    Please inform your administrator.",
    "XYZ Login Script", 0)
ENDIF
;MAP Drives by Group Membership

```

```

;Map Domain F & A to M: drive
IF INGROUP ("Domain F & A") = 1
    use M: "\\server1\F&A Control"
    ? "F & A Drive Mapped"
ENDIF
;Map Domain Sales to S: drive
IF INGROUP ("Domain Sales") = 1
    use S: \\server1\Sales
    ? "Sales Drive Mapped"
ENDIF
;Map Domain Tech Services to T: drive
IF INGROUP ("Domain Tech Services") = 1
    use T: \\server1\TechSvc
    ? "Tech Services Drive Mapped"
ENDIF
;Map common drives for Domain Users
IF INGROUP ("Domain Users") = 1
    use G: \\server1\apps
    use P: \\server1\public
    use N: \\server1\infosys
    use H: @HOMESHR
    ? "Global Drives and Home Directories Mapped"
ENDIF

```

Finally, the script will call the `update.bat` script, which checks to make sure the system has all the current virus definitions and software patches installed.

```

    shell update.bat
    ? "Login Script Complete"
EXIT

```

## Understanding User Permissions and Rights

Much of what we've got to do as administrators is to both provide our users with access to *some* network resources and keep the users *from* other network resources. Ever since NT 3.1, Microsoft operating systems have let you control access with two tools: permissions and rights.

### Object Permissions, ACLs, and ACEs

You've seen some references to permissions so far, and you'll see a lot more of them in the next chapter, which is on file and directory shares. Basically, a *permission* is just a setting that controls your level of access to some object on the network. For example, I could create a file called `MYSECRETS.TXT` and set its file permissions so that only I can read, write, and delete it and so that some other user—perhaps a father-confessor figure?—can read it, but nobody else can access it at all. Permissions let me do that; they control access to an object.

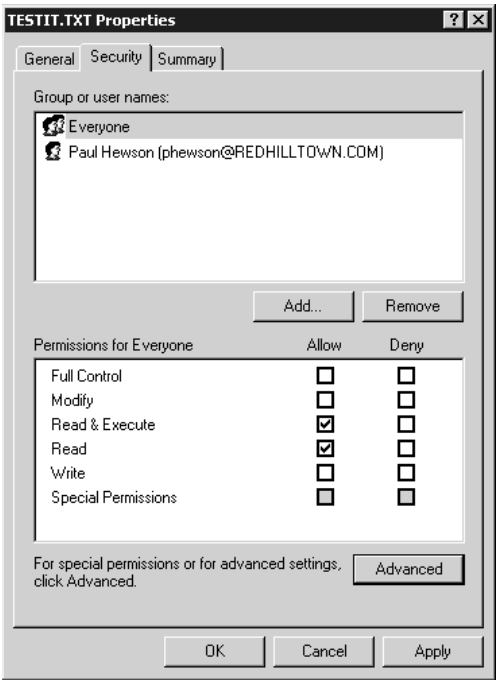

You probably think of permissions mainly in terms of files and directories, but there are many more things in the NT family of Microsoft operating systems that have permissions. A few include the ability to control things like the following:

- ◆ Registry keys, which determine who can read or modify a given key or value entry
- ◆ Contents of domains and organization units, which determines who can add things (for example, users or machine accounts) to a domain or an OU
- ◆ System services, so you can control who can start or stop a given service
- ◆ Directories and files, both of which have permissions

As you’ll learn throughout the rest of the book, many things have permissions. You can usually find an object’s permissions by right-clicking the object and choosing Properties. In the resulting property page, there is usually a tab labeled Security. That’s not always true, and in some cases, the UI doesn’t reveal the underlying security items. In other cases, you may have to take some extra steps to see the permissions. For example, you will not see the Security tab on a domain or organizational unit in Active Directory until you choose View/Advanced in Active Directory Users and Computers, as you may recall from the “Advanced Delegation” section in Chapter 8.

Here’s a simple example of permissions. I’ve right-clicked a file named TESTIT.TXT on my hard disk, chosen Properties and then the Security tab. It shows me Figure 9.32.

**FIGURE 9.32**  
Security tab for a file

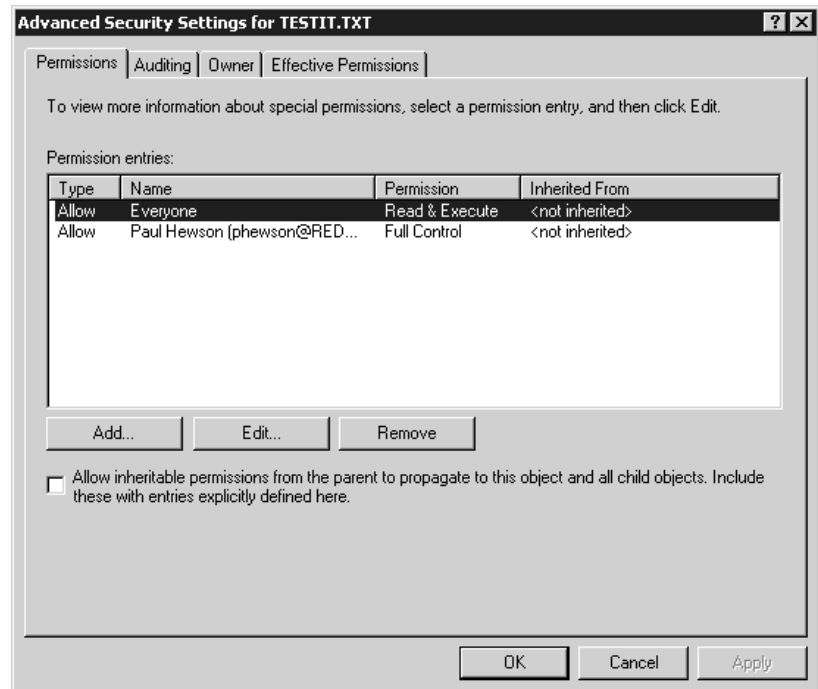

You see from it that the Everyone group has read permission. To see the permissions for the other account shown in the figure (phewson@REDHILLTOWN.COM), you have to highlight

the account name in the permissions dialog box. Also notice that the object has six possible permissions: Full Control, Modify, Read and Execute, Read, Write, and Special Permissions. The Special Permissions are accessible using the Advanced button; they include permissions like Change Ownership and Write Attributes. Collectively, this set of permissions is called an access control list or ACL (pronounced *ackel*). Each entry in the ACL—the phewson@REDHILLTOWN.com and Everyone entries, I mean—are called access control entries (ACEs). But there’s a lot more detail possible; click the Advanced button to see more, and you’ll see a dialog box like the one in Figure 9.33.

**FIGURE 9.33**

Advanced Security Settings dialog box

You can get to this dialog box from *any* Security dialog box, as far as I can see, by clicking the Advanced button. It makes more or less sense, depending on the object type. In the case of this file, you can see that it really doesn’t show you much that you didn’t already know. But the other two tabs are useful; Auditing lets you tell the system whether or not to audit access to this file and what level of detail to log, and Owner lets you find out who owns the file and lets you change the owner. (In Microsoft terms, an object’s “owner” is a person who has an unstoppable right to change permissions on that object. We’ll discuss that in greater detail in the next chapter.)

