions of well-understood technologies. One standard that you'll hear of a lot is X.509, a certificate format that Microsoft adopted for their certificate services.

That was the good news. The bad news is that PKI on 2003 Server is still something of a work in progress. If you were to, for example, “get religion” about PKI and decide that you'd like to rip out the standard underlying Microsoft security systems and replace them with just PKI, then you can't. You can't, for example, tell domain controllers to stop authenticating each other with Kerberos and start using PKI. You *could* set your users up to log on using certificates, but it'd be a bit expensive (see the following comments about smart cards). Here's what you can do with PKI under Windows Server 2003:

- ◆ **Create and use certificates to allow two systems from different domains use IPSec.** As you read in Chapter 6, IPSec is a very nice way to authenticate and/or encrypt IP communications between two (or, actually, more than two) systems across the Internet. But those systems need to be able to authenticate and Microsoft (and the RFCs) only offer three options: Both sides share a simple phrase as the password (yuck), both sides authenticate via Kerberos (not bad, but only works if their systems are in the same forest), or via certificates. Certificates are really the only way that two systems that are not members of the same forest can accomplish IPSec.
- ◆ **Securing Web access.** One of the many ways that you can control who accesses your Web sites is via certificates.
- ◆ **Create and use certificates to secure e-mail inside an organization.** You can create user-specific e-mail certificates that users can use either to authenticate or encrypt their e-mail communications. The only problem is that all parties involved must accept as valid certificates that *your* server creates. Clearly that's a doable thing if we're talking about one company or a couple of companies in partnership, but it wouldn't work so well to secure mail to the great wide world. For that, you need to go to a generally trusted certificate source such as Thawte, which I'll cover later.

- ◆ **Smart card logons.** Certificates are a neat tool...but can you use them for logons? After all, that's the authentication that I'm most interested in most mornings. Sure, you can use them...but there is the small problem of entering the certificate to begin with. In a normal logon with a normal user account and password, you type in your logon name, such as jane@acme.com, and a password. But typing in a certificate would be pretty difficult, as they can be thousands of bytes long. So you *can* log onto a domain or server with a certificate, but only if you've got that certificate stored on a credit-card-sized device called a *smart card*. You also need a smart card *reader* on your system to do this. I found that add-on USB smart card readers cost about \$40 apiece—not a deal-breaker, but, if you need a lot of them, probably a bit much to spend for a technology that's just getting started in the Microsoft world. In any case, smart cards relate to certificates in this way: If you want to do smart cards, then you *must* use certificates.
- ◆ **EFS recovery agents.** The Encrypted File System lets you set up people who can decrypt your files in the event that you don't remember your password. You designate new *recovery agents*—the emergency decrypter guys—with certificates.
- ◆ **Signing programs.** As you probably know, Windows 2000 and later operating systems support the idea of “signing” a given program, software installation package or driver, ensuring either the software's provenance or that it's been tested by Microsoft's hardware lab. That signing is done with certificates.

All of this is a good thing, but as I say it's just an interim step. In the future, it'll be possible (as a matter of fact, this is possible now, but it's unusual) to carry around one smart card that holds your personal certificate. Now suppose you have an account that you use on a Novell network, one on an Active Directory forest, a One-Click account at Amazon.com, and so on. Here's how public keys will make your life easier: You give a copy of your certificate to the Novell network's administrator, the AD forest's admin, Amazon, and the other folks who have an account of yours. They then make an association between your certificate and the local account that they keep for you, a process called “mapping the certificate to the account.” From that point on, your smart card gets you access to all of those accounts. Just one password to worry about, and finally that Holy Grail of account management—single logons. Log on once at your PC and you're connected everywhere.

Of course, that's not the only way that PKI could work. You could keep a certificate encrypted on your workstation and then use a standard login to decrypt it; it would then get you logged onto your Novell, Amazon, and other accounts. Or why not just put the certificate on a floppy? That'd work too...but in every case security is the issue, and as floppies are easy to copy and hard to secure I suppose that's why you don't see this answer. It's a shame, though, because although smart cards are a neat idea, it's going to be years (if ever) before smart card readers are standard on PCs. (And then we get to fight over which vendor's smart card technology we adopt, and, well, you've seen that movie before.) So personally I wish that we could use floppies as a sort of interim smart card, but I don't imagine it's going to happen soon.

Let's look a bit at how PKI works under the hood, then look at some of the specifics of PKI in Windows Server 2003.

## Public Key Pieces I: Public Keys, Private Keys, and Authentication

Certificates and PKI terminology includes a lot of references to *public* and *private* keys. Let's see what they are and how they let people identify themselves to others. For example, suppose I want to

negotiate a contract with you electronically, over e-mail. It's easy enough to send proposed documents back and forth, but the last part—the legally binding signature indicating agreement—that's been tough to do over e-mail. But what if I could send you an e-mail saying “I agree” that you could be 100-percent sure came from me? That'd do the trick.

All I'm looking to do here is prove that I sent it. There's nothing secret in the e-mail, so I have no need to encrypt it; I just want to *authenticate* it, or, in public key terminology, to “sign” it.

### KEY FACTS ABOUT KEYS

To do this, I ask my computer to generate two numbers called a *private* key and a *public* key. They're called *keys* because I can use them to lock (that is, encrypt) some bunch of data, or to unlock (that is, decrypt) that data. (I know I just said that I don't want to encrypt the e-mail, but we *will* need to encrypt a bit of data, as you'll see.) PKI can be easy to understand, but you'll find it puzzling unless you're clear on a couple of things:

- ◆ Again, there are two different “keys” generated.
- ◆ They are quite long numbers, hundreds of digits long. That's so that it'd be nearly impossible for someone to just try every combination with a computer program—some keys are so long that the fastest computer in the world would take trillions of years to try every combination! (And by then, I probably wouldn't worry about the attacker cracking my data.)
- ◆ PKI uses the keys for encryption and decryption of data.
- ◆ We arbitrarily choose one of the two keys to be the private key and keep it hidden—no one should ever see this. The other key is the public key, and we can hand out it to anyone. For a long time, cryptographic algorithms used “symmetric” encryption, meaning that you used the same key to *encrypt* as to *decrypt*. But in 1970 or 1976—depending on whose story you believe—mathematicians came up with an interesting new kind of cryptographic method that uses *one* key to encrypt and a *different* key to decrypt. This is called *asymmetric* encryption. PKI uses asymmetric encryptions.

**NOTE** I say “depending on whose story you believe” because for a long time the researchers credited with first describing and making practical an asymmetric encryption technique were two American mathematicians named Whitfield Diffie and Martin Hellman, who first presented their technique in 1976. In 1997, however, a British cryptologist named James Ellis claimed he'd created the idea for British intelligence back in 1970.

- ◆ If you encrypt something with the public key, only the private key can decrypt it. If you encrypt something with the private key, only the public key can decrypt it. Things encrypted with the public key *cannot* be decrypted with the public key, and things encrypted with the private key cannot be decrypted with the private key.

### PREPARING AND SIGNING A MESSAGE

So let's see how I can use public and private keys to send some secured e-mail.

First, I run a program to generate a public/private key pair. I hide the private key somewhere safe on my hard disk. I make my public key easily available to anyone who wants it—hand it out on floppies, put it on my Web site, whatever. (We're going to refine this process soon, I promise, but for now let's just hand out public keys this way.)

Next, I prepare my message for you, something like “I agree to the following contract,” followed by the text of the contract. That’s our message body. I give it to my e-mail client and tell the client to “sign” the message.

The e-mail client then runs the message text through a program called a *hash function* that boils down the message to just a few bytes, a *digest*. Hash functions are also called *one-way functions* because you stuff in some data (your message, in this case) and get out a digest, *but you can’t necessarily reverse the process*. That’s not necessary. For example, suppose I wanted to hash the message “Meet me at the bridge.” I want to boil that down to just a single number. I could do that by noticing that text files are all ASCII and that ASCII codes are numeric—“m” is 109, “e” is 101, a space is 32, and so on. My message then becomes this:

```
m e e t <space> m e <space> a t <space> t h e <space> b r i d g e
109+101+101+116+32+109+101+32+97+116+32+116+104+101+32+98+114+105+100+103+101 = 1,920.
```

Thus, I’ve boiled down the message into a single number, a digest. We’re going to use that in a minute to prove that the message did indeed come from me. But before I do, let’s notice why this is a one-way function. There would be no way to deduce from 1920 that the original message was “meet-me-at-the-bridge” short of generating all possible messages, computing their digests and then looking at the messages whose digests were 1920—and there’d be a lot of them—and guessing which one was my original message. (And, by the way, I just showed you the simplest hash function possible—crypto systems actually use more complex ones.)

So let me stress—digests aren’t for *transmitting* data; they’re for *authenticating* a data stream’s author, or at least that’s what we’re about to try to do.

Now we’ve got a message body and a digest created from that message body—now it’s time to do some encrypting. Using my private key, my e-mail program encrypts the digest. It then sends you an e-mail containing two things: the message text and the encrypted digest of the message text.

## RECEIVING AND VERIFYING THE MESSAGE

Now let’s see what you do on your end. Your e-mail client receives the message and notices that it is signed. Time to check the signature! So the e-mail program takes the message and, using the same hashing function as my e-mail client, computes a digest for the message.

Now, if the digest that I sent you (based on the message text that I sent) is the same as the one that you compute (based on the message that you received), then we can be pretty sure that you received the message accurately. But how do you know that the message came from *me*? That’s where the encrypted digest comes in. You compute that the digest of the received message equals 1920. You want to check that against the digest that I sent you—but it’s encrypted. Remember that I encrypted it using my private key. The only key that can decrypt it, then, is my public key—which you’ve already gotten. So your e-mail program decrypts the digest and sees that the decrypted value is 1920.

You could only have gotten a decrypted value of 1920 from my public key if the original value that encrypted the digest was my private key. You got a matching value—1920—so the message digest must have been sent by me. If anyone had tampered with the message en route, then you’d have a message that would lead to a different message digest value.

In this way, we can use public keys to verify that a message did indeed come from a particular sender.

### WHY THIS IS IMPORTANT: NO “SHARED SECRETS”

Notice something about that communication—I sent something to you that I was able to guarantee came from me using encryption; I was able to perform the equivalent of physically signing a contract, but at a distance. We didn’t *need* public and private keys to do that, however. Alternatively, I could have just called you up at the beginning of our negotiation process and said, “Let’s do this over e-mail, but to make sure that we authenticate each communication, we’ll send along encrypted digests of the mails.” So far, this is no different from what we did. But if we didn’t have public key technology, then you’d say to me, “Okay, how do I decrypt these digests?” I’d then have to say, “Hmmm...for this negotiation, I’ll encrypt the digests with the password u8Kj\$3NsF. Use that password to decrypt the digest.” In other words, we’d do the same thing as we did before, but instead of using an asymmetric encryption method, we’d use a symmetric encryption method. That involves no great brain power, as people have been doing symmetric encryption for centuries. This password, which is known to us both, is called a *shared secret*, and all symmetric encryption methods require shared secrets.

But do you see the weaknesses in this method?

I’d have to get on the phone with you and read you a password—quite a pain. You might mis-transcribe it, as uppercase and lowercase matter. You’ll probably write it down somewhere, certainly as you’re taking the message from me. And what if it’s just plain difficult to find a time when we both can get on the phone, such as if you’re on the other side of the Earth? (That may be the reason we’re creating a business agreement electronically to begin with.) Or I guess I could just send it to you in an e-mail, but then I’m sending a password over the Internet—the not-so-secure Internet—and then I’d have to worry that someone intercepted that password.

Additionally, I’d have to come up with a different password every time I negotiated something via e-mail, as I wouldn’t want to use the same password with more than one person—if word got out that I always used “rutabaga” as my password, then anyone could digitally impersonate me.

That’s the neat part about public/private key pairs. I didn’t have to tell you anything except my public key, and I don’t care *who* has that.

### Public Key Pieces II: Encrypted Communications (SSL)

You’ve seen that one of the keys—no pun intended—to PKI is encryption. We just used it to verify a message’s sender, but we didn’t really encrypt much of anything—just a few bytes of a message digest. But sometimes we want to carry on an entire conversation in secret, to encrypt the entire transmission.

For example, let’s consider an encrypted transmission method that you’ve probably used quite a bit over time—a Secure Sockets Layer, or SSL, communication. You do one every time you buy something on the Internet and that little lock icon appears in your Internet Explorer status bar. That communication depends upon public and private keys, as you’ll see.

Suppose you’re going to buy something from Bigfirm on its Web site. You click the Buy Now link next to some piece of merchandise, and your Web browser sees that the destination of that link wants security—the URL of the page is <https://something> rather than <http://something>. (The extra *s* means *secure*.)

Your browser and Bigfirm’s Web server will communicate via symmetric encryption. They’ll agree on some key and then they’ll use that key to encrypt transmitted data and also use that same key to decrypt received data. (Why not asymmetric encryption, you ask? Well, for one thing, it takes a *lot* more CPU time than symmetric encryption.)

So your Web browser and Bigfirm's Web server say, "Okay, just for today we'll agree that we'll use the key KD39z82fRnx+H to encrypt and decrypt. If we ever talk again, we'll pick another random key for *that* session—but use this one for this particular session."

Simple, eh? Sure, except for one problem: *How do they agree on the key?* The whole idea is that you don't want someone to be able to just listen in on the communication and decrypt the traffic as it goes by, particularly if that traffic includes the information "Joe Smith lives at this address and his credit card number is such-and-such." So we encrypt the communication, and so no one can listen in. Sounds good, except for one little thing.

How does Bigfirm's Web server tell your Web browser, "Let's use the key KD39z82fRnx+H?" Clearly it shouldn't communicate that information in cleartext (that is, unencrypted text), or the bad guys will just make use of the very same key to listen in on (and perhaps even modify) the conversation. So symmetric encryption will help us...if only we can get the whole thing started with a secure exchange of keys.

*That's* where *asymmetric* encryption comes in. Let's see how.

To begin with, Bigfirm's Web server has a public and a private key. Your Web browser, on the other hand, does not. (Why not? Well, do you remember telling it to create one? No? Then it hasn't got one. And even if it did, it wouldn't use it in this context, trust me.) So how could we use encryption to exchange keys? Well, the Bigfirm Web server *could* generate a session key—that's the phrase for these use-'em-one-and-throw-them-away keys, like that KD39z82fRnx+H key I've been talking about—and encrypt it before sending it to your Web browser.

But consider this: If Bigfirm encrypts the key with its private key, then the public key will decrypt it...but *everyone* has Bigfirm's public key. Well, then, what if Bigfirm encrypts the key with its public key? Well, then, you'll need Bigfirm's private key to decrypt it, and the bad guys don't have Bigfirm's private key, so they won't be able to steal the session key.

Unfortunately, *you* won't be able to use it either, as you also lack the private key. What to do?

Let's look at the other way around: What if *your Web browser* were to suggest the session key? Here's how it works:

- ◆ Your Web browser knows Bigfirm's public key and uses it to encrypt the session key.
- ◆ Your Web browser then sends the encrypted session key to Bigfirm's Web server, which uses its private key to decrypt.
- ◆ Now you've got an agreement on a key that you can use for encrypting traffic between your Web browser and Bigfirm's Web server!

You will hear the phrase *key exchange* a lot in PKI. It usually means the same thing: We intend to establish some communication that we want to encrypt using a symmetric encryption algorithm. But to agree on a key in the first place, one side encrypts a suggested session key with the *other* side's public key. The other side can then decrypt it, and no one can snatch the session key as it goes by on the wire but the intended recipient.

### Public Key Pieces III: Certificates and Certificate Authorities

Thus far, you've seen that we can "sign" or "authenticate" a communication, leaving the communication in cleartext but allowing the receiver to verify that I'm the message's sender and that the message wasn't modified along the way. You've also seen that we can use public and private keys to

exchange session keys that we can then use to encrypt an entire transmission, both authenticating it and ensuring that no one snoops on it.

But there's something I've kind of swept under the rug so far—how those public keys get disseminated. How would your Web browser get a copy of Bigfirm's public key? How would your e-mail client get my public key to use in verifying my message in the first place? I kind of waved my hands and said that I could give you my public key on a floppy or put it on my Web site, and that's only partly true. Yes, I could put my public key on a floppy, but then how would I get it to you? If you lived down the street, then I could hand it to you. If you lived far away, I could FedEx it to you, but that would get kind of expensive, and takes time. Sure, I could put my public key on my Web site, but then we're faced with a chicken-and-egg question: How do you know that you're actually looking at my Web site when you grab that public key and not a clever copy that some bad guy creates while somehow diverting your DNS lookups of `www.minasi.com`? You can't, so we need another method of handing out public keys. That method is called *certificates*.

### WHAT'S IN A CERTIFICATE

A digital certificate isn't a physical certificate with an attractive border and your name in big fancy letters; instead, it's just a bunch of bytes that contain, at minimum:

- ◆ The name of the thing that the certificate describes—it might be a person (the e-mail example), a server (the SSL example), or anything else. Certificate documents call this the *entity*, as it's a nice generic name for “person, server, or whatever.”
- ◆ The public key of the entity. (Notice how quickly we slip into that cert-speak—entity.)
- ◆ When the certificate expires. Certificates have an expiration date. For example, the SSL certificate on my Web server expires every two years.
- ◆ What kind of certificate this is. There are certs for securing e-mail, certs for identifying servers for IPSec, certs for securing Web servers via SSL, and so on.
- ◆ Who issued the certificate. I'll explain this in a minute.
- ◆ Other identifying information, which varies with the type of the certificate.

### GETTING A CERTIFICATE

That's what's *in* a certificate—but what *is* a certificate? Put simply, it is a public key and some identifying information about you, as you saw in the previous bullets, all collected and then digitally signed by someone else. The idea is that when I need to give you my public key then, as I said before, I can't just hand it to you unadorned, as you have no real way to know that it came from me. So instead I hand it to you...but the bytes that I hand you have been digitally signed by some third party that both you and I trust.

If that's not clear, let's see what happens a bit more specifically. First of all, I need a certificate before I can give one to you. Here are the steps to getting one.

First, I generate a public/private key pair. But why would anyone believe that it was actually me that generated the pair or, actually, the public key, as I'll never show you the private key? That's where the next step comes in.

Next, I contact a company that issues certificates, a *certificate authority*, or CA. Examples of such companies would be VeriSign, Thawte, or Baltimore. I give them my public key and ask them to create a certificate. Only *they* can create a certificate signed by them, as only they have their private key,

and they generally charge for the service. (Or, in some cases, I might instead create my *own* CA and start minting my own certificates. I'll show you how to do that later.)

After that, the CA wants to make sure that I'm actually me, so they usually want to see something that validates my claim. For example, if I want a certificate for `www.minasi.com`, then I've got to prove that I actually own `minasi.com` and am doing business under that name. Verifying *some* certificate types is easy; to validate an e-mail certificate, you've just got to send the certificate to that e-mail address.

Once the CA is satisfied that I'm me, they build the certificate, including my name, public key, expiration date, and who they—the issuing CA—are. Then they run it through their hashing function, and the digest for the certificate pops out. They then pull out their private key and encrypt the digest. Put it all together and it's a certificate. They e-mail it to me and I install it on the appropriate software—it might be Outlook if it's a “Hey, I'm really Mark Minasi” certificate for e-mail, or IIS if it's a Web server certificate.

### USING A CERTIFICATE

Once I've installed the certificate on my system, here's how it gets used. Suppose again that I send you a piece of e-mail that I want to digitally sign. I'll take you through the steps on it, but first let's cover certificate types.

#### Types of Certificates

I'm about to explain how I could use a certificate to prove that a piece of e-mail that I send you actually came from me. But I want to note that while I've been just saying “certificate” as if they were all the same, they are *not*, not by any means. Certificates associate some identity and usually some attribute to a computer, user, or service. For example:

**E-mail** I've already mentioned e-mail signing certificates and encrypting certs without actually saying that they are two different kinds of certs. You can get a certificate that does both, but you sometimes won't. Inside that certificate would be a bit of information that says, “This certificate can be used for e-mail signing,” or, “This certificate can be used for e-mail encryption,” or both. *Why* would you have two different certificates for signing and encryption? Because you use them in different ways. You need the encryption key to decrypt encrypted mail that people send you. You need the signing key to prove that you are you over e-mail. You'd have two keys because you want to back up the encryption key, *and you never want to back up the signing key*. If you lost the encryption key, then you would not be able to read any old or new encrypted mail, so you'd want to restore that key. But if you lost your *signing* key, then there's no problem—you just get another one. But you would never want to back up your signing key because if someone got hold of the backup and installed it on her system then she could impersonate you! E-mail certificates are typically associated with a user.