To find out the most nitty-gritty details that you can about the ACE for Everyone, click it and then Edit. That shows you a dialog box like the one in Figure 9.34.

Again, you’ll see a dialog box *like* this for any object that has ACLs, but the exact contents of the dialog box vary from object to object. In this particular case, you see 13 very specific permissions, the lowest-level permissions possible on a file. The list of permissions that you saw in the first dialog box (Full Control, Modify, Read and Execute, Read, and Write) aren’t really permissions at all—they’re *groups* of these 13 lowest-level permissions.

**FIGURE 9.34**

Lowest-level permissions for a file

## User Rights

While permissions grant different access to different objects, rights give you the ability to do particular things. And yes, the line between permissions and rights *is* a little fuzzy. For example, is the ability to create user objects a permission or a right? Well, under the hood, a user is just an object in a particular “container” called the domain. So creating a user in a domain is very similar to creating a file in a directory, and it is permissions that control that. But what about the ability to physically sit down at a server and log on? That’s not a permission; that’s a right.

In general, rights tend to apply to a particular system (for example, the right to log on to the system, the right to change its time, and the right to shut it down). So I guess, in a sense, Microsoft could simply have considered any given system to be a “container” and then made those powers (local logon, time change, shutdown) into ACLs on the system. But they didn’t, and so we have rights.

Additionally, some rights are basically system-specific powers that override ACLs. For example, one right is the right to back up files. Clearly, you’d think that you can’t back up files if you can’t read them, but anyone with the back-up right *can* back up any file on a system, including the ones that he or she is denied access to—rights trump permissions. But don’t worry about your privacy, because the Backup Operators group’s rights are only valid in conjunction with a backup routine. Backup Operators can’t just open files on the server and read the contents, for example.

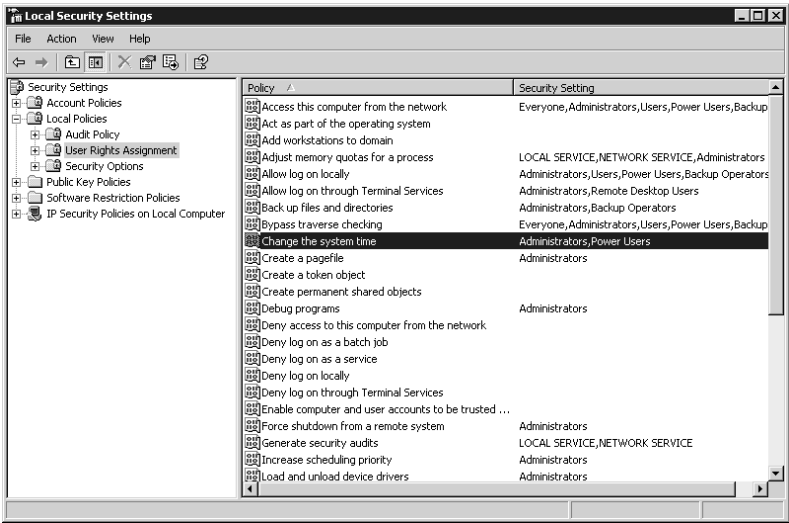

Windows Server 2003’s built-in groups have certain rights already assigned to them. You can also create new groups and assign a custom set of user rights to those groups. As I’ve said before, security management is much easier when all user rights are assigned through groups instead of to individual users.

To view or modify the local rights assignment for a user or group, open the Local Security Policy tool from the Administrative Tools group on a non-DC or use the Domain Controller Security Policy tool for a DC. Open `Local Policies\User Rights Assignment`. A listing of rights and

the users or groups to which those rights have been granted will be displayed in the details pane on the right, as shown in Figure 9.35.

**FIGURE 9.35**  
Local user rights policy

To add or remove a right to or from a user or group, double-click the right as displayed in the details pane or right-click the selected right and choose Properties. In Figure 9.36 you see the property information for the right to change the system time. To remove this right from a group, highlight the name of the group and choose Remove. To add a group or user to the list, choose Add User or Group and in the Select Users, Computers, or Groups dialog box, type in a name or use the Advanced button to search for the name. Table 9.4 lists the most commonly modified user rights with descriptions.

**FIGURE 9.36**  
Local security policy setting for a user right

**TABLE 9.4:** LOCAL USER RIGHTS

USER RIGHT	DESCRIPTION
Access this computer from the network	Connect over the network to a computer.
Act as part of the operating system	Act as a trusted part of the operating system; some subsystems have this privilege granted to them.
Add workstations to domain	Make machines domain members.
Back up files and directories	Back up files and directories. As mentioned earlier, this right supersedes file and directory permissions.
Bypass traverse checking	Traverse a directory tree even if the user has no other rights to access that directory. For example, if I have no access to C:\Files but <i>do</i> have access to C:\Files\Department\Sales, then I can't access C:\Files\Department\Sales <i>unless</i> I can bypass traverse checking.
Change the system time	Set the time for the internal clock of a computer.
Create a pagefile	Create a pagefile.
Create a token object	Create access tokens. Only the Local Security Authority should have this privilege.
Create permanent shared objects	Create special permanent objects.
Debug programs	Debug applications.
Deny access to this computer from the network	Opposite of the "Access this computer from the network" right; specifically revokes the right to users/groups that would normally have it.
Deny logon as a batch job	Revokes the right to log in as a batch job.
Deny logon as a service	Revokes the right to log in as a service.
Deny logon locally	Revokes the right to log in locally.
Enable computer and user accounts to be trusted for delegation	Designate accounts that can be delegated.
Force shutdown from a remote system	Allows a computer to be shut down from a remote system.
Generate security audits	Generate audit log entries.
Increase quotas	Increase object quotas (each object has a quota assigned to it).
Increase scheduling priority	Boost the scheduling priority of a process.
Load and unload device drivers	Add or remove drivers from the system.

*Continued on next page*

**TABLE 9.4:** LOCAL USER RIGHTS (*continued*)

USER RIGHT	DESCRIPTION
Lock pages in memory	Lock pages in memory to prevent them from being paged out into backing store (such as <code>PAGEFILE . SYS</code> ).
Log on as a batch job	Log on to the system as a batch queue facility.
Log on as a service	Perform security services (the user who performs replication logs in as a service).
Log on locally	Log on locally at the server computer itself.
Manage auditing and security log	Specify what types of events and resource access are to be audited. Also allows viewing and clearing the security log.
Modify firmware environment values	Modify system environment variables (not user environment variables).
Profile single process	Use profiling capabilities to observe a process.
Profile system performance	Use profiling capabilities to observe the system.
Remove computer from docking station	Remove a laptop computer from its docking station.
Replace a process level token	Modify a process's access token.
Restore files and directories	Restore files and directories. This right supersedes file and directory permissions.
Shut down the system	Shut down Windows Server 2003.
Synchronize directory service data	Update Active Directory information.
Take ownership of files or other objects	Take ownership of files, directories, and other objects that are owned by other users.

Many rights, such as the right to debug programs and the one to profile a single process, are useful only to programmers writing applications and are seldom granted to a group or user. When would you mess with these? Some third-party applications require you to extend some set of rights to a user before you can run the application.