**Web browser** Suppose you want to access a restricted Web site. How do you prove who you are? One way is to create a Web browser certificate and associate it with your user account. This is different from an e-mail certificate because it is typically associated with a particular user account *on the Web server*.

**Server** If you wanted to use IPSec to secure communications between two computers and wanted to use certificates, then each of those computers would have to have server certificates—a certificate associated with a computer rather than a person.

**CAs** CAs have certificates that identify them as certificate-issuing authorities.

**EFS recovery agents** You can designate extra people who can recover encrypted files, *EFS recovery agents*, only by issuing certificates identifying those people.

**Software** Microsoft signs drivers with certificates that are not user or computer-oriented, but instead certify that someone has tested a piece of software.

### **Using a Certificate to Sign an E-mail**

First, I create the message. As before, Outlook runs the message through a hashing function and gets a digest. It then uses *my* private key to encrypt the digest. Outlook then assembles the e-mail message by combining the message and the encrypted digest as before, but then adds *a copy of my certificate*, sending them all as one digitally signed e-mail message.

After a bit, your computer receives it. It sees that there's a certificate attached to the message and looks in the certificate for the issuing CA. (Let's just say that it was Thawte. They'll give you an e-mail certificate just for the asking at / [www.thawte.com/html/COMMUNITY/personal/index.html](http://www.thawte.com/html/COMMUNITY/personal/index.html).)

Next task: to validate this certificate. Remember that your system isn't validating my message; that'll come in time. Instead, this is your e-mail client—let's say you run Outlook also—saying, "I'm going to use Mark's public key to validate his message, but I only know that it's his public key because Thawte says that it is. But how do I *know* that Thawte actually generated this certificate? Ah, the certificate contains an encrypted digest *of the certificate*. I can check that. . ." and so it hashes the certificate to get a digest *of the certificate*, not the message. It then wants to compare to the digest attached to the certificate to the one that it just computed. But how does your computer decrypt this digest so that it can compare it to the one that it just computed? Well, Thawte created the e-mail certificate with its private key, so your computer needs Thawte's public key. But where does your computer get Thawte's public key?

You may be surprised to learn that it's already on your hard disk. So let's make a slight digression and talk about certificate stores and how to see the ones on your system.

### **Certificate Stores: User, Computer, and Service**

Your computer has a place in its Registry called its *certificate store*. And not only does your *computer* have a certificate store, your user account also has one. It's also in the Registry. Services running on a system even have certificates. (I'm not going to cover certificates for services much here, so I won't mention this again, but whenever I refer to computer and user certificate storage, remember that there's a certificate storage for each service as well.)

That's an extremely important point, so let me say it again: There is more than one certificate store on a computer. Sometimes you'll want a certificate in your user store rather than your computer store or vice versa. For example, you will find that your copy of Windows in just about any version comes with copies of certificates containing the public keys of Thawte, VeriSign, Baltimore, and dozens of other CAs. Those sit in the computer's certificate store, not yours.

To underscore how that might affect you, consider what might happen if a brand-new certificate authority appeared, Joe's Discount Certificates. Where VeriSign wants hundreds of dollars to issue a certificate to your Web server so that you can do SSL transactions, Joe will issue one for five bucks. So a favorite vendor of yours, Acme Closeout Center ([ac-close.com](http://ac-close.com)), buys and installs some Joe's Discount SSL certificates, saving themselves a few bucks.

You notice this the next time that you try to visit ac-close.com. Your computer wants to set up a secure SSL session with ac-close.com and when it examines ac-close.com's certificate, then your computer wants to validate that certificate. It sees that Joes' Discount Certificates signed the certificate, and so it wants to validate Joe's Discount Certificates...but your computer can't, as it doesn't already have a copy of Joe's public key in a certificate. So IE pops up a scary-looking message informing you that it can't validate the SSL transaction.

The Acme guys know this and have placed a note on their Web page explaining that you need to first download and install Joe's certificate containing his public key. So you download the certificate. But here's the question: Do you download it to your machine's certificate store or your user account's certificate store? It depends. If your user account roams then you might want to have Joe's public key in your user store, as it'd roam with you. No matter what computer you were sitting at, the copy of IE on that computer could set up secure SSL sessions with Acme Closeouts, as it'd find a certificate for Joe's, the issuing CA for Acme's SSL certificate. On the other hand, if you wanted anyone who sat at a particular computer to be able to connect to Acme without any complaints, then you'd put the certificate into the machine's certificate store.

**NOTE** *I should mention here that if you're using the Active Directory then a lot of this stuff becomes automatic. I'm showing you the simpler non-AD setup so that you can understand what's going on under the hood.*

**WARNING** *If you're using Netscape Navigator, then things work a bit differently—for some reason, the PC version of Netscape doesn't use the certificate store built into the operating system. So assume that when I'm referring to some behavior in a Web browser I'm referring to Internet Explorer.*

### **Installing the MMC Certificates Snap-In**

But how do you acquire, view, and remove certificates? You manage certificates with an MMC snap-in. You're going to create a custom MMC that will let you manage certificates for both your accounts and your computer's account:

1. Start up a blank MMC: Click Start/Run, then fill in **mmc**, and press Enter.
2. In the MMC, choose Console, then Add/Remove Snap-in, then Add and choose Certificates, and click Add again.
3. As you can manage certificates for your user account, your computer's account, or a service's account, the MMC needs to know which you intend, and offers you all three choices. Tell it that you will manage certificates for Computer Account rather than My User Account or Service Account, then click Next and Finish.
4. Now you'll add a *second* Certificates snap-in, but this second one will manage your user account's certificate store. In Add Standalone Snap-In, Certificates will already be highlighted. Click Add again to add it to your MMC the second time. This time, when it asks whether you'll manage a computer, user, or service account, just click Finish.
5. Now click Close to clear the Add Standalone Snap-In dialog box and OK.
6. You're going to save this snap-in, so do a bit more cleanup. Click File, then Options.
7. Where you see Console Mode, choose User Mode—Limited Access, Single Window.

8. Next to the icon at the top of the dialog box, click the Change Icon button so you can find a better icon than that lame old hammer.
9. In the Change Icon dialog box, click the Browse button. It'll take you to `winnt\system32`. Navigate to `C:\WINNT\system32\certmgr.dll` and double-click it to display its icons.
10. Pick an icon and click OK.
11. Click OK to clear the Options dialog box.
12. Save the tool so you don't have to build it again. Click File/Save As and in the File Name field, fill in a name, such as **Certificate Manager** and then click the Save button. Now, when you open `Certificate Manager.msc`, if you expand all of its folder, then you'll see something like Figure 8.92.

**FIGURE 8.92**

Certificate Manager for user and computer certificate stores

**TIP** You may well have other folders in your Certificate Manager, particularly if you're on a system that's a member of an AD. Don't worry about it; all of what I'm describing will still work.

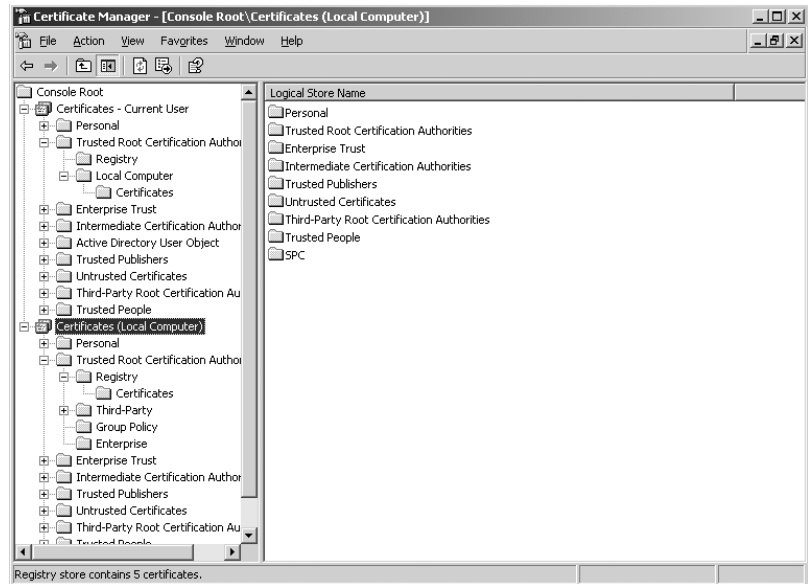

Look in the folders named **Trusted Root Certification Authorities\Certificates** under both the computer and the user store, and you'll see the certificates that I mentioned—VeriSign, Baltimore, Thawte, and dozens of others.

But even though it *looks* as if all of those CAs have certificates in your user store, they don't really. Instead, when you log onto a system, you temporarily “inherit” all of the certificates that the machine's store holds. You can see this with a little more clicking.

Click **Certificates (Local Computer)** and then choose **View/Options**. You'll see a **Physical Certificate Stores** check box; check it and click OK. Then click **Certificates—Current User** and, again, choose **View/Options** and check **Physical Certificate Stores**. When you open the folders under **Trusted Root Certification Authorities**, then your MMC will look something like Figure 8.93.

**FIGURE 8.93**

Certificate Manager with physical stores revealed

Notice that under the computer's folder, there are four folders—**Registry**, **Third-Party**, **Group Policy**, and **Enterprise**. This reflects the four places that together make up the machine's certificate store. Click **Registry/Certificates** and you'll see all of the CAs that you saw before. But now look under the **Current User's** icon for **Trusted Root Certification Authorities**—there is a **Registry** folder again (which you'll probably find is empty), and a folder called **Local Computer** with a folder inside it called **Certificates**.

That **Local Computer** folder is nothing more than a kind of “shortcut” to the **Third-Party** section of the *machine's* certificate store! Click there and you'll see all of the same CAs that you just saw.

And in case you're wondering, the **SPC** folder (which also has subfolders for **Registry**, **Group Policy**, and **Enterprise**) holds certificates of software publishers that you have agreed to trust—or at least Help says that it's supposed to be. Mine's empty even though I've trusted Microsoft and Macromedia software signing certs in the past.

### **Outlook Verifies the E-mail Key**

Now that I'm done with the side-trip about certificate stores, let's finish up the signed e-mail example. Recall that your computer had just gotten the e-mail and needed to verify the certificate. Your system has a copy of Thawte's public key and uses it to decrypt the digest on the certificate. It checks out—the digest created by Outlook from the certificate's contents matches the decrypted digest attached to the certificate—and so Outlook knows that it can trust the information on the certificate.

Now that Outlook knows that it can trust the information on the certificate, it reads *my* public key from the cert. It can then use that public key to verify the message that I sent, by again computing a digest, this time on the entire message, and then decrypting the enclosed digest and comparing them.

## Trusting Certificate Authorities

Thus far, you've seen that:

- ◆ Public/private key pairs provide a way to authenticate or sign communications and to encrypt communications without having to use shared secrets.
- ◆ I need your public key for us to communicate, and you must enclose it in a certificate when providing it to me.
- ◆ I want to know that this is indeed *your* public key and so you ask a certificate authority to digitally sign the certificate.
- ◆ To validate that CA's digital signature I need the CA's public key, also provided in the form of a certificate.
- ◆ This could lead to the question "who validates the CA's certificate" *ad infinitum*, so Microsoft makes life easier on us by prestoring the certificates of major CAs on my computer in a certificate store.
- ◆ Computers and user accounts (and services as well) each have their own certificate stores.

The fact that Microsoft preloads Thawte's certificate on my computer relieves me of having to worry about how to get an honest-to-God copy of that certificate. But what if I want to use a CA other than the ones preinstalled? And that's not an unlikely circumstance, as two very common events would require me to answer that question:

- ◆ My company will probably set up its own CA for issuing certs that it will use internally.
- ◆ My firm might also have business partners, and we might have agreed to trust each other's certificates. Thus, if Bigfirm and Acme agree to give each other some amount of access to each other's servers, then they need to authenticate each other. Certificates can be quite a useful way to do this. If Bigfirm agrees to accept Acme's certificates, then Bigfirm will need to install a certificate containing Acme's CA's public key on its systems, and Acme will need to do the same things for Bigfirm's CA's public key.

### TRUST AND SELF-SIGNED CERTIFICATES

Consider that *trust* word I've been using. What does it mean in a certificate sense? Consider a real-world thing that is sort of like a certificate: my driver's license. Suppose I want to get on an airplane. The ticket agent needs to see my ID or I don't get a boarding pass; let's see why.

The airline's desire is to verify that the ticket issued to Mark Minasi is indeed in the hands of Mark Minasi. It tries to do that by reasoning in this way: First, match the written name on the ticket to the written name on the driver's license. Then, verify that the name Mark Minasi goes with the person holding the driver's license by looking at the picture on the driver's license and then comparing it to the face of the person holding the license. Finally, they know that the license, which associates the name Mark Minasi with the face in the picture, is trustworthy because it was issued by the state of Virginia.

*That's* the key to understanding trust here—they don't really trust the driver's license, they trust that the state of Virginia has done some work to validate my identity. If a driver's license is a certificate, then, Virginia is the certificate authority.

But why should they trust Virginia? I mean, they don't have an army, issue currency, or have treaties with foreign countries; they don't have a seat on the UN, so why trust them? The answer is, "Because

we just do.” Even if I’m in a state other than Virginia, the driver’s license is still accepted—Florida residents, for example, trust Virginia. As a matter of custom and convenience, at some point you choose to trust some authority for identification.

But that doesn’t always work. Most places outside of the United States don’t accept driver’s licenses issued by U.S. states as proof of identification. Instead, they want a passport. But let’s imagine that some country, say, Turkey, didn’t require a passport, and instead accepted U.S. driver’s licenses as proof of ID. Why would Turkey “recognize” Virginia? It probably wouldn’t. Instead, Turkey might reason in this way: “We have treaties with the U.S.; we believe that they are a viable and relatively reliable political entity. Now we look at this certificate—driver’s license—for this guy Mark Minasi. We don’t know him, but he’s got this ID issued by some ‘state’ called Virginia. We don’t know *them*, either, but they’re vouched for by the U.S. government—and *them*, we know! So we accept that this guy is indeed Mark Minasi.”

This is an example of a “hierarchy of trust.” Let’s apply it to the e-mail example. To review:

- ◆ You wanted to validate my certificate, which was signed by Thawte.
- ◆ So you needed Thawte’s public key to check my digest.
- ◆ You found it in Thawte’s certificate, which was sitting in your certificate store.

But now let’s take it a step further: How do you validate Thawte’s certificate, the one that Microsoft put in your certificate store when you installed Windows on your system? Well, if you take a look at Thawte’s certificate, then you will see that it, too, is digitally signed and therefore can be validated.

But who signed it?

Thawte, that’s who. The certificate containing Thawte’s public key is signed, all right—using Thawte’s public key. It’s a “self-signing” certificate.

Well, what the heck good is *that*? Well, it’s a *little* useful. After all, it’s at least *internally* consistent; if the certificate’s digest didn’t match an actually computed digest, that’d be bad. But in the end analysis, you are simply trusting—in the colloquial sense of the word—that Thawte is a well enough run company that they won’t give out bogus certificates (it’d be bad if Thawte gave some hackers a certificate for a Web server that said, “Yes, this is the dell.com Web server”) and that Microsoft didn’t put the wrong certificate for Thawte into your copy of Windows.

In the PKI sense, “trusting” a CA means that you have installed their certificate in your certificate store.

## TRUST MODELS

So you’ve seen that PKI can’t work without trust and that a given machine trusts certificates issued by a given CA by placing that CA’s root CA certificate in the machine’s certificate store. You might call this the *Web trust* model—just as Microsoft has placed 98 root CA certificates in your Windows Server 2003 certificate store, you can add root CA certs for other CAs as well.

But there’s one more piece to trusting that’s worth mentioning here—delegation of trust. It’s possible for your organization to have a *hierarchy* of CAs. Instead of just one machine issuing all of the firm’s certificates, a number do. Why divide up the job? Three basic reasons: to spread out the work, to let subdivisions of the organization control their own machines acting as CAs, and to *truly* secure the root CA machine.

The first reason should be obvious. I haven't mentioned this yet, but if you integrate your PKI with the Active Directory then every user and machine account *automatically* requests a certificate. With a large organization of tens of thousands of people, it'd be just impossible to get fast enough turn-around from one machine. So perhaps the Chicago office gets its own CA, Minneapolis gets one, and so on. But instead of having to run around and tell every machine to trust certs from Chicago, Minneapolis, and the other cities, you just tell them all to trust your root CA. What happens, then, when a machine gets a certificate created by a subdivision's CA? Well, recall the sequence of trust—you used my e-mail cert's signature to trust it because it was signed by some CA and you trusted that CA because it had a certificate which was signed...by the CA itself. With a lower-level or "subordinate" CA, you just add a layer: A machine in Minneapolis has a cert signed by the Minneapolis CA, which has a cert signed by the root CA, which has a cert signed by itself. No more administration, but a good way to balance out the load. Nice—very scalable.

The second reason may happen if your firm's divisions tend to run their own IT infrastructure. Maybe Engineering wants their own CA. Or perhaps you view different kinds of certs as more or less important—maybe you want to secure the system that hands out SSL certificates more than the one that hands out e-mail certificates. In any case, it's the same approach. The subordinate CA has a certificate signed by the root CA.

The final reason is kind of interesting. I did some work for a large public certificate authority and at one point, they said, "Would you like to go see the Root CA?" (I could just hear the capital letters in their voices.) "Sure," I said. They took me through this vault into a room with layers and layers of security, which led to a room that contained...a computer. Just a computer, no network connections. Just a stand-alone machine. The idea is this: Companies such as VeriSign, Thawte, Baltimore, and the like don't have just one CA, they have many machines. But it's a hierarchy and *something's* got to be at the top. So they build a bunch of subordinate machines that generate certificates. Once that's done, there's really not much for the root CA to do but to generate certificates for the subordinate CAs. Once that's done, it probably makes good sense to keep the top dog off the network, as the hierarchy of trust ends with it. If someone were to hack that system and steal its private key, then they could issue bogus certificates in the CA's name...and they'd be instantly out of business. This way, the worst thing that happens is that a subordinate CA gets hacked. Then *it* could be impersonated, but not the entire CA.

## Running Your Own Certificate Authority with Windows Server 2003

Let's sit down and try it. You'll build a simple CA with Windows Server 2003 and create a few certificates.

### CREATING A CERTIFICATE AUTHORITY

All you need to make a Windows Server a CA is to install Certificate Services...and convince some systems to trust your certificates! I'll establish a CA called Avian Secure CA on a system called SPARROW, a system with an Active Directory.

**TIP** If you plan to set up Web enrollment support to allow people to get certificates, set up IIS before installing Certificate Services, and be sure to explicitly enable ASP pages. (They're normally disabled in Windows Server 2003.) If you install Certificate Services first and then install IIS, you'll need to create the required virtual roots by hand by typing **certutil -vroot** at the command prompt.

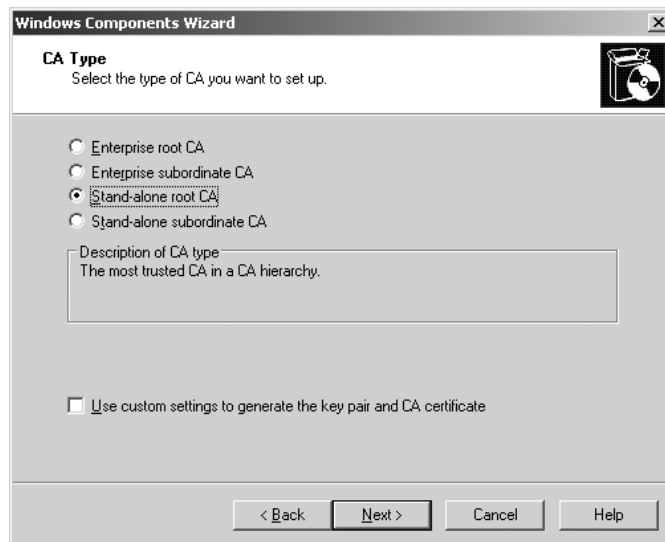

To install the Services, open Control Panel, choose Add or Remove Programs, and then choose Windows Components. Click Certificate Services and Details and you'll see a dialog box like Figure 8.94.

**FIGURE 8.94**  
Details view of  
Certificate Services

Check both boxes if they're not already checked. When you choose to install Certificate Services CA, Control Panel will check that you really mean it, warning you that you can't rename the computer or change its domain membership after installing Certificate Services, as this would invalidate the certificate, and asking if you want to continue. Choose Yes and OK so that Control Panel reconfigures your server. You'll get a few screens that ask about how to configure this certificate server; the first looks like Figure 8.95.

**FIGURE 8.95**  
Which kind of  
certificate server?

I've chosen Stand-Alone Root CA for my example here. Click Next, and you'll see a screen like Figure 8.96.

**FIGURE 8.96**  
Describing the CA

This box will list the information needed to find the server in the Active Directory. Fill it in and click Next. Windows Setup will generate the cryptographic key, and you'll see something like Figure 8.97.

**FIGURE 8.97**  
Where to store  
the certificate  
information

If you choose to store the certificate database on a network share, you'll need to provide the folder for it. Click Next and Finish and the software's installed.

**CREATING AND INSTALLING CERTIFICATES**

Now that the Avian's CA is up and running, let's issue a certificate. Let's suppose that I've got a system named PERMADC that wants a server certificate, so it asks SPARROW for one.

There are three steps to getting a certificate: You first request that the CA issue you one, then the CA decides to actually give you the certificate, and then you download and install it.

## Requesting the Certificate

**NOTE** I request the certificate from the new CA by pointing my Web browser to the enrollment pages, prebuilt forms that I can get to by typing in the CA's DNS address and adding the phrase /certsrv to make a URL. As PERMADC is requesting a certificate from SPARROW, another computer on its same intranet, I just log onto PERMADC as an administrator, start up IE and type <http://sparrow/certsrv> to see a screen like Figure 8.98. If you get a 404 error and you installed Certificate Services before installing IIS, make sure that you've created the virtual root folder.

**FIGURE 8.98**

Opening a  
certificates  
Web page

You see that there are three options here, but the one that will get me a cert is clearly Request a Certificate, so I click that if it's not already clicked and then the Next button to see a screen like Figure 8.99.

**FIGURE 8.99**

What kind of  
certificate?

I guess the most commonly requested certificates are e-mail certs and Web browser certs, hence their presence here. But I'm just looking for a basic server certificate, so I need to click Advanced Certificate Request and choose Create and submit a request to this CA. That shows Figure 8.100.

**FIGURE 8.100**

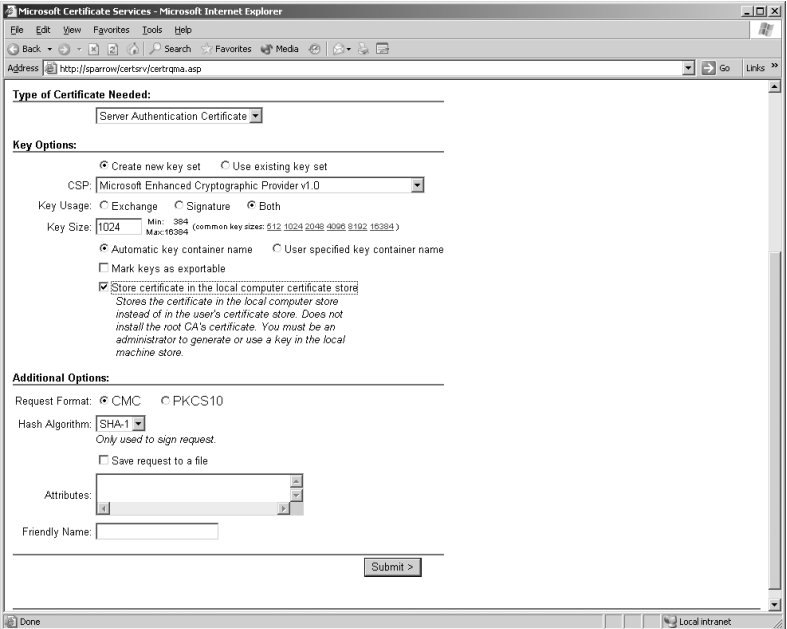

More details on certificate type

I have to fill in two items, the name of the server and a contact e-mail. Then I choose the type of certificate that I'm looking for under Type of Certificate Needed:— Server Authentication Certificate. But there's more to see here also, so I scroll down in the browser to see something like Figure 8.101.

**FIGURE 8.101**

Putting the certificate in the machine store

Notice a few things in this option screen. First, recall that I talked earlier about the fact that you might sometimes want a separate key for signing and encryption; you see that here in the Key Usage options—Exchange means “use for encryption.” You can set the key length—longer keys are more secure but require more CPU power to encrypt and decrypt. I tend to use the default. The only thing that I change here is checking Store Certificate in the Local Computer Certificate Store. I do this because it’s me running IE, and so any actions that I do—including creating certificates—will by default be associated with me rather than the computer. But this is a *server* authentication cert, and so it goes in the *machine’s* store of certificates, not mine. This check box ensures that the key goes to the right place.

I click Submit to start the process. PERMADC creates a private and public key pair, encrypts the private key, stores it and the public key somewhere in the Registry, and sends the public key to the CA so that the CA can bind it into the certificate. I then get a message that the request was submitted, and to return later to retrieve the certificate.

### The CA Issues the Certificate

Now the certificate request sits at the CA, waiting to be approved by an administrator. (That “administrator” would be me in this case.) So I log onto the CA computer, SPARROW, to approve the certificate.

There’s a tool on SPARROW that arrived with the Certificate Services—an MMC called Certificate Authority. I start it and click the Pending Requests folder to see Figure 8.102.

**FIGURE 8.102**  
Certificate Authority  
snap-in

You see the certificate request in the figure; I need only right-click it and choose All Tasks /Issue and the certificate is issued. (If someone requested a certificate that I did not want to issue, I could choose Deny from the same context menu.)

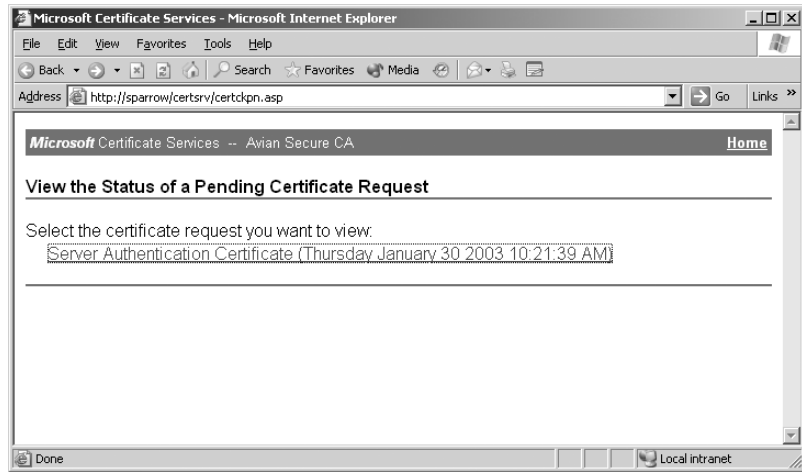

**NOTE** You can, if you want, tell your CA to automatically generate any CA requested. Just open up the Certification Authority snap-in and right-click the icon for the server. Choose Properties (no surprise there, eh?) and the Policy Module tab. In that tab, click the Properties button and choose the Default Action tab in the resulting policy page. On that tab you’ll see two radio buttons telling the CA what to do when it receives a certificate request. By default, the first option, which sets requests to Pending until the administrator explicitly issues them, is selected, but there’s also a second option to automatically issue newly requested certificates. However, I can’t see why you’d do that. Handing out certificates to any random person who requests one doesn’t sound very secure.

### Retrieving the Certificate

Moving back to PERMADC, I return to <http://sparrow/certsrv> and this time I choose the radio button for the task Check on a Pending Certificate and click Next to show me a page like Figure 8.103.

**FIGURE 8.103**

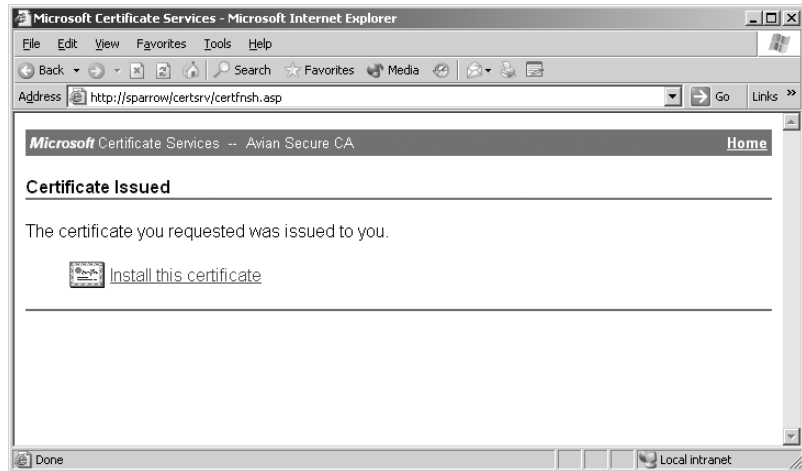

Choose a pending certificate request

There's only one pending request so I just click it and get the news that it's been issued, as you see in Figure 8.104.

**FIGURE 8.104**

The certificate is ready for installation

I click the Install This Certificate link, confirm that I trust the Web site issuing it, and get a final Web page telling me that it installed without a hitch.

**WARNING** Remember, I'm assuming that you're using Internet Explorer. You've got to do more work to make this work with Netscape.

Remember that I checked that box telling the system to create the key pair in the local machine store? I can check that now by opening up the Certificate Manager snap-in on PERMADC. The new cert is *either* in the Personal folder on the Local Computer store or in the user store, as you see in Figure 8.105.

**FIGURE 8.105**

The new certificate is installed

Notice that the certificate turns out to be in the Local Computer store, as I wanted. If I were to do everything else the same—but hadn't asked to put the certificate in the local computer store—then the certificate would end up in the user's store. That's not to say that I couldn't *move* it from the user's **Personal** folder to the computer's **Personal** folder by just cutting and pasting in the Certificate Manager snap-in—but specifying where to put it from the beginning saves a bit of work and keeps me from forgetting to do that and wondering why the cert isn't where I expect it to be.

**NOTE** In an Active Directory—integrated CA, your machine could automatically request the certificate, the CA could automatically issue the cert, and the machine would automatically install it.

### TRUSTING THE NEW CERTIFICATE AUTHORITY

So PERMADC now has a certificate created by a certificate authority called Avian CA—but isn't something missing here? *PERMADC doesn't trust Avian CA!* We never introduced them! So what happens when a system holds a certificate created by a CA that it doesn't trust? Well, you can see that by double-clicking the certificate and then the Certification Path tab, as in Figure 8.106.

**FIGURE 8.106**

Certification path for new certificate

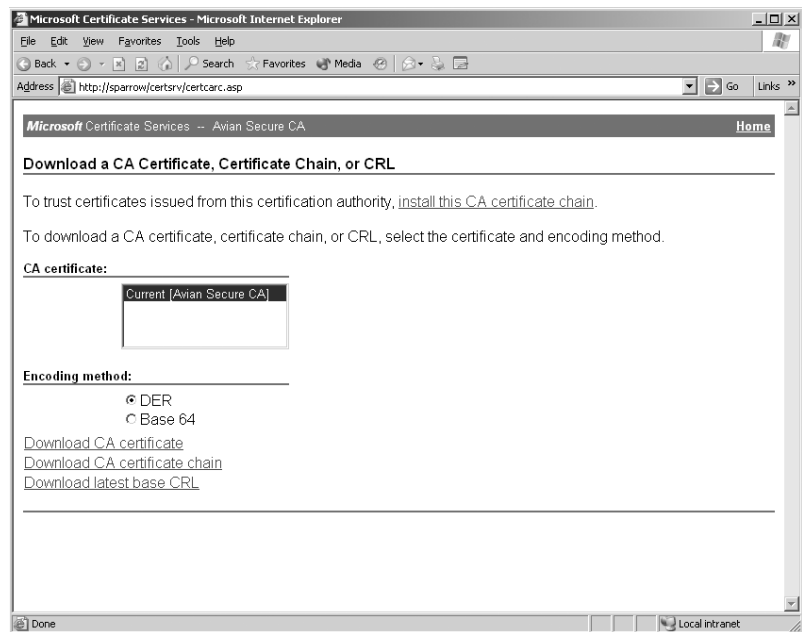

Hmmm...now, is *that* odd—it seems that PERMADC likes this certificate and the whole idea of the Avian CA altogether. What’s going on here? A look in the **Trusted** folder shows that *there’s an Avian certificate in there*. Windows Server 2003 got a little sneaky and stayed one jump ahead of us—when it installed the new certificate for PERMADC, it also installed the root CA certificate for the CA that created the certificate. Well, that saves us some work.

But sometimes you’ll want a system to trust a CA even if that system *doesn’t* hold any certificates issued by that CA. In that case, you need to download and install the root CA certificate for that CA.

There’s an easy way to do it, via the `/certsrv` URL that you’ve already met. You might have noticed that one of the options on the first page was to Download a CA Certificate, Certificate Chain, or CRL. Click that and you’ll see a screen like Figure 8.107.

**FIGURE 8.107**

Fetching the root CA’s certificate

Click **Install This CA Certificate Chain**, and you’ll get the CA’s root certificate. IE will put the new certificate into the **Trusted Root Certification Authorities** for both **Local Computer** and **Current User**.

Windows 2000–based CAs also maintain a URL for direct download of their root CA: `http://servername/certenroll/servername_CAname.crt`, where *servername* is the DNS name of the server and *CAname* is the certificate authority’s name. So, for example, if the certificate server’s DNS name were `swallow.bigfirm.biz` and the CA’s name were `Avian`, then the URL would be `http://swallow.bigfirm.biz/certenroll/swallow.bigfirm.biz_Avian.crt`. You can represent blanks in a URL with `%20`—for example, as our CA’s full name is `Avian secure CA` on a server simply named `swallow`, its URL would be `http://swallow/certenroll/swallow_avian%20secure%20ca.crt`.

## Using PKI in Windows Server 2003

Now that you’ve seen how to get a simple certificate, let’s look at the specifics of getting some of Windows Server 2003’s PKI-aware components to work.

## IPSEC

You read in Chapter 6 that IPsec is a pretty powerful and flexible way to sign and/or encrypt communications between two machines or amongst a greater number of machines. But IPsec needs authentication and only supports three kinds—Kerberos (which is simple but only works between machines from the same domain), a shared secret (which is all too easily compromised, as all sides must agree upon the secret), and certificates. If you want to use IPsec to secure communications between two systems in different domains, or for that matter any set of systems that might be in any number of domains or workgroups, then certificates are the way to go.

Using certificates for IPsec is simple, once you know what *kind* of certificate to use. First of all, you're looking for a certificate that goes on the Local Computer certificate store, so use the Advanced Certificate Request and check the Use Local Machine Store when filling out the form. Under Intended Purpose, choose either Client Authentication Certificate or IPsec Certificate. (For some reason, a *server* authentication certificate won't let two servers communicate via IPsec. Go figure.) Make sure that all systems that want to use IPsec to talk to each other have a certificate from the same CA.

Finally, when you select the authentication method for your IPsec rule, then choose Use a Certificate from This Certificate Authority and click Browse; you'll see a list of the CAs that the system recognizes. Choose the one CA that lists all of your IPsec-ing systems, and IPsec will work like a charm.

But before you try this the first time, do yourself a favor: Get the IPsec working, and *then* add the certs. If you're unfamiliar with both IPsec and certificates then you're bound to miss a step somewhere and not know where to go. Start out with a simple shared secret for authentication—it's just a configuration step. Once IPsec's working, get the certificates from the CA onto the machines and check their Local Computer stores to ensure that the certs are there and are the right type. *Then* change the IPsec rule to use certificates.

## E-MAIL

As I've already said, a Windows Server 2003 PKI can generate certificates for signing and/or encrypting e-mail. It's even fairly simple to create the certs because, as you may recall, e-mail certs are one of the two "one-click" certificates in the Web-based request page. But there are few specific wrinkles about e-mail certificates that you should know.

First, recall that when you request a certificate you must fill in a small form. Two of those items are Name, which you can use to name the certificate, and e-mail address, which was pretty irrelevant in the server certificates that we've talked about so far. (In fact, I've often left the field blank, and it works fine.) But for e-mail, that's not the case: Whatever e-mail account you fill in there is the only e-mail account that can use this certificate. If you regularly use several e-mail addresses, then you'll need at least one certificate for each one.

Second, when you *do* request the certificate, either through the simplified or Advanced Request interface, the type of certificate that you want is called an E-mail Protection Certificate. You *can* use the simplified interface, but you might choose to use the Advanced Request interface for two reasons.

- ◆ First, you can mark the private key as exportable in Advanced; you can't do that in Basic. Why would you want to? Because you can export the keys to a floppy and lock them away somewhere. Then, if your system crashes and you must rebuild it, you can reinstall (*import* is certificate-ese) the keys to the new system.

- ◆ Advanced lets you create separate certificates for signing and encryption. (Recall that for some reason Advanced calls encryption certificates *Exchange* certificates.) That's important because you *would* export and store your *encryption* keys, you'd never export and store your signing keys. If you lose a signing key, just revoke its certificate (more on that later) and request a new one.

**TIP** If you start requesting an e-mail certificate from the simple interface and want to use the advanced options such as marking a private key for export, you can click a link in the simple interface to fill out the advanced form.

Third, both the sender and receiver of a piece of e-mail may need certificates. If all I want to do is send you a piece of signed e-mail, then all I need is an e-mail certificate issued by an authority that you recognize. You need not have any certs. But if I want to send you *encrypted* e-mail, well, that's a bit tougher.

Recall how SSL encryption worked: The server has a certificate and the client (your Web browser) usually doesn't. So they need to agree on a password for symmetrical encryption in their session. But how to agree on that key without sending it in plaintext? Simple—the client offers a password (*session key* is the better phrase, actually) to the server by encrypting it *with the server's public key*. No one can decrypt this but the server, so the secret's safe.

Now suppose I want to encrypt some e-mail to you. As with SSL, I'll use *your* public key to encrypt the mail that I want to send to you. But e-mail's not a real-time communication process, so you might not even be online when I try to mail you. Therefore, I would have no way to *get* your public key unless you send it to me beforehand! To send you encrypted mail, then, I'd *first* have to ask you to send me a piece of mail with your public key on it. *Then* I could use that from this point on to encrypt mail to you.

Finally, you must tell your e-mail client software to use your certificates and when to use them. As there are a ton of popular e-mail clients, I can't explain how to do it on all of them—but most clients have an Options/Security or the like. You can usually tell your system whether to sign and/or encrypt everything (which seems a mite extreme to me), or just pick which items to sign or encrypt.

Remember also that the e-mail certs that you issue with your CA won't be much good on the public Internet. But Thawte is generous enough to hand out Internet-friendly e-mail certs for free, so if you'd like to start signing your e-mails then visit [www.thawte.com/html/COMMUNITY/personal/index.html](http://www.thawte.com/html/COMMUNITY/personal/index.html).

## WEB BROWSER

Browser certificates are popular in so-called “extranet” situations, where you want to secure a Web site—that is, you don't want just anyone to be able to access it—but you want some people outside your firm to be able to get to the pages. So how do you limit access to a Web page or pages?

One simple way is to secure the pages with NTFS permissions. You can say that only Joe, Jane, and Sue can read `blahblah.htm` on your Web site; so if anyone tries to access `http://yourwebservername/blahblah.htm`, then a logon dialog box will pop up in Internet Explorer asking for a name, password, and domain. NTFS permissions on Web pages are simple to set up and secure for logons—that dialog box does a challenge-response authentication, so no passwords are flying around in cleartext.

But that means that you've got to create user accounts for Joe, Jane, and Sue and, worse, that means that you've got to maintain them. Even worse yet, it's really only going to work if Joe, Jane, and Sue sitting on-site at that other company are using Windows and Internet Explorer! A better answer is

a client authentication system that works across platforms; X.509 certificates are good ones. An in-depth discussion of this would require more details about IIS than I've got space for here, but here's the overview.

### **Setting Up Certificate-Based Access Control**

Basically you can limit who gets access to a Web site server in a few steps.

**WARNING** *Notice that this will only apply at the Web site level—you cannot use certificates to control access to particular Web pages.*

1. First create and install a Server Authentication Certificate from your internal CA. Don't forget to tell the enrollment page to place the certificate in the local computer's certificate store. Now the certificate is on the server and IIS sees it, but IIS doesn't know which, if any, Web sites to associate the certificate to.
2. Then attach it to this particular Web site in IIS. In the Internet Information Services Manager, right-click the icon for the Web site that you want to secure, choose Properties and click the Directory Security tab. Then click the Server Certificate button to start a wizard. Choose to assign an existing certificate, pick the available certificate from the list, choose a port for SSL to use (the default of 443 is fine), and then click Next again to install the certificate with those options. Click Finish to finish the wizard.
3. Next, require people to use certificate-secured communications; in the same Secured Communications area as the Server Certificate button that you just pushed. Click Edit and, in the resulting dialog box, check the Require Secure Channel (SSL) box and Require Client Certificates. Click OK twice to clear the dialog boxes.
4. That Web site can only be accessed with URLs starting with `https://` rather than `http://`, so set up all of your hyperlinks accordingly on pages that refer to your newly secured site.
5. Clients will also need certificates. Just run the Web enrollment page as you've seen before, and this time choose a Web Browser Certificate.