You can set user rights on a machine-by-machine basis with Local Security Policy or, as you'll learn soon, `SECEDIT . EXE`; you can also set rights wholesale over a number of machines with Group Policies.

## Local and Domain-Based Group Policies

An administrator's work is never done. Users are constantly fiddling with their settings. It's hard to maintain "standard builds," and rolling out new applications is a big headache in large networks or small. It's a pain to package up applications, remote management systems like SMS are unnecessarily

complex, and Admin privileges are needed to install many applications on NT, Win2K, and XP machines. What a marketing opportunity!

When it comes to configuration management, there are a lot of buzzwords flying around these days: system policies, Group Policy, Change and Configuration Management (CCM), Intellimirror. What do these words mean to an everyday admin who just wants to maintain some continuity in Desktop configurations?

CCM and Intellimirror are marketing monikers for a group of Win2K, XP, and 2003 Desktop management features, including roaming profiles and folder redirection, offline folders, software distribution, and Desktop configuration control (I mean management). Despite the fancy terms, many of these features (including folder redirection, software distribution, and remote Desktop configuration) are easily implemented with group policies.

## Group Policy Benefits

The term for the most broad-reaching control and support technology, however, is *group policies*. It's a confusing term because it doesn't really refer to groups. There are two kinds of group policies, the kind *with* a domain to back them up and the kind *without* a domain. (In case you're wondering, *domain* here means Active Directory domain.) Without a domain you use a tool called Local Security Policies and a command-line tool called SECEDIT; *with* a domain you use domain-based group policies (where the Active Directory does much of your work).

But what exactly can you *do* with group policies? Here's a brief list:

- ◆ Publish or assign software packages to users or machines.
- ◆ Assign startup, shutdown, logon, and logoff scripts.
- ◆ Define password, lockout, and audit policy for the domain.
- ◆ Standardize a whole bunch of other security settings for remote machines—settings previously configurable only by editing the Registry or using a third-party security configuration tool. Some features, like the ability to enforce group memberships and services configuration, were made available with the release of Windows 2000 Server.
- ◆ Define and enforce settings for Internet Explorer.
- ◆ Define and enforce restrictions on users' Desktops.
- ◆ Redirect certain folders in users' profiles (such as **Start Menu** and **Desktop**) to be stored in a central location.
- ◆ Configure and standardize settings for features like offline folders, disk quotas, and even Group Policy itself.

Many of these features are discussed in sections of their own throughout this book. Software distribution is covered in Chapter 12, "Software Deployment." Chapter 11, "Creating and Managing Shared Folders," touches on offline folders. User profiles are discussed later in this chapter. Folder redirection is really a lightweight approach to user profiles ("Profiles Lite"), allowing you to use a subset of the full, roaming profile features, so we'll talk about that, too, later in this chapter. The key point here is that Group Policy provides a single point of administration, allowing administrators to easily install software and apply standardized settings to multiple users and computers throughout an organization.

## Group Policies Compared to System Policies

Group policies have been around since Windows 2000. Before that, a much smaller subset of these things, mostly just Desktop restriction and a few security settings, were accomplished using system policies. Group policies have improved on system policies in a couple of major ways.

### THE ACTIVE DIRECTORY HANDLES REPLICATION

With NT system policies, you had to see to it that a file named `NTCONFIG.POL` was properly replicated to every domain controller's `NETLOGON` share. You did that by setting up the NT directory replication service, which was a nice try but tended to be a bit flaky. In contrast, domain-based group policies live partially in the Active Directory and partly in Sysvol, the Windows 2000-and-later replacement for `NETLOGON`. Both Active Directory and Sysvol replicate themselves automatically, with no work required on your part.

### DOMAIN-BASED GROUP POLICIES UNDO THEMSELVES WHEN REMOVED

NT 4–type system policies write permanent changes to the Registry when they are applied. This phenomenon is commonly called *tattooing*. Remove the policy and the settings remain. You actually have to “reverse the policy” (by applying a policy with opposite settings) or change the settings manually. Group policies, on the other hand, write their information only to certain parts of the Registry and so are able to clean up after themselves when the policy is removed.

For example, suppose you'd created an NT 4–type system policy that set everyone's background color to some nauseating hue and also set up a policy that kept them from changing the color back. Those changes got written into the system's Registries. So if you deleted the policy, then they'd still have those items in their Registries, and therefore the ugly background as well. You'd actually have to write a *second* policy to undo the Registry effects. With domain-based group policies, that's not necessary. Just removing the policy will undo its effects.

### YOU NEEDN'T LOG ON TO GET DOMAIN-BASED GROUP POLICIES

System policies are applied only once: at logon for user settings and at startup for computer settings. Group policies are applied this way, too, but they are reapplied at specific intervals. Furthermore, Windows NT always had the peculiar characteristic of taking its policies from the user's domain. Why was that a problem? Well, suppose your workstation was a member of a domain called `MACHINES` and your user account was a member of a domain called `USERS`. Presumably, you'd want the machine policies that affect your machine to come from the machine's domain, `MACHINES`. But under NT 4, that never happened. Instead, when the user logged on, the machine would go grab a `NTCONFIG.POL` file from the user's domain, `USERS`. It would then hand any machine policies to itself and any user policies to the user. Under Windows 2000 and later with Active Directory, machines get their policies from their domain when they power up (recall that machines log on also) and users get policies from *their* domain when they log on.

Additionally, workstations check with Active Directory every 60 to 120 minutes to see if there are any new policies. If there are, then the workstations apply them—both user and machine policies. Further, group policies do a lot more than just modify Registry settings.

### GROUP POLICIES ONLY WORK ON WINDOWS 2000 AND LATER MACHINES

The bad news about group policies, both locally and domain-based, is that they only work on Windows 2000, XP, and Server 2003 machines, and they require Active Directory, although it is possible to apply a more limited set of “local policies” without AD.

You can only use group policies to control Windows 2000 Server, Windows 2000 Professional, XP Professional, and Windows Server 2003 systems. If your users run Windows 9x or Windows NT Workstation 4 on their Desktops, you’ll have to use the same old tools as before—Windows 9x profiles and system policies and Windows NT 4 profiles and group policies. Yes, you read that right—you may have to worry about one set of policies for the Windows machines, another for the NT 4 machines, and a third set of group policies for the 2000 and XP machines. Similarly, you might have a set of profiles for Windows 9x users, another for the NT 4 users, and a third set for the Win2K/XP users. If it’s any consolation, you can store *all* of these things on Windows Server 2003—you don’t have to keep an old NT 4 server around to hold the NT profiles.

In the sections that follow, you will learn how group policies work and how to create and modify them. You will become familiar with the different nodes and settings in the Group Policy snap-in and look at a few examples of deploying group policies in your organization. Finally, we’ll discuss some of the dos and don’ts of group policy.

### Local Group Policies: Security Templates

You’ll see in a minute that having a domain around to hang domain-based group policies on is a pretty attractive thing. But if your domain is still an NT 4–based domain (or perhaps if you have Windows 2000 and XP systems around in a network based on Unix, Novell, or some other network OS), then you will still want to be able to accomplish what policies can do, and you can, in the main, albeit with a bit more work. That’s where local group policies come in.