Now when a client tries to connect to the Web site they will be refused unless they've got a certificate from a CA trusted by the IIS machine.

### **Tightening Up Certificate and IIS Security: The Certificate Trust List**

Notice that—all you need is a certificate from *any* trusted CA. Unfortunately, that's probably not what you wanted.

To see what I mean, suppose ABC company wants to set up a Web site that a few of XYZ company's employees can access. So ABC does what I just described—sets up the Web site, creates a CA, puts a server authentication certificate on the Web server, tells IIS to use that certificate for directory security, requires secure channel, and hands out Web browser certificates to the small number of XYZ employees who they want mucking around on their Web site. This will work fine, and those XYZ employees will be able to access the ABC Web site.

Unfortunately, so will other people.

All IIS requires in this case is a Web browser certificate from *any* CA that the IIS server's operating system trusts. Therefore, any Joe Blow coming to ABC's restricted Web site will get access even *without*

a Web browser certificate from ABC's CA; a Web browser certificate from Thawte, VeriSign, Baltimore, or any of the dozens of other in-the-box, "pretrusted" CAs will do.

Fortunately, IIS has a mechanism to restrict the CAs that it should accept certificates from to authenticate to a particular Web site. It's called a *certificate trust list*. When you create and activate one, you modify IIS's behavior in this way: Where it previously would take certs from any trusted CA, now it only takes certs from the specific CAs that you list. To create one:

1. Open up Internet Information Services Manager (Start/Programs/Administrative Tools/Internet Services Manager).
2. Right-click the site that you've secured with certificates and choose Properties.
3. Click the Directory Security tab.
4. In the Secure Communications section, click Edit.
5. In the resulting dialog box, check Enable Certificate Trust List.
6. You'll need to create a CTL now. Click the New button to start a wizard. Click Next to get to the first page.
7. In the Certificates in the CTL page, click Add from Store and choose the CAs whose certificates you want IIS to accept for access to your Web site. (Ctrl-click to choose more than one at a time.) Once you've done that, choose Next.
8. In the following panel, fill in the fields to describe the CTL. Click Next, Next again, and Finish. You should see a message telling you that the Certificate Trust List Wizard succeeded. Just click OK, and OK again, and you'll be set.

### **Other Certificate Uses In IIS**

You can take this further if you like, with *one-to-one* or *one-to-many* mapping. The idea here is that you could create a set of local or domain user accounts and associate particular certificates with particular user accounts. So if the Web browser certificate Lara Wilson is associated with—is mapped to—a user account lwilson then you can use IIS's normal security features to control Lara's access. But Lara can get to the Web site using, again, non-Windows desktops. In a *many-to-one* situation, you do something similar but instead of mapping certs to users one by one, you write some rules that the system uses to do that mapping on the fly.

If you use auditing, then you should be aware of a somewhat annoying side effect of certificates: Anyone accessing a secure Web site with certificates always generates a "logon failure" item in the Security event log. It's kind of annoying, as it gives the false impression that you're under a major hack attack.

You'll read more about IIS in Chapter 17.

### **EFS CERTIFICATES**

You'll read more about the Encrypting File System in Chapter 10, but the basics are that it lets you encrypt and thereby protect files. But if you forget your password to your user account, then you can't decrypt your files. That's why EFS requires that you create at least one account that has the ability to decrypt files, an *EFS recovery agent*. The Administrator account is a recovery agent, but if you want to delegate that job to someone else, you'll need to create a new EFS recovery agent. To do this, you'll need to get a file recovery certificate. You can download a recovery agent certificate from the CA

using the Web interface you've already seen. Just move to the Advanced page and choose that option from the list. If you don't see the option in the list, you can still get the certificate by choosing Other and filling in the proper OID. The object ID (OID) for the file recovery certificate is 1.3.6.1.4.1.311.10.3.4.1. Fill out the remainder of the form as you've already seen.

**TIP** You can find out the OID for any certificate by looking at its properties. For example, to find out the OID for a recovery cert, I looked at the extant one for the Administrator that's located in Public Key Policies/Encrypting File System. Turn to the Details tab and look for the Enhanced Key Usage entry. Select it, and you'll see the OID in the pane.

Once you've got the certificate, you can install it on the target machine, using the Local Security Policy snap-in under the Public Key Policies/Encrypting File System folder. Right-click it, choose Add Data Recovery Agent, and a wizard lets you assign the new Recovery Agent. The only catch is, as usual, that the system where you're installing the file recovery cert must accept certificates from the CA. For more about EFS and recovery agents, see Chapter 10.

## Revoking Certificates

This whole PKI/certificate thing is pretty neat, but there are a few wrinkles to be aware of. For one, what happens when you've got to get rid of a certificate? For example, suppose my laptop has a certificate on it and someone steals the laptop. I sure don't want them sending e-mail with my digital signature on it! There is an answer—certificate revocation. In this section, you'll see how that works.

Revoking a certificate is straightforward. Just start up the Certification Authority snap-in and look in the Issued Certificates folder. Find the certificate that you want to revoke and right-click it and choose All Tasks/Revoke Certificate. It'll offer you the chance to record one of seven reasons (including Unspecified), and the certificate then goes into the Revoked Certificates folder.

**WARNING** Although there is an Unrevoke Certificate option for revoked certificates, it only works if you choose Certificate Hold as the reason for revoking the cert. Choosing any other option, including Unspecified, permanently revokes the cert.

So the certificate is now officially *persona non grata* around the network? Well, not exactly, not just yet. Remember that one of the great strengths of certificates is the fact that they rely on a hierarchy of trust—that is, if your system holds a cert that's signed by a server whose cert your system also holds, then the system won't stop every time that it examines the cert to locate and contact the root CA or even the issuing CA. So it takes a little time for a client (or a server) to realize that a certificate is no longer any good.

In the PKI world there is an important acronym, CRL. It stands for Certificate Revocation List. CAs issue CRLs on a regular basis, weekly by default, but you can make it more or less often. (In Certificate Authority, right-click the Revoked Certificates folder and choose Properties and you'll see a Publication Interval, which you can change.) Or you can force a CA to generate—*publish* is PKI-ese—a new CRL—by right-clicking the Revoked Certificates folder and choosing All Tasks/Publish.

Different client systems check CRLs at different intervals and upon different events. But most will automatically get a new CRL when the old one expires, so you might want to set the expiration time to be more frequent than the weekly default value. Of course, that means more network traffic.

If you need to find out the age of the CRLs on an IIS server, look in `\system32\certsrv\certenrol` for files with the `.cr1` extension. (They are probably in folders *inside* that folder, and when you open one it will be copied to your profile directory.) Double-click the CRL files, and you'll see when they were published and when the next update will be.

Need to have an IIS server immediately recognize a revoked certificate? Then do this: First, force the CA that issued the certificate to publish a new CRL. Second, go to the IIS server and find and delete the CRL file for the CA that issued the certificate. Finally, restart IIS—not just the one site, but the entire IIS service. (Again, just the service—you needn't reboot the entire server.) Clients trying to access the Web site will see an “HTTP 403.13—Forbidden: Client certificate revoked” message.

By now, we've covered a lot of theory and a smaller amount of concepts. Let's move to more nuts and bolts, starting with a discussion of user accounts—in the next chapter.

## Chapter 9

# Managing and Creating User Accounts

BY NOW YOU'VE LEARNED the basics of Active Directory, how to install and configure major components of Windows Server 2003, and the ins and outs of the MMC, as well as the care and feeding of the Registry. Now let's tackle something at the heart of an administrator's job: creating and managing users and groups. In this chapter, you'll first learn how to create user accounts, both in a workgroup and domain-based environment. You'll then see how to use groups—there are four types—to simplify your administration tasks. After that, you'll understand how to use policies to simplify user management, extend user rights, and lock down desktops. Then you'll learn how to use and manage profiles.

## Creating Local and Domain User Accounts

While most of you will be using Active Directory, a few of you might still be using NT 4 domain controllers, and so, of course, you'd create any of those user accounts the old way, with User Manager for Domains. But if you need to create a *local* account on a Windows Server 2003 system, then you can still do that, using the Computer Management tool instead of Active Directory Users and Computers. In the next two sections, I'll show you how to create user accounts both locally and on an Active Directory domain.

### Use Computer Management for Local Accounts

The bulk of the chapter assumes an Active Directory context. By this point, you have already read about domains, forests, and trees and know the benefits of using Active Directory on your network. In many cases, particularly if you have NT 4 workstations, Windows 2000 Professional, or XP Professional systems as clients, it's desirable to create a domain (even if you only have one server) in order to take advantage of the additional features of Active Directory. However, it's possible that a small organization might want to keep life very simple or even (brace yourself here) that the company's primary network OS is not Windows 2000 or Server 2003. For example, in a network that is Unix- or NetWare-based, there may be a need to set up a special-purpose NT server without all that AD stuff. In that case, if your server is not a domain controller (DC) and you aren't using

Active Directory, create your user accounts using the Computer Management tool (COMPMGMT.MSC). Users and groups created with COMPMGMT.MSC are local accounts, which is to say they exist and are valid on that local machine only. However, COMPMGMT.MSC is a remote enabled tool, so you can use it to create and manage local users and groups on remote member servers in a domain or on remote stand-alone servers. Just choose Connect to Another Computer from the Action menu to do this.

**TIP** The Action menu is the menu that you see (instead of an Edit menu) to the right of the File menu in the Microsoft Management Console tools. See Chapter 3 for an overview of MMC and console anatomy.

To create user accounts on a non-Active Directory server, use the Computer Management tool. If the machine you are working on is a domain controller, use Active Directory Users and Computers (DSA.MSC) to create accounts. On a domain controller, the Local Users and Groups node is not available in the Computer Management tool.

In COMPMGMT.MSC, open System Tools and then Local Users and Groups, as shown in Figure 9.1. Notice the users and groups that are created by default when you installed the Server OS. (In Figure 9.1 the Groups container has been opened in a separate window for your viewing convenience) On a stand-alone server, with no particular network services such as IIS, Terminal Services, DHCP, or DNS installed, the only built-in accounts are Administrator and Guest. The Guest account is disabled by default as a security precaution. The Administrator account, of course, has powers and abilities well beyond those of mortal users. It cannot be deleted or disabled, even if you set stringent account-lockout policies (which lock the account after a certain number of bad logon attempts). The Administrator account is not ordinarily subject to this policy and therefore cannot be locked out, even after a million bad logon attempts, which could be more than enough to crack a weak password. However, you *could* deny the Administrator account access to the computer from over the network. Then the would-be hacker would have to physically sit at your computer to try those million passwords. You'll see how to deny the Administrator network access later, when we talk about user rights and policies.

**FIGURE 9.1**  
Computer  
Management/Local  
Users and Groups

The Guest account is disabled by default as a security precaution. The Guest account, on a stand-alone server or in an AD context, creates a huge hole in the security of a system by allowing unauthenticated access. That's right, unauthenticated access. No password is required for the Guest account. You can use it without any knowledge of a username or password, which is why it's disabled by default. So it's a good thing that Guest is a very poor account as far as powers and abilities are concerned.

**NOTE** One common security practice is to rename both the Guest and Administrator accounts. This prevents a would-be intruder from taking advantage of the well-known usernames when attempting to log in.

A non-DC Windows Server 2003 has a few more built-in local groups than its Windows 2000 counterpart; in addition to the Administrators, Backup Operators, Guests, Power Users, Replicator, and Users groups, Windows Server creates Network Configuration Operators, Performance Log Users, Performance Monitor Users, Print Operators, and Remote Desktop Users. Additional built-in groups are created on a domain controller system, as you'll see in a moment. All of these built-in groups have a predefined set of rights and permissions. To empower users with those rights and permissions, just make those users members of the appropriate group. We'll discuss the built-in groups and their rights a bit later in this chapter.

To create a new user account on a non-DC server, open the **Users** folder under **Local Users and Groups**. Then choose **New User** from the **Action** menu, or right-click **Users** in **Local Users and Groups** and choose **New User**. Fill in the fields for **Username**, **Password**, and **Confirm Password** (the other fields are optional) as shown in Figure 9.2, and click **Create**. To change account properties, or to assign group memberships, a logon script, and a home folder, or to grant dial-in permission to the user, right-click the user account and choose **Properties**. To set a user's password, highlight the account and right-click, then choose **Set Password**. All of these options and more will be discussed a bit later when we're creating AD accounts.

**FIGURE 9.2**

Creating a local user

The screenshot shows the 'New User' dialog box. The fields are filled as follows:

- User name: bflanagan
- Full name: Bill Flanagan
- Description: Technical Publications Department Head
- Password: [masked]
- Confirm password: [masked]

The checkboxes are:

- ☒ User must change password at next logon
- ☐ User cannot change password
- ☐ Password never expires
- ☐ Account is disabled

Buttons at the bottom: Create, Close.

**NOTE** *The local accounts you create on a stand-alone server, member server, or workstation are stored in the SAM (Security Accounts Manager) database, just as they were in NT 4. The SAM is located in \Windows\system32\config.*

That's it! To set account policies, such as lockout restrictions or auditing, use the Local Security Policy tool (SECPOL.MSC) or the Group Policy snap-in (GPEdit.MSC). The process is very similar to configuring Group Policy with the Active Directory tools except that, since the machine is not a domain controller, changes will apply to the local policy for the machine. (I'll show you how to use the Group Policy snap-in to set account lockout and password policy for the domain later in the chapter.) The policies created will be local policies, which will live in the local machine's Registry database. Not surprisingly, the scope of policy settings is more limited for local policies than for group policies in an Active Directory environment. I'll also discuss group policies and how they differ from local policies later in this chapter.

## Use Active Directory Users and Computers for Domain Accounts

Since the release of Windows 2000, Active Directory Users and Computers (DSA.MSC) has been the primary administrative tool for managing user accounts, security groups, organizational units, and policies in a single domain or in multiple domains. The Windows Server 2003 version of the tool only runs on Windows XP or another Server 2003. By default, DSA.MSC is only installed on Server 2003, and it only appears in the Start menu programs on domain controllers. To run DSA.MSC on a Windows XP Professional system, install the Admin Pack found in \Windows\system32\ADMINPAK.MSI on the server. The Admin Pack installs the three Active Directory tools on a workstation, and like other Windows Installer-based programs, it can be published using Group Policy and the Active Directory for installation on XP Professional desktops. See Chapter 12 for more information on publishing software in the Active Directory. DSA.MSC is also useful for managing computer accounts, organizational units, resources like printers and shared folders, and even domain controllers. However, the focus in this chapter is on creating and managing users and groups, including the management of users' environments and group policies.

**NOTE** *What about the Admin Pack that came with Windows 2000 Server? Can you still use that version of DSA.MSC to administer Active Directory from your Windows 2000 Professional workstation? Well, yes, you can. The tool will still function. However, some of the options and object properties have changed. You won't be able to manage the new properties using the old tool. Besides, the absence of drag-and-drop in the old tool is really annoying. Instead of trying to use the previous version of DSA.MSC to administer AD, use a Remote Desktop Connection to connect to Server 2003 or domain controller and you'll have access to all of the most recent versions of the admin tools.*

## WHERE DO USER AND GROUP ACCOUNTS LIVE?

Local user accounts on a stand-alone server, member server, or XP Professional workstation are stored in a Security Accounts Manager (SAM) database, usually located in \Windows\system32\config, depending on where you created your system root directory.

For Active Directory, the file is called NTDS.DIT, and it's found in Windows\NTDS by default, but you can specify a different path in the DCPROMO routine. As you learned in Chapter 8, the NTDS.DIT database stores a lot more information than the SAM does. It also stores information about servers and workstations, resources, published applications, and security policies. NTDS.DIT and the software that runs it are generally referred to together as the *directory service* or the Active Directory. This data

structure is replicated throughout the domain to all domain controllers in a given domain for fault tolerance and load balancing. It's actually a database that uses an engine similar to the one used by Access, but one that programs control via the Lightweight Directory Access Protocol (LDAP) specified in RFC 1777. Although Windows 2000 Server was somewhat lacking in robust AD management tools, the Server 2003 distribution includes a number of graphical and command-line programs for working with Active Directory, and the Support Tools package on the CD offers a few more.

### SECURITY IDENTIFIERS

User accounts, when first created, are automatically assigned a *security identifier (SID)*. A SID is a unique number that identifies an account. SIDs have been used since NT began; the system doesn't really know you by your name, but rather by your SID. User IDs are just there for the human interface. SIDs are never reused; when an account is deleted, its SID is deleted with it. A typical SID may look like this:

S-1-5-21-1659004503-193565697-854245398-1002

SIDs can be broken up into segments like this:

S-1-5-21-D1-D2-D3-RID

S-1-5 is just a standard prefix (actually, the 1 is a version number, which hasn't changed since NT 3.1, and the 5 means that the SID was assigned by NT); 21 is also an NT prefix; and D1, D2, and D3 are just 32-bit numbers that are specific to a domain. Once you create a domain, D1 through D3 are set, and all SIDs in that domain henceforth have the same three values. The *RID* stands for relative identifier. The RID is the unique part of any given SID. Each new account always has a unique RID number, even if the username and other information is the same as an old account. This way, the new account will not have any of the rights and permissions of the old account and security is preserved.

### QUICK TOUR OF USER- AND GROUP-RELATED FUNCTIONS IN DSA.MSC

Active Directory Users and Computers provides the network administrator with the means to perform the following tasks:

- ◆ Create, modify, and delete user accounts
- ◆ Assign logon scripts to user accounts
- ◆ Manage groups and group memberships
- ◆ Create and manage group policies

Open Active Directory Users and Computers from the Administrative Tools group on the Start menu, or choose Start/Run and type in the filename (**DSA.MSC**). The tool needs to connect to a domain controller to obtain information and transmit your changes. In **DSA.MSC**, you will see the name of the contacted DC at the top of the console tree (**zooropa**) and your domain name right under the console root, as shown in Figure 9.3. To manually connect to another domain or domain controller, click the console root to highlight it, and then choose **Connect to Domain** or **Connect to Domain Controller** from the Action menu.

**FIGURE 9.3**  
AD Users and  
Computers  
console

**NOTE** DSA.MSC seeks out any nearby domain controller if you're running in Windows 2000 native or Windows Server mode; if you're in Windows 2000 mixed mode, then of course it must contact the PDC operations master, as mixed mode means that you've still got a single-master model.

You can also specify the domain controller or a different domain to connect to when starting DSA.MSC from a command line or the Start/Run dialog box. To specify a particular domain controller, type **DSA.MSC /SERVER=servername**. To specify another domain, type **DSA.MSC /DOMAIN=domainname**.

In the left pane, you see listed a set of containers and organizational units (OUs) that were created automatically with the domain: **Builtin**, **Computers**, **Domain Controllers**, **ForeignSecurityPrincipals**, and **Users** (Brunswick is an organizational unit that I created). As with all the console applications, click an object in the console tree (on the left) to see its contents and information in the details pane (on the right). Notice also that the description bar for the details pane tells you how many objects there are in the container. The description bar, like the status bar and the toolbars, can be hidden if you want a more simplified view. Just choose **Customize** from the **View** menu and uncheck the **Description Bar** check box.

The **Users** and **Computers** containers are the default places to put user, group, and computer accounts when a machine is upgraded from NT 4. They gotta go somewhere. But you don't have to put new ones there, and you can move them to OUs as needed. As you'll quickly discover, you can put a user account in any OU, even directly in the "domain" container. **Builtin** is the container for those special built-in local groups—such as **Administrators**, **Account Operators**, **Guests**, and **Users**—that exist on every server machine, including domain controllers. More on this in a bit.

**Domain Controllers** is the default OU for new domain controllers. This is where the accounts are located when you first create a DC. Like the accounts in the **Computers** container, DC accounts can be moved to other OUs.

**ForeignSecurityPrincipals** is a default container for objects from external, trusted domains. In this chapter, we'll be working only with users and groups from this domain.

To create something new, select the container object where you want to locate it, then select **New** from the **Action** menu or right-click to select **New** from the context menu. As shown in Figure 9.4, you can choose to create a shared folder, a user account, a printer, an OU, a group account, a contact, or a computer account. There are also two new choices with Server 2003: **InetOrg Person** and **MSMQ Queue Alias**. An **InetOrg Person** is a type of user account that exists for compatibility with

and migration of user accounts from non-Microsoft LDAP and X.500 directories. The MSMQ Queue Alias exists for use with Message Queuing 3 (commonly known as MSMQ). MSMQ is a distributed or store-and-forward messaging application. An MSMQ alias creates a reference in the Active Directory to a queue (another word for a distribution list) that does not exist in the directory.

**FIGURE 9.4**  
Creating a new  
object

Any of these choices kicks off a corresponding wizard to create the object. In each case, to fill in all the details, go back and edit the properties of the object after creating it (right-click the object and choose Properties).

Because they aren't really OUs, but instead mere containers, you can't create an OU inside the **Users** or **Computers** containers, and you can only create users, computers, and groups inside the **Builtin** container.

DSA.MSC, like other MMC tools, is context-sensitive. Right-click an object to see its context menu. Notice that context menu choices change with the selected object. Right-click a user account and you have the option to disable it or reset the password, for example; right-clicking a computer account reveals options like Move and Manage (Manage opens up COMPMGMT.MSC connected to the selected computer).

This chapter is really not about managing machine accounts or printers or shared folders, so I'll leave those discussions for another chapter. However, contacts and OUs do relate to user and group management, so we'll take a look at those items in a moment.

#### **PREBUILT ACCOUNTS: ADMINISTRATOR AND GUEST**

If you have just created a new domain, you'll notice that several accounts were created automatically during the process: Administrator, Guest, and SUPPORT\_388945a0. If you've been working with NT and Windows 2000 for a while now, you'll already be familiar with the Administrator and Guest accounts. The SUPPORT account, however, is a new account in Server 2003; it exists to provide Help and Support Service interoperability with non-Microsoft systems.

The Administrator account is, as you've guessed, an account with complete power over a machine or a domain, depending on the context. You can't delete the Administrator account but you can rename it. You assigned a password for the Administrator account when you installed the server software and then again when you ran `DCPROMO.EXE` to create a new domain. The first was a local Administrator account and password, but when you created a domain, a new Administrator account and password for the domain replaced it. Don't lose that password, as there's no way to get it back! (Well, you can always rebuild from scratch, but that's no fun.)

The Guest account is for users who don't have their own account on the domain. *Guest* means "anyone that the domain controller doesn't recognize." By default, this account is disabled, and it should *stay* that way. If you've ever worked with a different network, like a Unix or NetWare network, you're probably familiar with the idea of a guest account—but *Server 2003 works differently, so pay attention!* You can get access to most other operating systems by logging in with the username Guest and a blank password. That Guest account is usually pretty restricted in the things it can do. That's true with Server 2003 as well, although the Everyone group also includes guests.

Here's the part that *isn't* like other operating systems. Suppose someone tries to access a shared printer or folder on a server or domain that has the Guest account enabled. She logs on to her local machine as `melanie_wilson` with the password `happy`. Even without an account on the server or domain, Melanie can still work on her local machine. Windows 9x machines don't care who you are, having no local accounts at all. On an NT 4, Win2K, or XP Professional workstation, she would have to log in to an account on the local machine. However, none of these operating systems requires authentication by a server or domain controller in order to access the local workstation. Suppose that this domain or server doesn't even *have* a `melanie_wilson` account? Now she's working at a computer and tries to access a domain resource. Guess what? She gets in. Why? The Guest account does not actually require a password at all.

**WARNING** *Even though an explicit domain login requires that you use a username of Guest, you needn't explicitly log in to a domain to use guest privileges. If your network is attached to my network and your Guest account is enabled, I can browse through your network and attach to any resources that the Guest account can access. I needn't log in as Guest; the mere fact that there is an enabled Guest account pretty much says to leave the back door open. So be careful when enabling the Guest account.*

## CREATING A NEW USER ACCOUNT

Before I discuss the ins and outs of account properties, UPN names, profile information, and all the other user settings, let's just go through the steps to create a new user account with the wizard. Then I'll go back and discuss all the settings for the newly created account.

To create a user account, in `DSA.MSC` select the `Users` container (or any other container/OU where you want the account to be located), then pull down the Action Menu or right-click and select `New/ User` (shown in Figure 9.4 a few pages back). A wizard appears with a dialog box shown in Figure 9.5. Fill in the First Name, Initials, Last Name, and Full Name fields as shown in the figure. (You don't actually have to fill in all the name fields, but you must supply information for at least one of the name fields to continue.) Next, fill in the user logon name (`devans`) and choose the Universal Principal Name (UPN) suffix to be appended to the username at logon time; recall that we discussed UPNs in Chapter 8. For logging in to an NT 4 or Windows 9x machine, there is also a downlevel logon name, which uses the old-style `DOMAINNAME\username` syntax.

**FIGURE 9.5**  
Creating a new user

The screenshot shows the 'New Object - User' dialog box. At the top, it says 'Create in: REDHILLTOWN.COM/Users'. Below this, there are several input fields: 'First name' with 'Dave', 'Last name' with 'Evans', and 'Full name' with 'Dave Evans'. There are also 'Initials' and 'User logon name' fields. The 'User logon name' field has 'devans' and a dropdown menu showing '@REDHILLTOWN.COM'. Below that, the 'User logon name (pre-Windows 2000)' field has 'REDHILLTOWN\' and 'devans'. At the bottom, there are three buttons: '< Back', 'Next >', and 'Cancel'.

Windows Server 2003 usernames must follow these rules:

- ◆ The name must be unique to the machine for local accounts (or unique to the domain in the case of domain accounts). However, a domain user account name may be the same as a local account name on a non-DC that is a member of the domain, a fact that causes much confusion because they are completely separate entities.
- ◆ The username cannot be the same as a group name on the local machine for a local account (or the same as a group name on the domain in the case of domain accounts).
- ◆ The username may be up to 20 characters, upper- or lowercase or a combination.
- ◆ To avoid confusion with special syntax characters, usernames may not include any of the following:  
“ / \ [ ] ; | = , + \* ? < > ”
- ◆ The name may include spaces and periods, but may not consist entirely of spaces or periods. Avoid spaces, however, since these names would have to be enclosed in quotes for any scripting or command-line situations.

Before going on, I want to point out that there are *three* significant usernames in Figure 9.5. First, the Full Name is Dave Evans. That was nothing but decoration in NT 4, but it’s significant in Active Directory, as it is part of your LDAP name. Dave’s LDAP name would look like this:

```
cn="Dave Evans",cn="Users",dc="REDHILLTOWN",dc="com"
```

You should know what Dave’s LDAP name is if you want to use some of the command-line tools that “speak” in LDAP, (such as `DSMOD.EXE` or `DSADD.EXE`) or if you wish to do some WSH scripting using the AD Services Interface (ADSI). In LDAP-ese, `cn` is container, and yes, user accounts are containers. So there’s a container Dave Evans inside a container named Users (the Users folder), and

that folder is in a domain named REDHILLTOWN.com. You describe domain names in LDAP in terms of their components, the pieces separated by a period—in the case of REDHILLTOWN.com, it'd be REDHILLTOWN and com. You separate those with **dc**, which means domain component. If Dave's account were not in the **Users** folder, but instead were in an OU called, say, Brunswick, then you'd replace the **cn** (container) with **ou**:

```
cn="Dave Evans",ou="Brunswick",dc="REDHILLTOWN",dc="com"
```

The second name, **devans@REDHILLTOWN.com**, is the Active Directory logon name or UPN (user principal name). You read in Chapter 8 that while this *looks* like an e-mail address, it's not—it's just a convenient, easy-to-remember name to give a user instead of making the user remember a domain name and username.

The third name, **REDHILLTOWN\devans**, is the older-style NT 4-type logon name. You can use this name when logging on from a Windows 9x workstation or an NT 4 workstation. Or you might find yourself using it on older programs that run fine on Windows 2000/XP/Server systems, but that don't understand UPNs. I find, for example, that some Windows 2000 Resource Kit tools require you to identify yourself, but don't understand a logon name like **Injustice@REDHILLTOWN.com**; they need to see something like **REDHILLTOWN\Injustice**.

Once you've filled in all the username information, choose **Next**. In the following screen, shown in Figure 9.6, set a password for the user account and confirm it. Set the password and account options summarized in Table 9.1, then choose **Next**. **User Must Change Password at Next Logon** is the only option selected by default.

**FIGURE 9.6**

Setting password and account options

The final screen of this Create New Object Wizard, shown in Figure 9.7, simply confirms all the information you've supplied, including the container/OU where the account will live, the full name, the logon name, and the password or account options selected. Choose **Finish** and your user account is created.

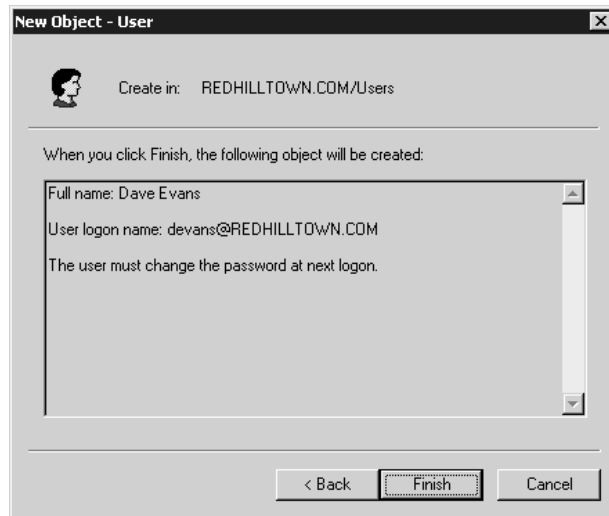

**TABLE 9.1:** PASSWORD AND ACCOUNT OPTIONS FOR CREATING A NEW USER ACCOUNT

OPTION	DESCRIPTION
User Must Change Password at Next Logon	Forces a user to change their password the next time they log in; afterward the box will be unchecked.
User Cannot Change Password	If checked, prevents the user from changing the account's password. This is useful for shared accounts and accounts that run services like Exchange.
Password Never Expires	If checked, the user account ignores the password expiration policy, and the password for the account never expires. This is useful for accounts that run services and accounts for which you want a permanent password (such as the Guest account).
Account Is Disabled	If checked, the account is disabled and no one can log in to it until it is enabled (it is not, however, removed from the database). This is useful for accounts that are used as templates and for new user accounts that you create well in advance, such as new hires that will not begin work for several weeks.

**FIGURE 9.7**

Confirming new user information

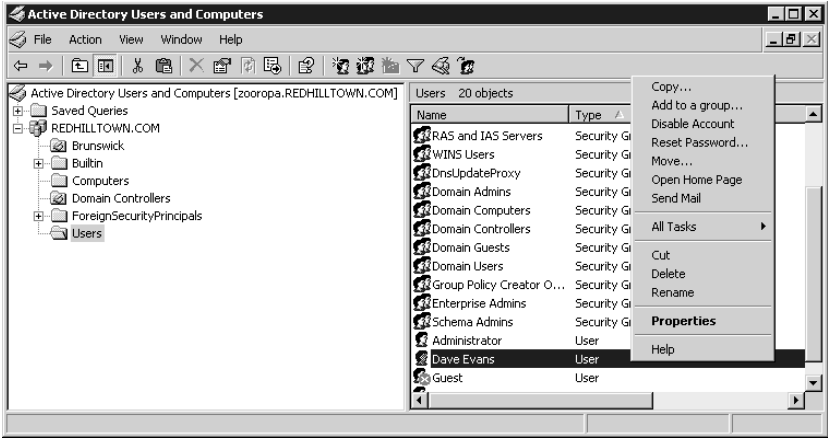

### USER ACCOUNT PROPERTIES

Now let's go back and look at the properties of the account you just created. Right-click the user account object and you'll see several options in the context menu, shown in Figure 9.8. From here you can quickly copy the account, manage the user's group memberships, disable or enable the account, reset the user's password, move the account to a different container or OU, open the user's home page, or send him mail (these last two require that the home page URL and e-mail address be specified in the account information). You can also choose to delete or rename the user account from this menu.

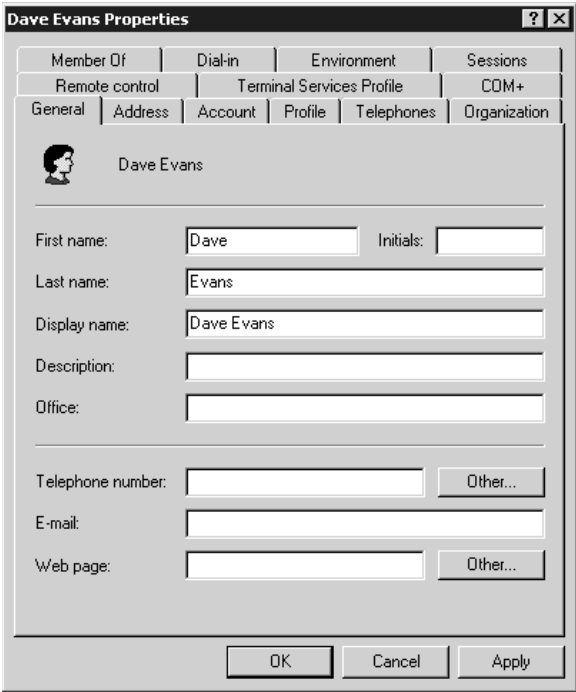

**WARNING** Each user and group account is assigned a unique identifier, called a *SID*, when it is created. Deleting a user or group account deletes the unique identifier. Even if you re-create an account with the same name, the new account will not automatically have the rights or permissions of the old account.

**FIGURE 9.8**  
The context menu  
for a user account

Choose Properties from the context menu to bring up the full user account information. Figure 9.9 shows 13 different properties tabs for this user account. In the General tab shown in Figure 9.9, you can add a description of the user account, supply the name of the office where the user works, and add telephone numbers, an e-mail address, even Web page addresses. The Address tab in Figure 9.10 shows fields for a user’s mailing address. The Telephones tab (Figure 9.11) offers a place for home, pager, mobile phone, fax, and IP phone numbers, as well as a place to enter notes.

**FIGURE 9.9**  
User properties  
General tab

**FIGURE 9.10**

User properties  
Address tab

The screenshot shows the 'Dave Evans Properties' dialog box with the 'Address' tab selected. The dialog has a title bar with a question mark and a close button. Below the title bar is a tabbed interface with the following tabs: 'Member Of', 'Dial-in', 'Environment', 'Sessions', 'Remote control', 'Terminal Services Profile', 'COM+', 'General', 'Address' (selected), 'Account', 'Profile', 'Telephones', and 'Organization'. The 'Address' tab contains the following fields: 'Street' (a large text box with a vertical scrollbar), 'P.O. Box' (a text box), 'City' (a text box), 'State/province' (a text box), 'Zip/Postal Code' (a text box), and 'Country/region' (a dropdown menu). At the bottom of the dialog are three buttons: 'OK', 'Cancel', and 'Apply'.

**FIGURE 9.11**

User properties  
Telephones tab

The screenshot shows the 'Dave Evans Properties' dialog box with the 'Telephones' tab selected. The dialog has the same title bar and tabbed interface as Figure 9.10. The 'Telephones' tab contains a section titled 'Telephone numbers' with five rows of input fields and buttons: 'Home:', 'Pager:', 'Mobile:', 'Fax:', and 'IP phone:'. Each row has a text box and an 'Other...' button. Below this section is a 'Notes:' label and a large text box with a vertical scrollbar. At the bottom of the dialog are three buttons: 'OK', 'Cancel', and 'Apply'.

In Figure 9.12 you see the Organization tab, where you can enter information about someone's actual job title, manager, and direct reports.

**FIGURE 9.12**  
User properties  
Organization tab

So 4 of the 13 tabs displayed in the user account properties are just about contact information, not what we old-time NT admins would call account properties. You begin to understand why they call it directory services.

**NOTE** So why does the Active Directory need to hold all this contact information for users? If you have used Exchange on your network, you know that you can enter almost all of this stuff in the Exchange mailbox properties. Exchange 2000, however, has no separate method for creating user accounts; it uses the information that AD has about the user.

Of the remaining properties tabs, four (Remote Control, Terminal Services Profile, Sessions, and Environment) pertain to Terminal Services, covered in Chapter 16. In Chapter 12, you'll learn about using the COM+ property tab to assign users to applications on COM+ partitions configured on application servers. We'll also leave the Dial-In tab to Chapter 20, which covers the Routing and Remote Access Service. That leaves us with four "core" property tabs: General, Account, Profile, and Member Of. In the next few sections we will tackle account settings, profile information, and group memberships.

### Account Settings

If you need to modify the user's logon name or UPN suffix, go to the Account tab (Figure 9.13). This is also the place to specify permissible logon hours, account options, and all that stuff. By default, users are allowed to log in any day of the week at any time of the day (24/7), but you can choose the Logon Hours button to designate particular permitted hours and days (see Figure 9.14).

**FIGURE 9.13**

User account properties

The screenshot shows the 'Dave Evans Properties' dialog box with the 'Account' tab selected. The 'User logon name' is 'devans' and the 'User logon name (pre-Windows 2000)' is 'REDHILLTOWN\devans'. The 'Logon Hours...' button is visible. Under 'Account options', the 'User must change password at next logon' checkbox is checked. The 'Account expires' section shows 'Never' selected.

**FIGURE 9.14**

Setting logon hours

The screenshot shows the 'Logon Hours for Dave Evans' dialog box. It features a calendar grid for setting logon hours. The 'Logon Permitted' radio button is selected. The text at the bottom indicates 'Sunday through Saturday from 12:00 AM to 12:00 AM'.

**NOTE** By default, a user will not be logged off automatically when logon hours expire, but there is a setting to accomplish this. The setting is called *Automatically Log Off Users When Logon Hours Expire*, and it's found in the Group Policy snap-in, under **Computer Configuration\Windows Settings\Security Settings\Local Policies\Security Options**. This parameter can also be set using the *Domain Security Policy* tool or the *Local Security Policy* tool (depending on the context). In either case, look for the setting under **Local Policies\Security Options**. (We'll look at *Local Security Policy* and group policies a bit later in this chapter.)

By default, users can log in to the domain from any workstation, but logon workstations may still be specified by NetBIOS names (see Figure 9.15). However, you must still be using NetBIOS on your network in order for this to be enforced.

**FIGURE 9.15**  
Permitted logon  
workstations

Looking back at the Account tab (Figure 9.13), you'll see that the Account Is Locked Out check box is grayed out. If the account is locked as a result of bad logon attempts (configurable using one of the various Policy tools, as I'll explain later), the box will show up as checked and available. If you wish to manually unlock the account, just uncheck the box. At the bottom of the Account tab you see the account expiration setting. By default, an account never expires, but if you enable the option, the default interval is 30 days. Notice also that a number of account options are available (scroll down in the Account Options box to see all the options). Several of these, like User Must Change Password at Next Logon, are familiar to Windows administrators and fairly self-explanatory to others. Table 9.2 summarizes the available account options.

You may have noticed that the user's password cannot be reset from the Account tab. To reset a user's password, close the account properties sheet and right-click the username in the details pane of DSA.MSC. Choose the option to reset the password, and you will be able to type in and confirm a

new password, as shown in Figure 9.16. You should also select the check box to force the user to change their password at the next logon.

**TABLE 9.2: ACCOUNT OPTIONS FOR USER ACCOUNTS**

OPTION	DESCRIPTION
User Must Change Password at Next Logon	Forces a user to change their password the next time they log in; afterward the box will be unchecked.
User Cannot Change Password	If checked, prevents the user from changing the account's password. This is useful for the Guest account, other shared accounts, and accounts that run services like Exchange.
Password Never Expires	If checked, the password for the account never expires. This is useful for the Guest account and accounts that run services.
Store Password Using Reversible Encryption	Enable this option only for users logging on from Apple computers.
Account Is Disabled	If checked, the account is disabled and no one can use it until it is enabled. Use this option to protect accounts that are used only as templates.
Smart Card Is Required for Interactive Login	This user has a smart card reader attached to their computer. The user must swipe the card into the reader and supply a PIN number instead of their username and password.
Account Is Trusted for Delegation	Enable this option only for service accounts that need to gain access to resources on behalf of other user accounts.
Account Is Sensitive and Cannot Be Delegated	Use this option on a guest or temporary account to ensure that the account will not be delegated by another account.
Use DES Encryption Types for This Account	Enable to support Data Encryption Standard (DES). DES supports multiple levels of encryption, including MPPE Standard (40-bit), MPPE Standard (56-bit), MPPE Strong (128-bit), IPSec DES (40-bit), IPSec 56-bit DES, and IPSec Triple DES (3DES).
Do Not Require Kerberos Preauthentication	Enable to permit an account to use an alternate implementation of the Kerberos protocol.

Resetting a user's password

### Profile Information

Use the Profile tab, shown in Figure 9.17, to specify a user's profile path, a logon script, and a home folder. These options exist to support pre-Windows 2000 clients; these settings and many more can be specified using Group Policy. However, Group Policy only works on Windows 2000 and XP systems. It may be a while before companies abandon Windows NT and 9x workstations completely. Until then, you'll want to use the options in the Profile tab. I'll discuss user profiles and logon scripts in more detail in the sections to come, but the following paragraphs give you the basics about these features.