You’ve already met the Local Security Policy snap-in; it’s the simple, GUI way to control a particular right on a particular machine. But domain-based group policies let you do considerably more than the Local Security Policy snap-in does, so you need something a trifle more powerful, and Windows 2000 and its descendants have that: a very useful tool called security templates. Let me suggest that if you’ve been overlooking them, then you’ve *got* to start using them. In this section, you’ll see why.

Worms, viruses, disgruntled employees, and our ever-growing reliance on computers all add up to one thing: a need for security. Clearly there are more and more reasons to secure our computers and, for most of us, there are more and more computers around to secure! But who wants to make security a full-time job? Not me. That’s why you should know about a set of tools that can simplify your job of locking down 2000 (and later) boxes.

Let’s say that you’ve decided that you want to ensure that the Power Users groups on your workstations should be empty—you don’t want anyone in those groups. You also are awfully tired of stomping out Code Red on all of those computers that installed IIS by default, so you’re going around and disabling Web Publishing Service on all servers that don’t need it.

But, man, that’s a lot of work. So you adopt Plan B: The Security Requirements Document. In this document, you outline exactly what must be done for any workstations or servers approved here at Acme Corporation. You distribute the document. And no one has time to read it. Nor is there any easy way to check up on systems to see if they meet the requirements. Or so it seems.

Wouldn't it be great to just push a button and make those changes on every system? You can, with a few tools: `secedit.exe`, an MMC snap-in named Security Configuration and Analysis, and Security Templates.

### WHAT TEMPLATES CAN DO

Basically, a security template is an ASCII file that you feed into a program named `SECEDIT.EXE`. That template is a set of instructions—basically a script—that tells `SECEDIT` to make various kinds of changes in your system.

Templates don't let you modify anything that you couldn't modify otherwise; they just provide a nice, scripted, reproducible way to make modifications and then easily audit systems to ensure that they meet the template's requirements. You could make any of these changes by hand with the GUI, but it'd be time-consuming. With templates, you can change the following:

**NTFS permissions** If you want the directory `C:\STUFF` to have NTFS permissions of System/Full Control, Administrators/Full Control, and to deny access to everyone else, then a template can make that happen. And as you can apply templates not only to one machine but also to many (provided you're using group policies), you could enforce that set of NTFS permissions on the whole domain.

**Local group membership** Perhaps you have a policy that workstations are set up so that the only accounts in the local Administrators group should be the local Administrator account and the Domain Admins group from the domain. But now and then, some support person “temporarily” elevates a user account to the Administrators group, with the innocent intention of undoing the action “as soon as the need is over.” And, as that support person is as busy as all support folks are, that undoing never gets done. By applying a security template that says that “only Administrator and Domain Admins can be in the local Administrators,” reapplying the template kicks everybody out who's not supposed to be there.

**WARNING** *Templates automate the process of setting some security information, just as if you'd sat down and done it from the GUI. There's no magic guardian angel that constantly monitors a system to ensure that your desired template settings are always enforced. The only way to ensure that your settings remain in force is to either reapply the template on some regular basis or create a group policy to apply the template, as group policies reapply themselves to a system roughly every 90 minutes.*

**Disable IIS and control over who can start and stop services** Want to shut off IIS on all machines but a few? That can be a pain, as Windows 2000 (unlike Windows Server 2003) installs IIS on every server by default. With a security template, you can turn off or even disable services. Templates also let you control who has the permissions to *change* that—you can restrict who can turn a service on or off, or you can grant that power to some user who you want to be able to do that, but who you don't want to make into an administrator.

**Registry key permissions** The Registry contains a lot of information that users can read, but can't change. For example, you may have noticed that there are a number of Desktop applications that worked fine under NT 4 and that allowed someone with just user privileges to run them, but those same applications won't let a user run them under Windows 2000 or XP Professional—

only an administrator can run them. What's the difference? There are a few keys in the Registry that users could both read and write under NT 4, but that they can only read under Windows 2000/XP. Thus, if you have one of those applications—AutoCAD is one example—and you want users to be able to run those apps on their Windows 2000 or XP Desktops, then you can either make all of your users local administrators (which may not sound like a great idea) or just loosen up the permissions on the Registry keys to dial them back to their NT 4 settings. You could do that painstakingly from REGEDT32.EXE, but it's so much easier to just apply a template to accomplish the same thing.

**Local security policy settings** Every machine has dozens of local security settings, things like, “Should I show the name of the last person who logged in?,” “How often should passwords on locally stored accounts be changed?,” and “Who should be allowed to change the time on this system?” to name a few. The Local Security Policy snap-in, or `secpol.msc`, helps you define these policy settings.

## Working with Templates

It's easiest to show you how to work with templates with an example, so let's build a template to do three things:

- ◆ We'll ensure that no one is in the local Power Users group.
- ◆ We'll set NTFS permissions so that a directory `C:\SECRET` will only be accessible to the local Administrators group.
- ◆ Finally, we'll shut down Internet Information Service, that pesky Web server that seems to install itself on every operating system that Microsoft makes.

First, we'll need some tools. Let's build an all-in-one tool using the MMC. We'll need two snap-ins: Security Templates and Security Configuration And Analysis. Set it up like so:

1. Click Start, then Run, and type `mmc /a` in the Open field, then press Enter to bring up the empty MMC.
2. In the empty MMC, choose Add/Remove Snap-in from the File menu.
3. In the Add/Remove Snap-In dialog box, click the Add button. That raises the Add dialog box.
4. In the Add dialog box, click Security Configuration And Analysis and then the Add button. Then click the Security Templates object and Add.
5. Click Close and then OK.
6. Save your new custom tool for future use.

Your tool should look like the one in Figure 9.37.

Expand the Security Templates node and you'll see a container named `C:\Windows\Security\Templates`. Expand that and you'll see a list of eight prebuilt templates in that directory with descriptions of each template. These correspond to .INF files in the Templates directory. If you want to point the Security Templates node to another directory with other templates, right-click it and choose New Template Search Path. If you are going to modify the existing templates, it's a good idea

to go ahead and create another directory for your modified templates, copy the existing ones from `C:\Windows\Security\Templates` into the new directory, and then add that directory to the search path in your tool. This way, you can make changes to the copies of the templates without worrying about messing up the originals. Figure 9.38 shows my Security Console tool with a second search path added (`C:\Windows\Security\REDHILLTOWN templates`). The eight templates you see in that directory are just copies of the default templates.