**FIGURE 9.17**

User profile properties

A user's Desktop settings, from Start menu content right down to a color scheme and mouse orientation, can be stored in a network location so that the user can log in from any system on the network and see the same Desktop. You can specify a shared network location for that purpose. This is also useful if you want to force a user (or group of users) to keep the same settings all the time. Such an arrangement is called a *roaming profile* if it's not forced on a user and if they can make changes. If the user is compelled to load that profile and can't log in without it, it's called a *mandatory profile* (or a *shared mandatory profile*, if more than one user is shackled to it). This feature is most useful for NT 4 clients because Windows 2000 and XP clients support folder redirection and Desktop configuration using group policies. For many more details, refer to "Working with Roaming User Profiles."

A *logon* or *login script* is one that runs at logon time to configure a user's environment and assign network resources, such as mapped drives and printers. Though the art of the logon script is well known in other network operating systems, including NetWare, logon scripts in Microsoft networks have not always been emphasized. Many Microsoft networks were small in the beginning, and users could browse for network resources. Login scripts are, however, filling a more important role for Windows environments; today's networks are larger, and administration of resources and users is becoming increasingly more complex. See "Zen and the Art of Login Scripts" later in this chapter for details, but for now, you should know that the server provides a default path where the logon script will be stored (in the SYSVOL share, which is by default the \Windows\SYSVOL\sysvol directory, but it's configurable). That's why you only need to specify the script's name in the dialog box. However, it is possible that the logon script could be stored in a subdirectory of SYSVOL, for example in SYSVOL\Sales\saleslogin.bat. In that case, you would need to specify the relative path from the SYSVOL root, such as Sales\saleslogin.bat.

A *home folder*, also known as a *home directory*, is a folder assigned to the user for their private use. Although applications may have their own default folder for saving and opening files, the home folder will be the default working folder for a user at the command prompt. You can specify a local path for a user's home folder, but it's only useful if the user will be logging in locally to the machine. For users logging in from the network, you need to choose the Connect option and specify a network path following the UNC convention \\machinename\servername\directoryname. You can also use a variable as a folder name, %username%, to indicate that the home folder name is the same as the user ID.

When you specify a home folder path for the user, if the network share already exists and you have permission to write to it, the server will create the user's home folder automatically. This saves admins a lot of time. If you need a step-by-step procedure to create and assign home folders, see Chapter 11, which covers creating and managing shared folders.

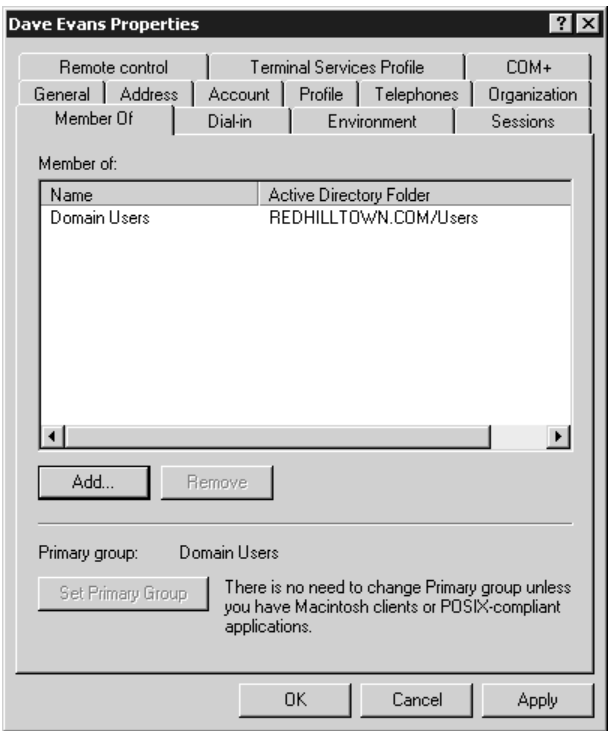

In any discussion about home folders, questions about how to limit disk space consumption are bound to arise. Windows NT 4 had no built-in mechanism to set or enforce disk quotas at all. One strategy was to set up a separate partition for user directories, confining the problem to that partition (kind of like growing horseradish). The hapless admin sometimes ran routine "diskhog" scripts and asked, begged, or publicly humiliated users into cleaning up their home folders. Others threatened to start deleting files at random if users didn't comply. But the best option was to purchase a third-party disk quota tool. However, Windows 2000, and now Windows Server 2003, comes with a simple quota management system for NTFS volumes. You simply enable it for a volume and then set thresholds for warnings and so forth. Read about it in Chapter 10.

### **Group Memberships**

To specify group memberships for a user account, open the Member Of tab in the account properties sheet. As you see in Figure 9.18, by default a new user is a member of the group Domain Users. The Active Directory Folder column on the right indicates the container or OU path for the group. To add a user to another group, choose Add to open the Select Groups dialog box (Figure 9.19). Now you see something interesting. Instead of finding and displaying a list of all available groups, as you did in Windows 2000, now you can specify the object type (groups or built-in security principals) and the location of the object (REDHILLTOWN.COM domain, in this case) and either type in the group name or perform a search for groups within the given context.

**FIGURE 9.18**

Setting group memberships

**FIGURE 9.19**

The Select Groups dialog box

The purpose of this change is not to make your life miserable. Your network could conceivably contain hundreds or thousands of groups in dozens of organizational units; the new Select Groups function prevents you from having to wait while DSA searches for all those groups. It also prevents you from having to scroll through a long list of groups to find the one you are looking for.

If you know the name of the group or groups, just type in the group names, separated by semicolons. Then click the Check Names button to confirm that the names you typed are valid group names. If you don't remember the exact name of the group but want to select it from a list, click the Advanced

button to expand the dialog box and permit searches (shown in Figure 9.20). Use the Locations button to narrow your search within the domain to selected containers or organizational units. Use the Common Queries options to find the group, or simply choose Find Now to pull up a list of all groups within the location context you specified. Figure 9.20 shows the results of a search for all groups in the REDHILLTOWN.COM domain. Select the group name from the list, and click OK. The group name will appear in the Select Groups dialog box. Click OK to add your user to the group and return to the Member Of property tab. The groups you selected should now display in the list. Click OK or Apply to save your changes. Now that wasn't too difficult, was it?

To remove users from groups, use the Remove button in the Member Of tab. See the section “Working with Security Groups” for the skinny on group memberships.

**FIGURE 9.20**

Using the Advanced Options in Select Groups

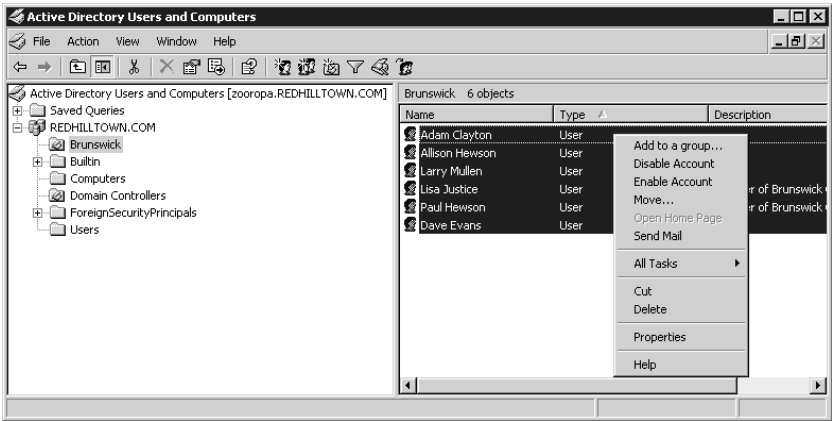

## MANAGING ACCOUNTS

In the preceding sections, I discussed how to make changes to a single user account. Now let's talk about how to make changes to several (or many) accounts at once. While we're on the subject, I'll cover a couple of other multiple-account issues, including how to create a bunch of users at a time.

In DSA.MSC you can select multiple accounts in the details pane by holding down the Shift key while you work the down arrow key, or you can hit the Ctrl key as you click each of the accounts and then right-click to see the context menu while those accounts are selected. As you see in Figure 9.21, you can choose to move them all to another container or OU; add them to a group (to remove members of a group, you'll need to go to the properties sheet of the group itself); or disable, enable, or delete accounts. You can also send them all mail, assuming you have specified e-mail addresses for the accounts.

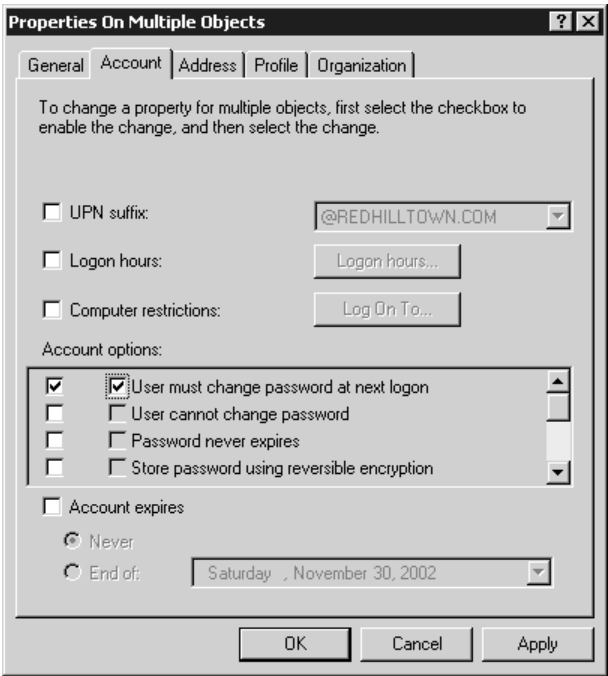

*TIP Remember, changes to a user’s account, such as group memberships, will not take effect until the next time the user logs in.*

**FIGURE 9.21**  
Selecting multiple  
users in DSA.MSC

Choose Properties from the context menu while several accounts are selected to open the properties screen for Multiple Objects (see Figure 9.22). This presents a subset of the properties configurable for each individual account. There is no Member Of tab, but you can use this function to have all selected users change their passwords at next logon.

**FIGURE 9.22**  
Account tab for  
multiple selected  
objects Account tab

Notice in Figure 9.22 that the Account tab for Multiple Objects looks a little different from the Account tab for an individual account. The first check box beside each option tells *DSA.MSC* that you want to configure that option for all of the accounts. Once checked, the button, drop-down list, or second set of check boxes becomes enabled so you can specify what you want the value to be for each property configured. For example, to expire all selected accounts' passwords, first select the leftmost check box beside User Must Change Password at Next Logon. Then you can select the second check box to expire all of the users' passwords labeled. If you checked the leftmost box and not the one closest to the option, you would be choosing to have none of these user's passwords expire.

To create multiple users with like settings, create an account template and copy it. Properties that are copied include account settings (such as Password Never Expires), group memberships, account expiration date (if supplied), and the UPN suffix. The profile information (home directory, user profile path, and logon script) is also copied, and if you used the *%username%* variable to set up the template user's home folder, it will be created automatically for new users when the account is copied.

What if you need to make changes to lots of users at once? You can't select all the users if they don't all display in the details pane of *DSA.MSC*. Members of a particular group may exist in different domains or organizational units, so it's not feasible to try to select all the members of a group at once to make changes. And how can you create, say, 50 or 500 users at a time? You could use the good old *net user* command that's been around since NT 3.51, but it's somewhat limited in its options. The *addusers* utility, which is available in the Windows 2000 Resource Kit, is much more flexible because it can accept input from a comma-delimited text file and assign global and local group memberships. However, *addusers* is not AD-aware; for example, you can't use it to put users into OUs as you create them. Windows Server now offers some robust command-line tools that can be used in batch files or scripts to add user accounts, modify properties, and import or export objects from the Active Directory. *DSADD.EXE* and *DSMOD.EXE*, invoked with the *user* argument, add and modify (respectively) users in the Directory. *CSVDE.EXE* is used to import or export data using CSV (comma-separated value) formatted files.

## RESETTING PASSWORDS

The most commonly changed part of a user's account is the password. You can reset a password from the GUI by right-clicking the user's account in Active Directory Users and Computers, but how about changing it from the command line?

Well, if it's a local user account, then simply type **net user *username* *newpassword***; so, for example, to change the local admin's password to *bigsecret*, you'd type the following:

```
net user administrator bigsecret
```

But that only works for local accounts. To change a password on a domain account, add the */domain* option. So to change the default administrator password on the domain to *reallybigsecret*, type this:

```
net user administrator reallybigsecret /domain
```

To reset the password to a random value, use the `/random` switch:

```
net user administrator /domain /random
```

The randomly created password will display on the screen after the command completes, so that you can write it down. Why would you want to set a password to a random value? Personally, I don't want people using the default Administrator account, but it's so hard to break them of the habit. So I randomize the password, make people use their own Domain Admin account, turn on auditing, and threaten Severe Punishment to anyone caught setting the Administrator password back to something else—unless there's a good reason.

Another way to change passwords, but only from a Windows XP workstation or Server 2003, is to use `dsmod`. It's not quite as simple as the `net user` command, however, because you have to use the Distinguished Name (DN) for the account. To reset Dave's password and force him to change it at next logon, you would type this:

```
dsmod user "CN=Dave Evans, CN=users, DC=REDHILLTOWN, DC=com"  
-pwd H@wkM0@n269 -mustchpwd yes
```

## Understanding Groups

Assigning users to groups makes it easier to grant them rights to perform tasks and permissions to access resources such as printers and network folders. Assisting you in this endeavor are several built-in groups with built-in rights. You'll also want to create your own user groups and assign them certain rights and permissions. The members of the groups you create can, in turn, be granted the ability to administer other groups and objects, even whole organizational units. Groups can contain computers and contacts as well as users and other groups. They can also be used as e-mail distribution lists. So it's important to understand the different types of groups that exist and how to work with them to delegate control, grant access to necessary resources, and configure rights. That is the subject of the next few sections.

## Creating Groups

To create a new group in Active Directory Users and Computers, navigate to the container where you want the group to live. Groups can be created at the root of the domain, in a built-in container such as `Users`, or in an OU. While you have the container highlighted, right-click or pull down the Action menu and choose `New/Group` (Figure 9.23). Supply the name of the group (Domain Engineering) and the pre-Windows 2000 name if it will be different; then choose the group scope and group type, as shown in Figure 9.24. By default, the group scope is `Global` and the type is `Security`. For an explanation of group types and group scope, see the upcoming sections. Click `OK` to create the group in the selected container.

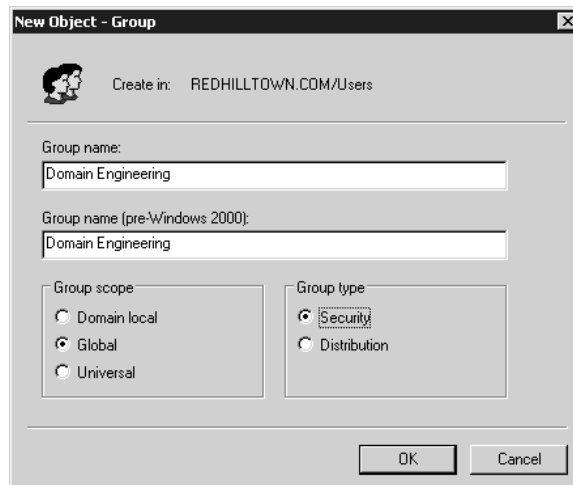

Now let's fill in the rest of the group information and add users to the new group. Find and double-click the group you just created to open the group's properties sheet. In the `General` tab shown in Figure 9.25, fill in a description if you wish and an e-mail address if a distribution list exists for the group.

**FIGURE 9.23**

Creating a new group

**FIGURE 9.24**

Information for a new group

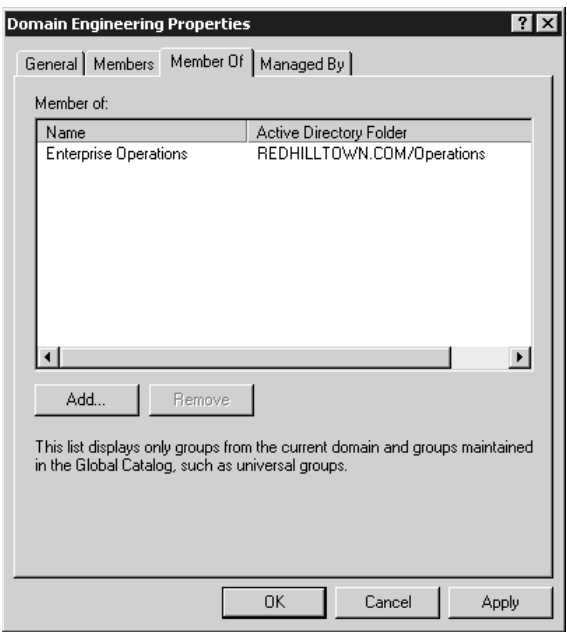

To populate the group, go to the Members tab and click Add. Except for the different object types selected, this is the same dialog box you saw back in Figure 9.19. In this context you may select users, other groups, contacts, and even computers to join the group. Group members can also come from different OUs. Type in the names of the users or groups you want to add, or use the Advanced button to find them. Click OK to finalize your additions and return to the properties pages. To view or

modify the local and universal groups to which the group (Domain Engineering, in our example) belongs, open the Member Of tab (Figure 9.26). The Managed By tab is for optional contact information and does not necessarily reflect any direct delegation of control.

**FIGURE 9.25**  
A group's properties on the General tab

**FIGURE 9.26**  
The Member Of tab in group properties

Another way to add members to a group is to right-click the user account and choose Add to a Group from the context menu. If you want to add several selected users to the same group at once, hold down the Ctrl key as you select the users, then right-click and choose Add to a Group. There's also a button on the toolbar to add one or more selected objects to a group.

One final how-to note: it will probably be necessary to move a group from one container or OU to another at some point. To do this, right-click the group icon in the details pane of the console and choose Move. Navigate to the container that will be the new home for the group (Figure 9.27), select it, and click OK. Alternately, just select your groups and use the new drag-and-drop feature to move them from one OU to another.

**FIGURE 9.27**

Moving a group to another container

**TIP** You cannot use Active Directory Users and Computers to move directory objects between domains. If you need to move users, groups, or organizational units between domains in a single forest, use the `MOVETREE` command-line tool included in the Windows Support Tools.

## Group Types: Security Groups versus Distribution Groups

When creating group accounts, you have the option to classify a group as a *security group* or as a *distribution group*. Security groups are not really new; they are equivalent to user groups as we knew them in all versions of Windows NT. Their new name serves only to distinguish them from distribution groups, which are sort of “non-security groups.”

### SECURITY GROUPS OVERVIEW

Security groups are groups used to assign rights and permissions. Like user accounts, security groups are assigned SIDs. When you view or edit an object's access control list (ACL), for example, the group names that appear on the list are security groups (sometimes they show up as SIDs if the friendly names are slow to resolve). These user and group SID entries on the ACL are matched up with a user's credentials to permit or deny access to the object.

There are three major types of security groups: local, global, and universal—although you might prefer to think of them as four different groups: local, domain local, global, and universal.

Local groups are the kind of groups you find on a stand-alone server, a server that is a member of a domain, a Windows 2000 or XP Professional workstation. Local groups are local to the machine. That is, they exist and are valid only on that workstation or that non-DC server.

Domain local group is the special name for a local group that happens to be on a domain controller. Domain controllers have a common active directory that is replicated between them, so a domain local group on one DC will also exist on its sibling DC. As you'll see when we get into the details, domain local groups are different from other local groups.

Global, universal, and, of course, domain locals live on the DCs in the Active Directory. Global groups are still pretty much like they were in NT 4; they are used to grant access rights and permissions across machine (and domain) boundaries.

Universal groups have been with us since Windows 2000 and can also serve the function of global groups, granting rights and object permissions throughout domains and between domains. Universals are more useful than globals or locals because they are infinitely more flexible with regard to nesting, but you can really use them only when your domain has gone “Windows 2000 native,” which requires that all domain controllers be running either Windows Server 2003 or Windows 2000.

#### **DISTRIBUTION GROUPS AND CONTACTS**

Until Windows 2000 appeared, all NT groups were security groups. They were assigned security IDs; they could be granted rights and permissions. A distribution group is simply a non-security group. Distribution groups don't have SIDs and don't appear on ACLs. So what are they for? If you've worked with Exchange or a similar product, you are familiar with distribution *lists*. These are groups of recipient addresses. It's easier to send mail to ACME Managers, for example, than to individually select each manager's name from a list.

Assuming that you have entered mail addresses for your users, your security groups in the Active Directory are also unofficial distribution lists. Just right-click a group name in *DSA.MSC* and you'll see the option to send mail to the group members, just as you see the option to send mail to a user account when you right-click it. This kicks off your default mail-handling program, and the system will try to send mail using the e-mail address supplied in the account information. So, if you have a set of people working in the finance department and you place all those people in a security group called Finance, you can not only assign permissions for resources to the Finance group, but you can also send mail to the members of the Finance security group, assuming you have filled in e-mail information for each member.

Sometimes organizations need distribution lists that are unrelated to their security groups. For instance, say your company is a communications provider and has a distribution list called Outage Alert. This distribution list is used to notify certain people in the case of a major outage that will affect service to your customers. The members of this list might include people from operations, customer relations, even the chief executive officer. Plus, the distribution list could include external e-mail addresses of key business partners (also known as *contacts*). These people will not have a security group in common, and it's silly to have to create a separate security group just because you need a distribution list. So you can classify a group in the Active Directory as a distribution group, a group with no security privileges. No security identifiers are created for a distribution group, and the membership is not included in a user's credentials at logon time. You can't grant printer permissions to a distribution list because it doesn't appear in the ACL. This group is strictly for e-mail.

In other words, distribution groups are basically only useful if you've adopted Exchange 2000. I can't resist saying it: "Resistance is futile. You will purchase our technology..."

It's part of Exchange 2000's *raison d'être*: it merges the list of e-mail users (the "directory") that Exchange 5.5 and earlier versions had to maintain separately with the list of domain users kept on domain controllers. Exchange 2000 basically doesn't *have* a directory anymore. Instead, it just exploits AD's directory parasitically. You can change a security group to a distribution group and back again, but not if you're still running in Mixed mode. As with everything else that's truly useful, this action requires that you be running in Windows 2000 Native mode or Windows Server mode.

**NOTE** *Contacts are to user accounts what distribution groups are to security groups. Contacts are objects that store information about people, including e-mail, telephone, and related information. Contacts can be members of security or distribution groups, but they are not accounts, so contacts have no security identifier (SID) and cannot be assigned user rights or permissions.*

## Group Scope: Locals, Domain Locals, Globals, and Universals

Where are they recognized and what can they contain? These are the main issues surrounding local, domain local, global, and universal groups. Since they are used to grant rights and permissions, you need to know where that group membership means something, where it is accepted (kind of like American Express). Since you want to nest groups to simplify rights and permissions assignment, you need to know the rules and recommendations for nesting as well.

### LOCAL OR MACHINE LOCAL GROUPS

The basic local group, also called a "machine" local group, is the only type of group that exists on stand-alone servers and Windows 2000 or XP Professional workstations. A stand-alone server or Professional workstation that is not a member of a domain is like an island nation with no knowledge of the outside world. It only recognizes its own local groups and users. Local groups are the only ones that can be granted permission to access resources, and membership is limited to local users. When the machine joins the domain, however, that island nation becomes a member of a greater governing body, like a federation of island nations. It can have local user accounts, as you saw earlier in this chapter, but it can also accept user accounts built on a domain controller—the domain controller's Active Directory is a centralized database of user accounts, saving you the trouble of re-creating them on every single machine.

A machine uses its local groups to simplify administration. For example, suppose I've got a server with a printer on it and I want to control who can use the printer. I create a local group called PrinterUsers and give the PrinterUsers group permission to print to the printer. But there's no one in PrinterUsers initially, so I'd better populate the group. Perhaps I want to let people from the domain print on the printer. I *could* insert user accounts from the domain into PrinterUsers one by one, but that's too much work, so it's more convenient to just grab a group that already *contains* those domain users and stuff the domain-based group into the local group. Just a few clicks and I'm done.

But I got a bit sneaky when I just said "domain-based group"—I left out a bit of important information. You can't insert local groups in local groups. You'd *think* that you ought to be able to just drop Group A into Group B indiscriminately, but you can't. That's why local groups are called *local* groups, to differentiate them from the other kinds of groups. The other kinds of groups—there are three types—can only be built on domain controllers. A local group can contain any of the three domain-based groups—they're called global, domain local, and universal.

### GLOBAL GROUPS

The first domain-based group type is the *global group*. (It resembles NT 4 global groups, if you're familiar with them.) They can only contain user accounts from the domain, as with NT 4 global groups. But Active Directory gives them a bit more power—global groups can exist inside other global groups, so long as the global groups are in the same domain.

You can put a global group inside a local group of any domain that trusts the global group's domain. So you could stuff a global group into a local group for a member server in the same domain as the global group or into a local group for any other domain in the forest. Think of global groups as “traveling groups.” They're a convenient collecting point for domain user accounts.

### DOMAIN LOCAL GROUPS

The second kind of domain-based group is called a domain local group. There are actually two factions of domain local groups: built-in domain locals and other domain locals. You see, when a server becomes a domain controller, its machine local groups become domain local groups and go live in the `Builtin` container in the Active Directory. They have familiar names, like Administrators, Backup Operators, and Print Operators. There are also some new groups that were created with the domain, like Server Operators and Account Operators. Now here's the tricky part. These groups are just like machine local groups, except for the fact that all of the domain controllers in a domain share the same security database. So each and every domain controller will have the same local groups and group members as all of the other domain controllers. If you are a member of Server Operators on one DC, you are a member of Server Operators on all DCs (they are all of one mind...). These “built-in” domain local groups cannot be moved or deleted, and they cannot become members of other local groups at all. Furthermore, other local groups cannot be members of built-in domain local groups. Just think of the built-in domain local groups as machine local groups on domain controllers.

As if things weren't already complicated, there are also domain local groups that are not subject to the limitations of the built-in domain local groups. Unlike the domain local groups in the `Builtin` container, these domain local groups start off life in the `Users` container, but they can be moved and deleted. Any new domain local groups you create will have these properties. I'll warn you right up front that I'm still not quite sure why they exist or what good they do. They're basically domain-restricted versions of global groups.

**NOTE** *In the following paragraphs, assume that I am referring to “non-built-in” domain local groups, unless they are specifically called built-in local groups.*

You just read that global groups are groups built on a domain controller, can contain user accounts from the local domain, and can be placed in any local group in any machine in any domain within the forest (or in any other domain that trusts the global group's domain). So if you have a global group built in domain A and domain B trusts domain A, then you can put that global group in any local group on any machine in domains A or B. A domain local group acts like a global group, except that it cannot be used outside of the domain. You can only put a domain local group into the local groups of machines within the same domain. In this example, then, a domain local group created in domain A could only be placed in a local group on a machine on domain A. Even if domain B trusts domain A, you still can't put any of domain A's domain local groups into domain B's local groups.

So why do these domain local groups exist at all? To tell you the truth, I'm just not sure. I can think of one benefit only: domain local groups do not increase the GC's workload; globals do. The global catalog includes, among other things, names and members of all global groups in all domains in the forest. In contrast, the global catalog does not contain any information about the domain local groups. So I guess a domain local group has a smaller impact on a global catalog. If a large organization wanted to use a single domain model instead of multiple domains, domain local groups could be used instead of global groups to lower the GC replication overhead. But, in any case, it's not much of a difference.

One reason you *do* want to know about domain local groups is if you intend to take the Microsoft certification exams. Now, *they* like domain local groups. You'll get a question or two that will try to trip you up by offering you a solution that involves putting a domain local group into a local group of a different domain. You always know *that* answer's wrong.

### UNIVERSAL GROUPS

The third, and coolest, type of domain-based group is a universal group. Summarized, a universal group can do *anything*, just about. You can only create them on a domain controller, as with domain local and global groups. But you can do the following:

- ◆ Put a global group from any domain in the forest into a universal group
- ◆ Put a universal group into any kind of local group (machine local, domain local, or built-in domain local)
- ◆ Put a universal group inside a universal group (this is the cool part)

Finally, the group that we've always wanted. Just like the Russian *matryoshka* dolls (those dolls that open to contain a doll, which can be opened to contain a doll and so on), you can have universal groups in universal groups inside universal groups...

So the logical question is why don't we just use universal groups for everything and not even worry about domain local or global groups anymore? There are two reasons. First, universal groups can only be used in Windows 2000 Native mode or Windows Server mode. This is only possible after you have upgraded all NT 4 domain controllers to Windows 2000 or Server; the NT 4 DCs can't handle this universal group thing. Second, if you use only universal groups, your global catalog will become bloated and replication issues could occur. You see, universal group names and membership are both replicated to the other global catalog servers (typically, one for each site); global group names, in contrast, appear in the global catalog, but their members don't. With multiple domains, the global catalog contains replicated information for every domain in the forest, and the size (and replication time) will increase exponentially if universal groups contain a large number of objects. A close examination of universal groups, then, leads me to echo Microsoft's general advice about them: they're pretty neat, but use them sparingly.

### OTHER FACTS ABOUT GROUPS

You should know two other things about groups.

First, you can put machine accounts in groups. You couldn't do that in NT 4; you could only put user accounts in groups prior to Windows 2000. Why would you *want* to create groups of machines?

Well, when you start messing around with group policies, then you'll want to create policies that apply only to *some* people or machines. Groups with machines in them are an essential part of accomplishing that.

Second, there's a limitation in Windows 2000's Active Directory that limits a group's size to about 5000 members. That's fixed in Windows .NET Server, but you should keep it in mind if you're using Windows 2000 Domain Controllers. So if you want to have a group with 15,000 members, you have to break it up into, say, three smaller groups and then put those smaller groups into a group together.

If you're still unsure about which kind of groups can go into which other kinds of groups, I've summarized it in Figure 9.28.

**FIGURE 9.28**

Group relationships

## Working with Security Groups

All right, enough talk about global, local, domain local, and universal groups. You need some examples of how this works. However, let me first emphasize how important it is to think about your group structures ahead of time. Once you've "prenested" your larger membership groups (including the local and universal groups) and granted access to the local groups when you set up your resources, you'll only have to fiddle with global and universal group memberships from then on. This will save time and simplify the task of granting object permissions.

Some good, basic nesting examples can be drawn from the nesting patterns that are set up automatically within a domain. One is the nesting of administrator groups. The Administrator account on a local system draws its powers from membership in the local Administrators group. Take Administrator out of the Administrators group, and the account has no special powers or abilities (but I don't recommend it). The Active Directory automatically creates the Domain Admins global group, although it doesn't assign broad admin rights to the group as you might think. When a server joins a domain (or becomes a DC), the global group Domain Admins and the universal group Enterprise Admins are automatically placed in the membership of the local Administrators

group. Figure 9.29 shows the membership of the domain local group Administrators for the REDHILLTOWN.com domain.

**FIGURE 9.29**

Members of the  
Administrators  
domain local group

The net effect of this nesting is that a member of the Domain Admins or Enterprise Admins group is a local administrator on every member machine in the domain. You can override this default behavior by removing Domain Admins or Enterprise Admins from a machine's local Administrators group, but again, I don't recommend this unless you have a special reason to do so. You can replace the Domain Admins or Enterprise Admins group membership in the local Administrators groups with more specific Admin-type global groups, such as F&A Admins or CS Admins. However, having no global or universal groups at all in the local Administrators group limits control to local Administrator accounts and unnecessarily complicates remote administration tasks.

Another example of group nesting is the membership of the local Users group. On a domain member or domain controller, Users automatically includes Domain Users. When you create a new user account in a domain, the new user is automatically assigned to the Domain Users group. It's sort of an All Users in the Domain group. The net effect is that a user account in a domain is automatically granted local user privileges on every domain member machine by default. The user account goes into the global group Domain Users, and the global group Domain Users goes into the local group Users, which is granted local rights and permissions on a system.

You should also know, just for the record, about a couple of other nestings: Domain Guests is automatically a member of the local group Guests on all domain member machines, and Enterprise Admins (a universal group) is a member of the local Administrators group.

Now let's look at the fictional case of Green Onion Resources (GOR), a national IT consulting and integration firm. Green Onion uses Active Directory with Windows Server, Windows 2000, and NT 4 domain controllers. The company has grouped its IT resources into domains by regional offices—for example, GOR South domain, GOR West domain, and GOR East domain. Finance and Accounting (F&A) people are similarly grouped into global groups by region, as are other functional units of GOR. So there are global groups called F&A South, F&A West, and F&A East. Keeping the Finance people in different global groups within different domains allows finer control of region-specific resources and administration. Some central resources, however, must be accessible to all F&A people at GOR. Those resources are located in the Central Finance share on the server called GOR\_ALPHA1. Now, administrators (or their delegates) have set up a local group called F&A Central on GOR\_ALPHA1 and have put each global group (F&A South, F&A West, and F&A East) into the local group called F&A Central. The local group F&A Central has access to the shared resource Central Finance. The following diagram illustrates the GOR strategy for F&A Central access:

This will work and is definitely the way to go in Windows 2000 Mixed mode. When someone leaves or is hired for one of the F&A departments, admins have only to add or remove the user account from the global group to grant or deny access. This will also grant access to the region-specific resources already accessible by the global groups. But when Green Onion Resources upgrades all existing domain controllers to Windows 2000 and Windows Server 2003, they can raise the domain functional level to Windows 2000 Native mode (or Windows Server mode, if all DCs are running Windows Server) and the fun begins. Now they can keep the granularity of having global groups by functional unit and region and can also group these F&A regional groups into a new universal group called GOR F&A. The GOR enterprise admins put the three groups, F&A South, F&A West, and F&A East, into the universal group GOR F&A. They can now use the universal group to directly permit access to F&A organization-wide resources, such as the Central Finance folder, instead of using the three global groups—although it's still considered good form to put the universal group into a local group and grant access to the local group. The following diagram illustrates the adjustment once GOR switches to Native or .NET mode.

**NOTE** *Windows 2000 Native mode and Windows Server mode are identical in their support of universal groups and full group nesting.*

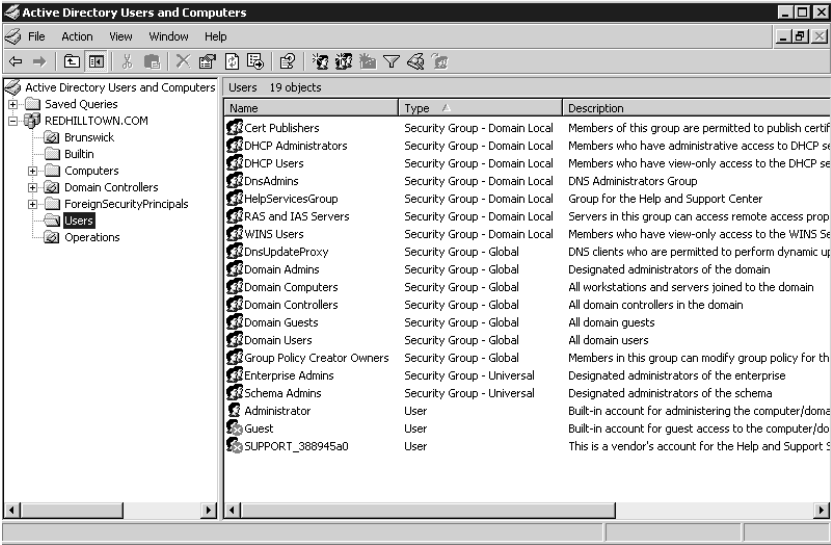

Why should you keep nesting global and universal groups into local groups even after switching to Windows 2000 or Windows Server mode? Certainly, you can instead just put a bunch of accounts into the GOR F&A universal group. If you have a single domain for your organization and never plan to add more, this strategy is perfectly acceptable. With multiple domains, however, remember that the global catalog must replicate the names and members of all universal groups throughout the forest. Domain local groups and global groups are listed in the global catalog, but each individual member is not. Having all 600 or so bean-counter accounts from the various domains in one universal group therefore becomes a replication (read “performance”) issue between designated global catalog servers.

You can also grant access to the shared resource directly to the universal group and bypass the local group nesting altogether. Current thinking holds that it’s easier to just set up access on the resource once, then modify it by manipulating the membership of the group that has access. This was especially true under NT 4, when managing permissions on remote shares was a bit cumbersome, but Active Directory management is changing all that. Granting access directly to the universal group seems to be in keeping with that principle, though, if you plan to keep universal group membership down and limit it to other groups. The drawback is that domains and their global groups might come and go—especially now that an entire domain can be wiped out without reinstalling the operating system. If ACL entries refer to global or universal groups that are no longer recognized, due to a defunct domain or a broken trust relationship, the ACL will report an entry as “Account Unknown” and the Forces of Darkness will increase and multiply and chaos will reign... Well, maybe not. But it’s messy. If you *always* grant access to a local group, the machine will *always* recognize it. Then you can simply grant or deny access to a resource by manipulating the membership of that local group.

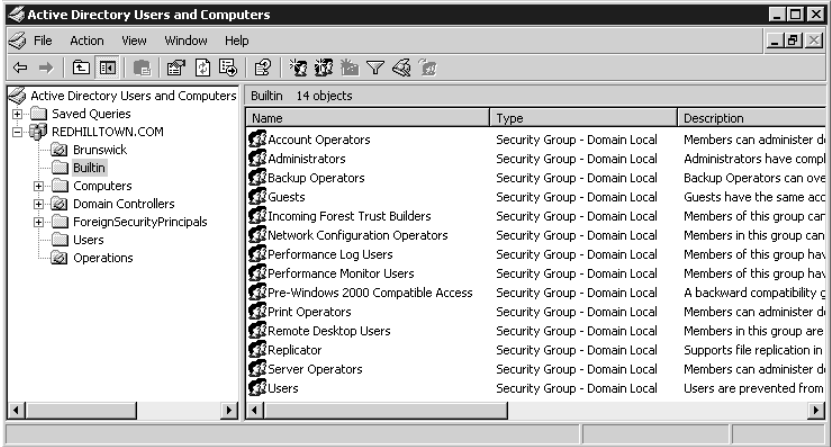

**BUILT-IN DOMAIN LOCAL GROUPS**

You might have noticed in our earlier tour of DSA.MSC that all the built-in user accounts, like Guest and Administrator, are placed by default in the Users container (shown in Figure 9.30). The Users container also contains predefined universal, domain local, and global groups. But some domain local groups were created in the BuiltIn container (shown in Figure 9.31) when you created the domain. There's a very important difference between groups that are created in the BuiltIn container and other domain local groups. Domain local groups that are homed in the BuiltIn container function like machine local groups, but on domain controllers. Like machine local groups, they can contain global or universal groups and accounts, but they cannot be members of local groups on other servers or domains. Unlike the domain local groups in the Users container, you cannot move the BuiltIn container's domain local groups to other OUs.

**FIGURE 9.30**  
DSA.MSC Users  
container

**FIGURE 9.31**  
DSA.MSC BuiltIn  
container

Built-in domain local groups have predetermined rights and permissions for the purposes of administration. Membership in these (or any) groups grants the user all the powers and abilities granted to the group. This is a way to quickly assign well-defined administrative roles rather than having to create them from scratch. For example, Server Operators have the rights needed for creating and managing shared folders. Backup Operators have the right to back up files and directories, even if they don't have permission to read or modify them.

The following paragraphs list the built-in domain local groups and their special abilities. Here are a few points to keep in mind about these groups:

- ◆ Unless otherwise noted, these groups also exist as local groups on non-DC servers. If they are local groups, their rights are limited in scope to the local machine. If they are domain local groups, their rights apply to all of the domain controllers in the domain.
- ◆ Some default group nesting patterns (sounds like we're describing migratory birds, doesn't it?) appear to extend built-in domain local group rights to all systems in the domain; however, this is an illusion. Global, and sometimes universal, groups are used to accomplish this. Take note of any automatic global group nestings that grant domain-wide administrative rights.
- ◆ Be aware that you can't delete the **Builtin** container domain local groups. You can, however, create other users and groups within the **Builtin** container, although they won't have any special rights unless you assign them.
- ◆ There should be no need to say this, but I will anyway. Exercise caution when adding accounts to these groups, or to any groups with administrative rights and special permissions.

***TIP** In general, rights grant the ability to do something, often something admin related or otherwise restricted. Permissions, on the other hand, give you the ability to access resources such as files and printers as well as Active Directory objects such as group policies.*

**Administrators** Administrators have almost every built-in right, so members are basically all-powerful with regard to administration of the system. Domain Admins and Enterprise Admins are by default members of the Administrators group, so members of the Administrators domain local group have full control of all domain controllers and full power in the domain.

**Account Operators** Members of the Account Operators group can create user, computer, and group accounts for the domain and modify or delete most of the domain's user accounts and groups. They cannot, however, delete or modify groups in the **Builtin** folder or the Domain Controllers OU, Administrator accounts, the Domain Admins global group, or the domain local groups Administrators, Server Operators, Account Operators, Print Operators, and Backup Operators. Account Operators cannot administer security policies, but they can log on locally to domain controllers and shut them down. This group only exists on domain controllers and has no default members. Members of the domain local Account Operators group cannot modify user or group accounts on member servers.