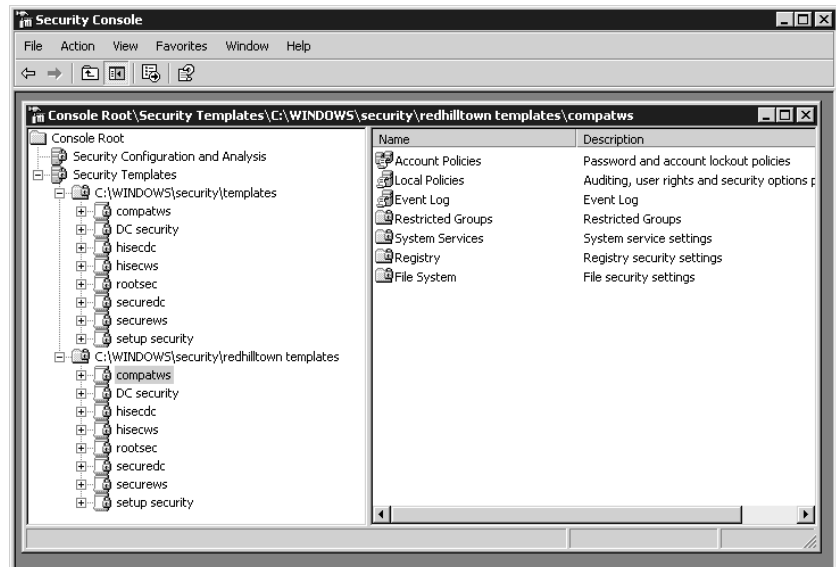

**FIGURE 9.37**

MMC with Security Templates and Security Configuration and Analysis Snap-ins

**FIGURE 9.38**

Security Console tool with custom template directory

Expand any of the prebuilt security templates, and you'll see, in the right pane, folders corresponding to everything that you can control—Account Policies (sets password, account lockout, and Kerberos policies), Local Policies (controls audit settings, user rights, and security options), Event Log settings, Restricted Groups (controls what goes into and stays out of various local groups), System Services

(turns services on and off and controls who has the rights to change any of that), Registry security (sets permissions to change or view any given Registry key and which keys will have changes audited), and File System (controls NTFS permissions on folders and files). The eight security templates in `C:\Windows\Security\Templates` are described next.

**Compatible (*compatws.inf*)** This template increases the default permissions of the Users group, enabling members to run applications that are not certified by the Windows Logo Program. This is an alternative to making local users members of the Power Users group.

**Domain Controller Default Security (DC *security.inf*)** These are the default security settings for a domain controller. Applying the template resets file and Registry and system security settings to the default values set during the promotion to domain controller. It may also overwrite permissions on new files and Registry keys created since `DCPROMO.EXE` was run.

**Secure Domain Controller (*securedc.inf*) and Secure Workstation or Server (*securews.inf*)** `securedc.inf` defines enhanced security settings for domain controllers, but with an eye on application compatibility. `securews.inf` elevates selected security settings for workstations and servers that are not domain controllers. Both templates include stronger password, lockout, and audit policy settings; limit the use of older, less secure authentication protocols; and enable server-side SMB packet signing.

**Highly Secure Domain Controller (*bisecdc.inf*) and Highly Secure Workstation (*bisecws.inf*)** These templates apply super-secure settings to domain controllers and workstations or non-DC servers, respectively. You'll want to read the documentation on this template carefully before applying it to your systems; it makes several changes to client-server authentication and encryption requirements. It also removes all members of the Power Users group and removes all members from the local Administrators group except Domain Admins and the local Administrator account.

**System Root Security (*rootsec.inf*)** This file contains, and can be used to reapply, the root permissions for the system drive.

**Setup Security (*setup.inf*)** `setup.inf` contains a record of the settings that were applied during the upgrade or clean installation of the OS. It's a really big file, in comparison to the other INF files, and you probably can't view it using your MMC console tool. This file can't be used on domain controllers; use the `DC security.inf` file instead. Microsoft warns you never to apply the `setup.inf` template using Group Policy because it contains such a large amount of data. It can be applied in parts, though, for disaster recovery purposes, using `SECEDIT.EXE`.

**WARNING** *Before applying any of the predefined templates to your systems, do your homework. Test the templates in a nonproduction environment before deployment. The templates do not roll your system back to default security settings before applying their own changes, so you might get unexpected results.*

But we're interested in building a new template from scratch. To do that, right-click the template path and choose New Template from the context menu. Type in a name for the template, and a description if you wish. The new template will appear as a folder in the left pane, along with the

prebuilt templates. I've named mine Simple. First, let's clean out the Power Users group:

1. Open Simple.
2. Inside Simple, you'll see a folder named Restricted Groups. Click it so that it appears in the left pane.
3. Right-click Restricted Groups and choose Add Group. Type in Power Users in the Add Group dialog box, or use the Browse function to select the Power Users group. Note that if you are working from a domain controller, then you won't, of course, have a Power Users group.

By default, including a group in a security template tells the template to remove everyone from the group, so we're done. If you wanted to use the security template to put someone in the group, then just right-click the group and choose Properties, which lets you specify members of the group.

Next, let's set up the security template so that any system with a folder named C:\SECRET will only be accessible to the local administrators.

1. Back in the left pane, right-click File System and choose Add File.
2. In the dialog box that appears, you can either browse to a particular directory or simply type the directory name in. Yes, the menu item was Add File, but you can choose directories as well. Type C:\SECRET and click OK.
3. Now you'll see the standard Windows NTFS permissions dialog box. Delete permissions for all users and groups except for Administrators. Grant Full Control Permission to Administrators.
4. The program will ask if you want these permissions to apply only to this folder or to all child folders. Set it as you like.
5. Click OK.

Finally, let's shut down IIS.

1. Click System Services.
2. In the right pane, right-click World Wide Web Publishing Services and choose Properties.
3. Check the Define This Policy Setting in the Template check box, and click the Disabled radio button.
4. Click OK.

Now save the template—right-click Simple or whatever you called the template and choose Save. Unless you set up a separate folder for your templates as I described earlier, you now have a file named `simple.inf` in your `\Windows\Security\Templates` folder.

#### CREATE A SECURITY DATABASE

Now, you'd think that all you need do to apply this template would be to just, well, apply it. But you can't. Instead, you have to essentially compile it from its simple ASCII form to a binary form called a "database." You do that from the other snap-in, Security Configuration and Analysis.

1. Right-click Security Configuration and Analysis and choose Open Database to open the Open Database dialog box, which asks what database you want to load.

2. Within the Open Database dialog box, you want to create a new database, but there's no option for that; instead, just type the name of the new database. Using my example, type **Simple** and press Enter. Typing in a name of a new database causes the snap-in to realize that you want to *create* a new database, so it then asks which template to build it out of. (Yup, it's nonintuitive.) By default, a dialog shows you the files with `.INF` extensions in the `Windows\Security\Templates` folder.
3. If you're following my example, choose `simple.inf`. Before you click, though, notice the Clear This Database Before Importing check box. That's useful. Otherwise, when you're experimenting with a template, the snap-in makes your changes cumulative (which might well be your intention, but it's not usually mine) rather than wiping the slate clean and starting from scratch.
4. Choose the template and click Open. Nothing obvious has happened, but the snap-in has now "compiled" (which is my word, not Microsoft's, but it seems a good shorthand for the process of converting your ASCII template into a binary security database) the template into a security template named `simple.sdb` in `My Documents\Security\Database`. In the details pane, you'll see an HTML message that "the page cannot be displayed."

Next, right-click Security Configuration and Analysis and you'll see two options: Analyze Computer Now and Configure Computer Now. Analyze doesn't change the computer. Instead, it compares the computer's state to the one that you want to create with the template. It then shows you—and saves a log file that explains—how your system varies from what the template instructs. The log file is written to `\My Documents\Security\Logs`.

But who wants to just find out how a system varies from our (administrative) desires? It'd be far more interesting to just tell the system, "Do this." And you can. Instead of choosing Analyze Computer Now, pick Configure Computer Now to modify the system's settings to fall into line with the template.