**Backup Operators** Members of Backup Operators have the right to back up and restore files, whether or not they have permission to access those files otherwise. They can also log on locally to servers and shut them down. There are no default members of the Backup Operators group. Members of the domain local Backup Operators group only have these rights on domain controllers.

**Guests** Members of the domain local Guests group have no special user rights. The Guest account (which is disabled by default) and the global group Domain Guests is a member of this group by default. Members of the local Guests group on non-DC systems can log in and run applications. They can also shut down the system, but otherwise their abilities are even more limited than Users. For instance, Guests cannot keep a local profile.

**Print Operators** Members of this domain local group can create, manage, and delete Active Directory printer shares and printers that are attached to domain controllers. Additionally, they can log in at and shut down domain controllers. There are no default members of this group and no default group nesting occurs with local Print Operators groups on non-DC servers.

**Server Operators** On domain controllers, members of the Server Operators group can create, manage, and delete printer shares and network shares; back up and restore files; start and stop services; format the server's fixed disk; lock and unlock servers; unlock files; and change the system time. Server Operators can also log on locally and shut down the system. This group exists only on domain controllers and has no default members. Members of the Server Operators group only have these rights on domain controllers.

**Users** Because the Domain Users group is a member of this group by default, all accounts created in the domain are also members of the domain local Users group. Members of the domain local Users group have no special rights on domain controllers, and they cannot log on locally to the servers. However, members of the local Users group on workstations can run applications (but not install them). They also can shut down and lock the workstation. If a user has the right to log in locally to a workstation, they also have the right to create local groups and manage those groups they have created.

**Replicator** This group is strictly for directory replication. The group has no default members. A user account is used to run the Replicator service, and that user should be the only member of the group.

**Incoming Forest Trust Builders** Members of this group can create incoming, one-way trusts to the forest. This group has no default members and only exists on domain controllers.

**Network Configuration Operators** Members can modify TCP/IP settings on domain controllers in the domain. Non-DC servers have an equivalent machine local group. This group has no default members.

**Pre-Windows 2000 Compatible Access** This group has read access to all users and groups in the domain and has the right to access domain controllers from the network and to bypass traverse checking. The only members of this group should be using workstations running Windows NT 4 or earlier. The special identity Everyone is a member of this group by default.

**Remote Desktop Users** Members of this group can log on remotely to domain controllers in the domain. There are no default members of this group.

**Performance Log Users** Members have remote access to logged performance counters on domain controllers. There are no default members of this group.

**Performance Monitor Users** Members have the ability to remotely monitor domain controllers. There are no default members of this group.

**Power Users** This group only exists as a machine local group on 2000 and XP Workstations, and on nondomain controller servers. Members have a subset of the Administrator's rights. Power users can create user accounts and local groups and can manage the membership of Users, Power Users, and Guests, as well as administer other users and groups that they have created.

### OTHER BUILT-IN GROUPS

In the Users container, other predefined domain local groups and global groups may be created as part of the configuration of a certain service. These groups might serve to allow users access to certain services (DHCP Users and WINS Users, for instance) or to provide a group container for administrators of the service, as in the case of DHCP Administrators and DNS Admins. These and other predefined global groups may also have special rights and/or permissions for particular actions, but not the broad rights and permissions of Administrators, Server Operators, or another built-in local group.

**NOTE** Some predefined groups, including Domain Computers and Domain Controllers, are designated for machine accounts, although you can add a user account to Domain Computers if it gives you a thrill.

A Windows Server 2003 domain controller has several built-in global and universal groups, among them Domain Admins, Domain Users, and Domain Guests. These groups will only appear on domain controllers. In fact, it's impossible to create global and universal groups anywhere *other* than on domain controllers. Although you might use an administration tool like DSA.MSC while sitting at a non-DC to create the global groups, the groups will exist only on domain controllers. Table 9.3 describes the most important built-in global and universal groups.

**TABLE 9.3: BUILT-IN GLOBAL GROUPS**

GROUP	WHAT IT DOES
Domain Admins	By placing a user account into this global group, you provide administrative-level abilities to that user. Members of Domain Admins can administer the home domain, the workstations of the domain, and any other trusted domains that have added this domain's Domain Admins global group to their own Administrators local group. By default, the built-in Domain Admins global group is a member of both the domain's Administrators local group and the Administrators local groups for every NT, Windows 2000, or XP Professional workstation in the domain. The built-in Administrator user account for the domain is automatically a member of the Domain Admins global group.
Domain Users	Members of the Domain Users global group have normal user access to, and abilities for, both the domain itself and any NT/Windows 2000/XP Professional workstation in the domain. This group contains all domain user accounts and is by default a member of every local Users group on every NT/Win2K/XP workstation in the domain.
Group Policy Creator Owners	Members of this group can modify domain Group Policy. Administrator is a member of this group by default.

*Continued on next page*

TABLE 9.3: BUILT-IN GLOBAL GROUPS (continued)

GROUP	WHAT IT DOES
Enterprise Admins	Members of this universal group have full power over all domains in the forest. You'll only see it in the forest root domain. Enterprise Admins is a member of all Administrators groups on all DCs in the forest. Administrator is a member of this group by default.
Schema Admins	This universal group only appears in the forest root domain. Members have the ability to modify the AD schema, which is very scary indeed. Administrator is a member of Schema Admins by default.

SPECIAL BUILT-IN GROUPS

In addition to the built-in local, global, and universal groups, several special “identities” that are not listed in DSA.MSC (or Computer Management Users and Groups for that matter) will appear on Access Control Lists for resources and objects, including the following:

- INTERACTIVE Anyone using the computer locally.
- NETWORK All users connected over the network to a computer.
- EVERYONE All current users, including guests and users from other domains.

NOTE Incidentally, the INTERACTIVE and NETWORK groups together form the Everyone local group.

- SYSTEM The operating system.
- CREATOR OWNER The creator and/or owner of subdirectories, files, and print jobs.
- AUTHENTICATED USERS Any user who has been authenticated to the system. Used as a more-secure alternative to Everyone.
- ANONYMOUS LOGON A user who has logged in anonymously, such as an anonymous FTP user.
- BATCH An account that has logged in as a batch job.
- SERVICE An account that has logged in as a service.
- DIALUP Users who are accessing the system via Dial-Up Networking.

How Do Organizational Units Fit In?

Organizational units (OUs) are logical containers in a domain. They can contain users, groups, computers, and other OUs, but only from their home domain. You can't put global groups or computers from another domain into your domain's OU, for example.

The usefulness of OUs is strictly for administration. Administrators can create and apply group policies to an OU and can delegate control of OUs, as well. The idea is to have a subdivision of a domain but still share common security information and resources. Grouping users, groups, and resources into organizational units allows you to apply policies in a more granular fashion and also

to decide specifically who manages what and to what extent. So when you're advised about how to group your OUs, keep in mind that the tool must fit your hand; your organization may be unique, so your approach to OUs may be as well.

Rather than creating OUs for locations (that's what sites are for), departments, and so on, think about how your organization will be administered. Design your OUs with delegation in mind. Keep it simple for your own sake. Thousands of nested OUs just make more work for you. Also, OUs are unrelated to the process of locating resources on your network, so you needn't group them with a browse list in mind, either.

What's the difference between an OU and a container? An OU is a container, but not just a container like the `Users` container in `DSA.MSC`. You can delegate control of a container (you can delegate control of anything), but you can't apply Group Policy to one.

How are OUs different from groups? A user can be a member of many groups but can only be in one OU at a time. Like groups, OUs can contain other OUs. Group names appear on ACLs, so you can grant or deny access to groups. OUs do not appear on ACLs, so you can't give everyone in the Finance OU access to a printer, for example. On the other hand, you can't assign a designated set of Desktop applications to everyone in a security group, but you can publish or assign the company accounting package to the entire Accounting OU.

## **Zen and the Art of Login Scripts**

Login scripts are an ancient revered method for configuring a user's working environment and assigning network resources. Before we had Network Neighborhood, in a time before Microsoft networks came into prominence, network clients were relatively unenlightened about the network around them. Login scripts were written in the common language of the client and ran from the server on the client at the time of logon. These scripts would create local drive mappings to the servers, redirect local ports to assign printers, synchronize the system clock with a central designated timeserver, and perform other honorable related tasks. One could say, Grasshopper, that logon scripts reached their peak in the Age of NetWare, when the color red blanketed the networking world. In the Age of NT 4, networking clients become more aware of the network around them. In small isolated networks, the Art was all but abandoned, but logon scripts still flourished in large complex environments, prized for their eternal usefulness. During this time, the Art became more sophisticated. While logon scripts are now used to perform increasingly complex tasks, the essential Art, the True Art of Login Scripts, has remained unchanged.

Since Windows 2000 came onto the scene, we've had the ability to use not only logon scripts, but also logoff scripts, startup scripts, and shutdown scripts. We're no longer confined to a limited set of shell commands, either. Organizations now use a myriad of scripting and even programming languages to accomplish eye-popping configuration feats compared with those of 10 years ago. There is no way to do justice to everything that's out there in the few pages allotted here, but I will discuss your choices of scripting language, take a look at an example logon script, and tell you how to assign a logon script to users.

### **SCRIPTING LANGUAGES**

A wide variety of scripting environments and languages are available today, including the native Windows shell commands, Windows Scripting Host (WSH), KiXtart, XLNT, Perl, VBScript, JScript, even Python. You can use literally any language that is useful to you and is understood by

your client machine. Login scripts are only limited by a couple of things: developers and clients. A script developer (that includes you) must know how to use the chosen tool. It's no good to try writing a logon script in C if you can't even figure out how to make it say "Good morning." The vast majority of us aren't programmers, so we must use simpler tools, such as shell scripts or special logon script languages like KiXtart or XLNT. The client, as well, must understand the language of the script, so if you want to use Perl, for example, you need a Perl interpreter installed on each client system.

If all of your clients are Windows 98 or later, you might want to look into Microsoft Windows Script 5.6, a package that seems to include all of the current Windows scripting technologies, including Windows Scripting Host (WSH), an environment for running Visual Basic Scripting Edition (VBScript) and JavaScript natively on Windows platforms. The Scripting Host and a Script Debugger are included with Windows Server 2003 and Windows 2000. WSH is an installation option for Windows 98, but if you need WSH for 95 or NT you'll need to download it from Microsoft (go to <http://msdn.microsoft.com/scripting>). The site is an excellent source of information on Windows scripting with links to newsgroups and other fun stuff.

Why not use Windows shell commands for logon scripts? Well, it's definitely an option. No special client software is required, although the command set for pre-NT clients is rather limited. Since NT 4, command-line language has become fairly robust in comparison to earlier Windows operating systems, and there is a great deal of backward compatibility built into the NT, Windows 2000, and XP shell language. However, Windows shell scripting is still less flexible or intuitive, in my humble opinion, than any of the various Unix shell languages. Remember that Windows software (even Win2K and XP) was not designed primarily for command-line geeks, but for people with mice (the electronic kind). However, Microsoft is showing some major improvements in the command-line arena, so let's encourage them.

Perl (Practical Extraction and Reporting Language) was initially developed for system administrators as a tool to run reports. It has become much, much more. Platform independent like Java, but without the memory overhead of the Java virtual machine, Perl has proven its usefulness to Unix administrators and developers and has become one of the more popular scripting languages in the Windows world as well. You will have to install a Perl interpreter and modules on your clients, although this process is relatively painless. Alternately, there is a utility called Perl2Exe that converts Perl scripts to executables. If you don't mind the overhead of running a program that's around 700K (script, interpreter, and any modules) across the network whenever users log in, download it from <http://www.indigostar.com>. The latest version of Perl for Windows, ActivePerl, is available as a Windows Installer (MSI) package from [www.activestate.com/Products/ActivePerl/](http://www.activestate.com/Products/ActivePerl/). ActivePerl includes Perlscript, an ActiveX scripting engine like VBScript or JScript. There is also a wealth of information on Perl in bookstores and at [www.perl.com](http://www.perl.com).

There are numerous other scripting environments, including C shell, PythonWin, XLNT, and the MKS Toolkit by Mortice Kern Systems, Inc. (MKS is a toolkit for Unix-heads; it includes Korn shell, Vi editor, AWK, and more). However, the login script processor of choice for many Windows-based network administrators is KiXtart. KiXtart was designed by Ruud van Velsen at Microsoft Netherlands. For a long time it was available as freeware, but today it is distributed as CareWare (Ruud asks that you make a charitable donation to support the people of Nepal). KiXtart is extremely flexible and easy to use. The latest version, KiXtart 2001 (Version 4.11) is available from <http://www.scriptlogic.com/kixtart>. An HTML help file and many other resources are

also available at this site. One big advantage of KiXtart is that a wide range of Windows clients can use the exact same command set. The bad news is that you do have to either install the KIX32.EXE executable locally, or run it from a location on the network. Windows 9x clients also require a couple of DLLs to be installed locally.

### ASSIGNING THE LOGIN SCRIPT

Specify a logon script in the user account profile information in DSA.MSC, or assign scripts using Group Policy. Either way, the scripts and any other necessary files must be in the SYSVOL share, found in \Windows\SYSVOL\sysvol on the domain controller. Pre-Windows 2000 clients look for a share called NETLOGON to get to the script. Windows 2000 Servers and Server 2003 create a NETLOGON share in \Windows\SYSVOL\sysvol\domainname\scripts for backward compatibility. Make sure that users have Read and Execute permissions on the script file.

If you have Win2K or XP Professional machines as clients, Group Policy can be used to assign a logon script. Scripts assigned to Win2K/XP machines using Group Policy run asynchronously in hidden windows, so the user shell may actually start before logon script processing is complete. Scripts assigned in account properties run synchronously in visible windows by default. In that case, the user shell does not start until the script is done.

### EXAMPLE LOGIN SCRIPTS

Login scripts can perform a wide variety of functions; the most frequent tasks are mapping network drives, connecting users to printers, gathering inventory information, and updating software or virus definitions. The login script can also be used to synchronize client systems with a timeserver on the network. The sample scripts in this section illustrate how to accomplish some of these common tasks in a logon script.

In my first and most basic example, I'll use the Windows shell language. The server's name is SERVER1.

#### **Example 9.1: Login.bat (Simple Shell Script)**

```
@echo off
REM Login.bat Version 1.0
REM Exit if user has logged on to the server
IF %COMPUTERNAME%.==SERVER1. GOTO END
REM Delete pre-existing drive mappings
NET USE H: /DELETE >nul
NET USE J: /DELETE >nul
REM Map H: to Users Share
NET USE H: \\SERVER1\USERS /YES >nul
REM Map J: to Apps Share
NET USE J: \\SERVER1\APPS /YES >nul
REM Synchronize time with server
NET TIME \\SERVER1 /SET /YES
:END
```

As you can see from the comment statements, the script first checks to see if the local computer name matches the server name and exits if it does. This is to prevent unnecessary mappings if an admin logs on locally to the server. After deleting any pre-existing drive mappings, the script maps

drives to the Users and Apps shares on the server. The final command tells the workstation to synchronize with the server without prompting the user for confirmation.

The script shown in Example 9.1 works great (for Windows 9x clients and XP systems) if you have only one server, if all users will have the same drive mappings, and if all users will use the same login script. It doesn't map any printer connections, though. And it's very likely that your network is more complex than this. You'll need to map drives based on group memberships; unfortunately there is no super-simple way to do this with the Windows shell.

My second example uses KiXtart to obtain group membership information, map drives, connect to printers, and call an update script to upload any new virus definitions or software patches. The software update script is not included here, but I show the `call` command in the main routine as an example of using logon scripts to perform other configuration tasks.

In this configuration, `kixlogin.bat`, the designated logon script, calls the main script (`kixlogin.scr`). This is to accommodate Windows 9x clients; if you have only Windows NT/2000/XP clients, the executable `KIX32.EXE` can be specified as the login script in the User's account properties with a script name as an argument (for example, `Kix32.exe kixlogin.scr`).

The KiXtart script (`kixlogin.scr`) uses semicolons for comments, which I have supplied to explain what the script commands are doing. `Kixlogin.bat` uses native shell scripting, so comment lines are preceded by the command `REM`. Since this is a sample logon script and not a textbook example of shell scripting or KiXtart scripting, I've included numerous comments instead of a line-by-line explanation or the usual commented-out statements in the script to let you know what's going on.

All of the executables used in the scripts are kept in `NETLOGON` for simplicity's sake (we have Windows 2000, XP, NT 4 workstations, and a few straggling Windows 98 clients).

### **Example 9.2: Kixlogin.bat (Shell Script that Calls Kixlogin.scr)**

First, turn off the command echo:

```
@echo off
```

Since NT/2000/XP and 9x call logon scripts differently, check the `%OS%` variable to see if it's set to `Windows_NT`. If it isn't, skip to the subroutine for Windows 9x clients:

```
@if not "%OS%"=="Windows_NT" GOTO 9X05
```

NT-based machines can run the script with a UNC path. The `kix32` executable takes as its argument the name of the script:

```
:NT05
\\SERVER1\NETLOGON\kix32.exe \\SERVER1\netlogon\KIXLOGIN.scr
GOTO EOF
```

Windows 9x machines temporarily map the Z: drive to `NETLOGON` during the logon sequence. They cannot run the script using a UNC path. The path statement is not for `KIX32.EXE`, but rather for other executables called later:

```
:9X05
path=z:\
z:\kix32.exe z:\kixlogin.scr
```

```
GOTO EOF
:EOF
EXIT
```

**Example 9.3: Kixlogin.scr (KiXtart Login Script Called by Kixlogin.bat)**

```
:STAGE1
```

Statements preceded by a question mark (?) cause the text that follows on the same line to be displayed on the console screen, much as ECHO does in the native shell language:

```
? "Login script now processing..."
? "Querying your System Information..."
```

I need to check again for 9x versus NT/2000/XP machines, because variables are set differently for each. @INWIN is a KiXtart variable used for this purpose. Again, the script processing skips to the appropriate subroutine, SETVARNT or SETVAR95, depending on the OS. Win2K and XP boxes will process like NT machines and Windows 98 systems will process like Windows 95 machines:

```
IF @INWIN = 1
    GOTO SETVARNT
ELSE
    GOTO SETVAR95
ENDIF
```

These commands set variables on Windows 9x clients using SHELL and WINSET.EXE. SHELL is a KiXtart routine to call a native shell command, and WINSET.EXE is an executable from the Windows 95 CD that sets environmental variables. @USERID and the other words preceded by @ are variables that KiXtart understands. Thus, I am using KiXtart variable values to set actual system environmental variables:

```
:SETVAR95
SHELL "winset.exe USERNAME=@USERID"
SHELL "winset.exe ADDRESS=@ADDRESS"
SHELL "winset.exe COMPUTER=@WKSTA"
SHELL "winset.exe DOMAIN=@DOMAIN"

On NT, Win2K, and XP boxes, the following commands set variables without “shelling out” to the native command environment. The SET command sets user variables, and SETM defines system variables:

```
:SETVARNT
;set variables on NT clients using set command
```

```

SET USERNAME="@USERID"
SETM ADDRESS="@ADDRESS"
SETM COMPUTER="@WKSTA"
SETM DOMAIN="@DOMAIN"
SET COMMENT="@COMMENT"
SET FULLNAME="@FULLNAME"
SET HOMEDIR="@HOMEDIR"
SET HOMESHR="@HOMESHR"
SET LSERVER="@LSERVER"
SET PRIV="@PRIV"

```

Time synchronization is an important function in many logon scripts. The `SERVER1` listed here is a designated timeserver that synchronizes regularly with a reliable external time source:

```

:STAGE2
? "Synchronizing your system's clock"
;synchronize with timeserver
SETTIME \\server1

```

Next, I check to see if the time synchronization was successful. If it wasn't, a message box pops up to get the user's attention.

```

IF @error = 0
    ? "System clock synchronized"
ELSE
    MESSAGEBOX ("Cannot synchronize the system clock.
    Please inform your administrator.", "XYZ Login Script", 0)
ENDIF
?

```

The most recent version of KiXtart automatically enumerates group memberships from the user's security token and stores them in the Registry. This makes it very simple to query group membership information when mapping network drives. Just in case, I'll first delete any preexisting drive mappings. Again, if there are errors while deleting previous drive mappings, a message box will get the user's attention.

```

? "Now mapping network drives..."
?
;delete any previous drive mappings and check for errors
USE "*" /DELETE
IF @error = 0
    ? "Previous mappings deleted..."
ELSE
    MESSAGEBOX ("Cannot delete previous drive mappings.