That's all very nice, you may be thinking, but how do I apply it to dozens of computers? Do I have to visit each one? No; you can use a command-line tool for that. A command-line program called `SECEDIT.EXE` will both convert templates into databases and apply databases. To read a template, apply, and then create a database in the process, use the following syntax:

```
Secedit /configure /cfg templatefilename /db databasefilename/overwrite
/log logfilename
```

To apply an existing database without first reading the template, just leave off the `/cfg` switch and argument. To apply the template to your workstations, you could include the `secedit` command in a logon script (be sure and specify full path names for the template, database, and log files) that will reapply it with every logon. You could also use the Task Scheduler service to run a batch file and reapply the template at specific intervals. Or you could enable the telnet server on your Windows 2000 and XP machines and just apply the template whenever you like.

By the way, there's another way to create a template, although you can't build a complete template—Restricted Groups and other functions of this snap-in aren't included here—by opening Local Security Policies and right-clicking Security Settings. Then choose Reload and Export Policy to create a template based on the existing local security settings.

### USING DOMAIN-BASED GROUP POLICIES TO APPLY TEMPLATES

*Secedit* is nice, but it has to be invoked manually or from a batch file, which means a lot of messy editing of logon batch files or fiddling with the Scheduled Tasks on all your systems. If you use a login script, the security template only gets applied at logon time. How do you enforce security settings more often? With group policies.

Domain-based group policies have a few benefits. First of all, it's easy to control whom they apply to, much easier than having to figure out which batch files go where. Second, they reapply themselves not only at logon time, but also throughout the day—the workstation seeks them out every 60 to 120 minutes. So, if domain-based group policies sound neat, then read on—we're just about to get started with them!

### Group Policy Concepts

Let's start with some important concepts, terms, and rules you need to know to master Group Policy. In the process of explaining the functionality of Group Policy, I will mention several settings without actually showing you how to turn them on in the Group Policy snap-in. Just focus on the concepts for now. Later on in this section, we'll take a full tour of the Group Policy console, and I'll point out all of the settings (such as No Override and Block Inheritance) that are discussed in this section.

Administrators configure and deploy Group Policy by building *group policy objects* (GPOs). GPOs are containers for groups of settings (*policies*) that can be applied to users and machines throughout a network. Policy objects are created using the Group Policy Object Editor, which is usually invoked with the Group Policy tab in *DSA.MSC* or *DSSITE.MSC*. The same GPO could specify a set of applications to be installed on all users' Desktops, implement a fascist policy of disk quotas and restrictions on the Explorer shell, and define domain-wide password and account lockout policies. It is possible to create one all-encompassing GPO or several different GPOs, one for each type of function.

There are two major nodes in the Group Policy Object Editor, Computer Configuration and User Configuration. The computer configuration policies manage machine-specific settings such as disk quotas, auditing, and Event Log management. User configuration policies apply to user-specific settings such as application configuration or folder redirection. However, there is a good bit of overlap between the two. It's not unusual to find the same policy available in both the User Configuration and Computer Configuration nodes. Be prepared for a certain amount of head scratching as you search for the policy you want to activate and decide whether to employ the user-based policy or the computer policy. Keep in mind that you may create a policy that uses both types of settings or you may create separate User and Computer Configuration policy objects.

Contrary to their name, group policies aren't group oriented at all. Maybe they are called group policies because a bunch of different configuration management tools are *grouped* together in one snap-in (maybe "assorted policies" just didn't have the same ring to it). Regardless, you cannot apply them directly to groups or users, but only to sites, domains, and OUs (Microsoft abbreviates these collectively with the term *SDOU*) within a given forest. This act of assigning GPOs to a site, domain, or OU is called *linking*. GPOs can also be linked to local policy on a particular Windows 2000, XP, or Server 2003 machine, as you'll see in a moment. The GPO-to-SDOU relationship can be many-to-one (many policies applied to one OU, for example) or one-to-many (one policy linked to several different OUs). Once linked to an SDOU, user policies are applied at logon time, and computer

policies are applied at system startup. Both policies also refresh periodically, with a few important exceptions.

When I said GPOs were stored in the AD, that wasn't exactly accurate. Group policy objects are stored in two parts, a Group Policy Container (GPC), and a policy folder structure in the SYSVOL. The container part is stored in the Active Directory and contains property information, version info, status, and a list of components. The folder structure path is `WindowsINNT\SYSVOL\sysvol\Domainname\Policies\GUID\` where *GUID* is a Global Unique Identifier for the GPO. This folder contains administrative templates (ADM files), security settings, info on available applications, and script filenames with command lines.

Group policy objects are rooted in the Active Directory of a domain. You can't copy them to other domains, but you can link them across domain boundaries (although it's not recommended). Windows Server 2003 now supports some cross-forest functionality that wasn't available in Windows 2000. For example, a user in Forest A can log on to a computer in Forest B and still have group policies apply from Forest A. Also, group policy settings can contain references to servers in other forests now.

**NOTE** *Group policies aren't just Registry changes. Several policies are applied with Client Side Extension (CSE) DLLs. Examples are disk quota policy, folder redirection, and software installation. In fact, there is a CSE DLL that processes the Registry changes, USERENV.DLL.*

### **POLICIES ARE "ALL OR NOTHING"**

Each GPO contains many possible settings for many functions; usually you'll configure only a few of them. The others will be left "inactive," sort of like putting REM in front of a command in a script or using a semicolon at the beginning of a line in an INF file. The workstation or server still has to read the whole policy, but it only acts on the options you've enabled. However, once you've configured a set of policies and told AD that "this GPO is linked to the REDHILLTOWN.com domain," for example, the individual settings or types of settings cannot be selectively applied. All User Configuration settings will be applied to all users on Windows 2000, XP, and 2003 systems in the linked domain. All Computer Configuration settings will be applied to all Windows 2000, XP, and 2003 machines in the domain. Remember that neither will be applied to NT 4 or 9x clients.

Now, let's say you've created a GPO that deploys a set of standard Desktop applications like Word, Excel, and Outlook, and you threw in a bunch of shell restrictions to prevent users from changing their configurations. If you don't want your IT support group users to be subject to those ridiculously stringent shell restrictions (although those users may need them most of all!), you can do a couple of things. You can create a separate GPO for those policies and link it to a lower-level container, such as an OU that contains all the regular users. But that OU will be the only one that gets the Office applications. You can alternately set permissions on the GPO that prevent the policy from being applied to the IT support group (this is called filtering). However, if you use filtering to solve this problem, none of the settings in the GPO will apply to the IT support group at all.

Group policy application is all or nothing, so sometimes you really need separate policies for separate functions. The best way to approach this might be to create a GPO for standard software deployment, and a GPO for shell restrictions. Both could be applied at the domain level, but shell restrictions can be filtered for the IT support group. The point is, it's not possible to create one

monolithic policy and then specify who gets what settings, and you wouldn't want to do that anyway. At least, you wouldn't want to troubleshoot it.

### **POLICIES ARE INHERITED AND CUMULATIVE**

Group Policy settings are cumulative and inherited from parent Active Directory containers. For example, REDHILLTOWN.com domain has several different GPOs. There is a domain-level policy that sets password restrictions, account lockout, and standard security settings. Each OU also has a policy to deploy and maintain standard applications as well as folder redirection settings and Desktop restrictions. Users and computers that are in both the domain and the OU receive settings both from the domain-level policy and from the OU-level policy. So some blanket policies can be applied to the entire domain, while others can be hashed out according to OUs.

### **REFRESH INTERVALS FOR GROUP POLICY**

Policies are reapplied every 90 minutes, with a 30-minute “randomization” to keep the domain controller from getting hit by dozens or even hundreds of computers at once. Policies on DCs are refreshed every 5 minutes. There is, however, a policy to configure all of this, as you'll see in the section coming up, “Group Policy Policies.” (So, if I set a policy for the refresh interval on Blanket Vanilla Policy Policy, would that be referred to as a Blanket Vanilla Policy Policy policy?) Exceptions to the refresh interval include folder redirection and software installation. These are only applied at logon or system startup time; otherwise, you might end up uninstalling an application while someone is trying to use it. Or a user might be working in a folder as it is being redirected to a new network location. That would be bad.

## **Local Policies and Group Policy Objects**

When you use Active Directory Users and Computers or Active Directory Sites and Services to create and link group policies, you are working with group policy *objects* to specify a collection of settings to be applied at user logon or machine boot time. The information in the GPO says things like “change this, change that, install this, disable that.” But administrators also need to be able to view the actual settings for these policies sometimes.

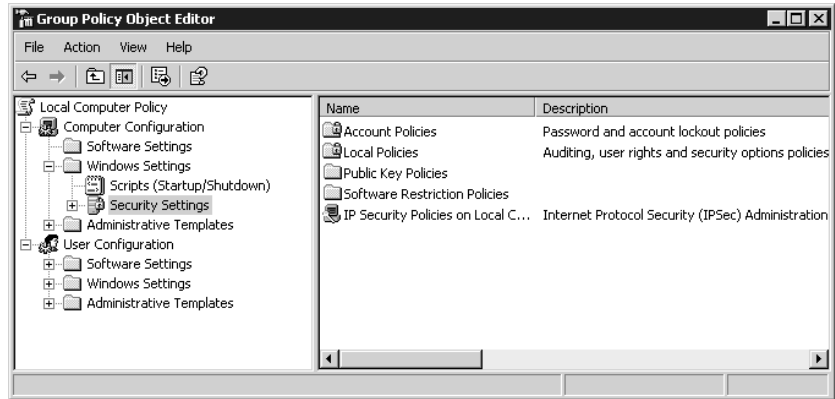

In NT 4, it was possible to use the System Policy Editor to view and edit those Registry entries for the local machine (rather than creating or editing a policy, you chose to open the Registry). As such, the System Policy Editor served as a more user-friendly Registry editing tool than either REGEDIT.EXE or REGEDT32.EXE. Similarly, the Group Policy snap-in provides the ability to view local policy settings on a machine.

When you open the Group Policy tool (GPEDIT.MSC), it automatically focuses on the local machine, as shown in Figure 9.39. Administrators can use the tool as they would use the Local Security Policy tool to configure account settings (such as minimum password length and number of bad logon attempts before locking the account) and to set up auditing. However, the domain-based policy editor includes a number of settings (including software installation and folder redirection) that are not available for local policies.

**NOTE** *The local Group Policy folder structure is equivalent to that of other GPOs and is found in \Windows\system32\GroupPolicy.*

**FIGURE 9.39**

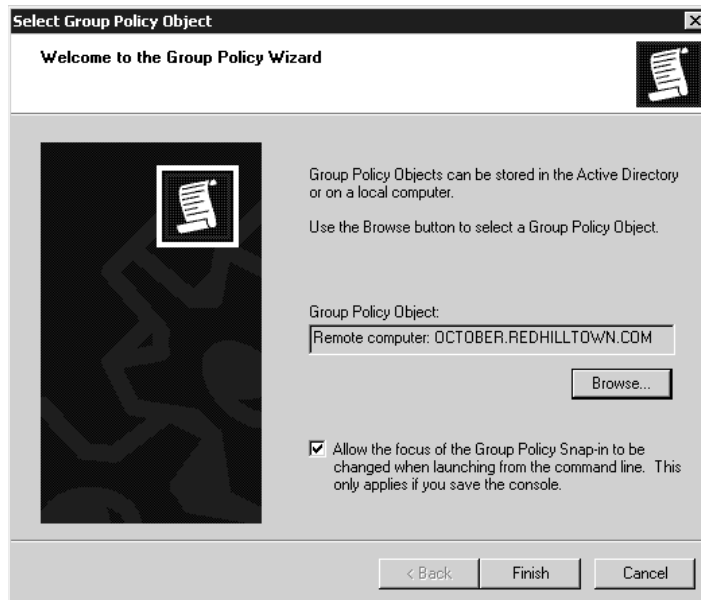

The Group Policy Object Editor—  
local machine

To focus on another computer's local policy, you must have Administrator rights on that machine. You can select a computer while adding the Group Policy snap-in to a custom management console, as shown in Figure 9.40. If you know the name of the computer, just fill it in or click the Browse button. The snap-in can focus on a local machine or on a group policy object; the Browse button allows you to locate and find group policy objects linked to sites, domains, OUs, or computers (Figure 9.41). Additionally, if you select the Allow the Focus of the Group Policy Snap-in to Be Changed option when opening the snap-in from the command line, it's possible to select the policy object as an argument when you start the console. GPEDIT.MSC, the Group Policy console that ships with Windows 2000 and Server 2003, has this option turned on.

**FIGURE 9.40**

Adding the Group Policy snap-in

**FIGURE 9.41**

Selecting a group policy object (GPO)

The syntax to open GPEDIT.MSC and look at the local policy on a remote machine is as follows:

```
GPEDIT.MSC /gpcomputer: machinename
```

So you could type, for example:

```
GPEDIT.MSC /gpcomputer: salome
```

Or you could type:

```
GPEDIT.MSC /gpcomputer: salome.REDHILLTOWN.com
```

Be sure to include a space between **/gpcomputer:** and the machine name, though.

There is one important limitation when using GPEDIT.MSC to modify policy on a remote machine. The security settings extension to the Group Policy snap-in will not work when the tool is focused on a remote machine. That's worth saying again. You cannot open GPEDIT.MSC with the switch **/gpcomputer: *computername*** and modify the security settings on a remote machine. Apparently, Microsoft considers it a security vulnerability to allow it. Another example of software telling us what's best for us?

**NOTE** *If you are using group policies, local policy is always processed before site, domain, or OU group policies.*

## Creating Group Policies

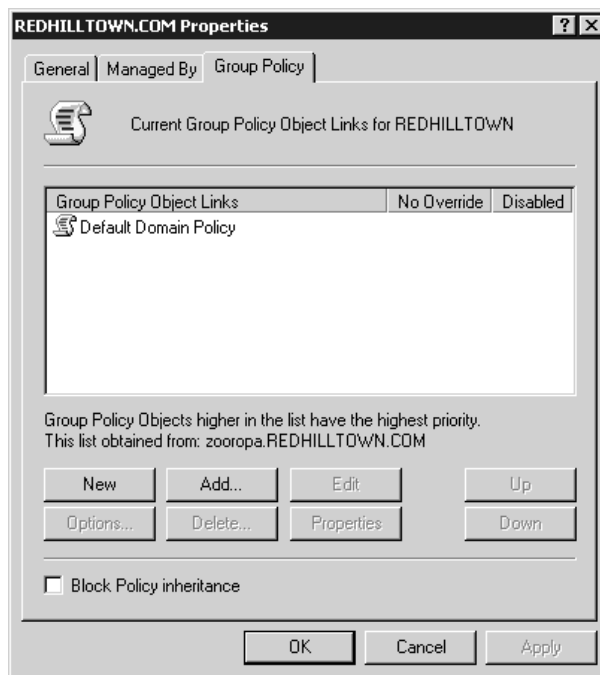

Now that you understand the major concepts involved in group policies and know the difference between local policies and group policy objects, let's go through the steps of creating and editing a group policy object. In this section, I'll show you all the settings we discussed in the preceding "theory" section.

To open the Group Policy snap-in in DSA.MSC, right-click your domain name at the root of the console and choose Properties from the context menu. Move to the Group Policy tab, shown in Figure 9.42, to see what GPOs have been linked at the domain level. If you haven't already created

other policies, you'll see only the default domain policy listed. Notice the Block Policy Inheritance check box at the bottom left of the Group Policy tab. It prevents any group policy settings at a higher level from trickling down to this one. Remember the order in which policies are applied: first is the site level, then the domain level, then policies for OUs.

**FIGURE 9.42**

A domain's Group Policy properties

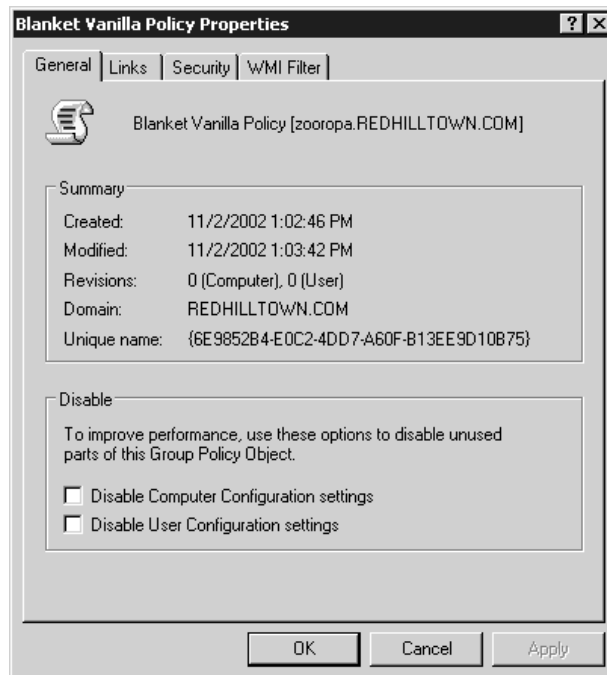

**NOTE** To view the GPOs that are linked to a container (site, domain, or OU), right-click the object in the console (DSA.MSC for domains and OUs and DSSITE.MSC for sites) and choose *Properties* from the context menu. Then navigate to the Group Policy tab. From that point, the interface to configure policies is the same regardless of the container it's linked with.

To turn on No Override, highlight the policy and choose *Options*, then select the No Override check box (see Figure 9.43). When this setting is on, other policies applied down the line are prevented from defeating the settings of this policy, even with Block Inheritance enabled. Note that Block Policy Inheritance is turned on at the link level (site, domain, or OU), whereas No Override is enabled per policy. Check the Disabled box to turn off the policy so that it won't be processed or applied at this level. Disabling the policy doesn't disable the object itself. For example, the same policy, disabled at the domain level, could theoretically be applied at the site or OU level. If either option (No Override or Disabled) is turned on, there will be a check in the corresponding column of the Group Policy tab. You can activate both options using the context menu for the policy. Just right-click a selected policy to view the context menu.

**FIGURE 9.43**Group Policy  
options

Back in the REDHILLTOWN.COM properties sheet, choose New to create a new GPO. This will create a policy called New Group Policy Object and then allow you to rename it. If you miss that opportunity and end up with a policy called New Group Policy Object, just highlight the policy, right-click, and choose Rename from the context menu.

Choose Properties to view and modify your new group policy object's properties. The General tab shown in Figure 9.44 shows creation and revision information as well as options to disable the User or Computer Configuration portion of the policy. Depending on how you subdivide your domain into OUs, you may choose to create some policies with only computer settings and others with only user-specific settings. In that case, if the unused portion of the GPO is disabled altogether, policy application and updates are faster. If, however, your cold medicine has caused a momentary lapse of reason and there are important settings in the node you disable, those settings will be removed from the client machine. So the GPO Editor will ask you to confirm that move, just to be sure.

**FIGURE 9.44**Group Policy  
General properties

The Links tab gives you the opportunity to search for sites, domains, or OUs that use this GPO, if there are any. Because searching for other links takes a few moments and some resources, no linked containers will be displayed until you perform the search. Click the Find Now button to start the search.

The Security tab in the properties sheet reveals the GPO's default permissions (see Figure 9.45). Highlight a name at the top to view the permissions in the lower section. Notice that Domain Admins and Enterprise Admins have Read and Write permissions as well as Delete and Create All Child Objects, whereas the Authenticated Users group only has Read and Apply Group Policy. Read and Write are required to change a policy; Read and Apply are required to be a recipient of the policy.

**FIGURE 9.45**  
Group Policy  
permissions list

**NOTE** Don't think that Domain Admins and Enterprise Admins are not subject to a group policy's settings just because they are not granted Apply Group Policy permission by default. Users will have all the permissions of all their groups; therefore, as members of Authenticated Users, the members of Domain Admins and Enterprise Admins will also be granted Apply Group Policy permissions.

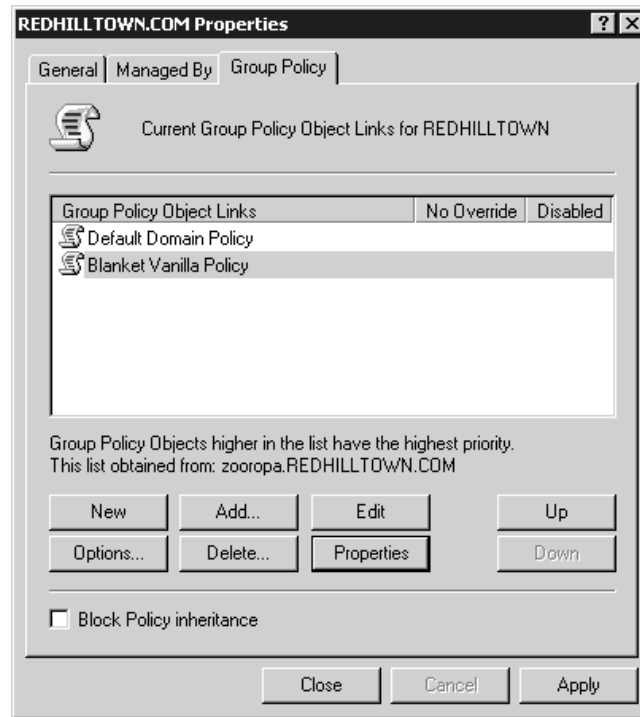

The WMI Filter tab reveals a capability that's new in Windows Server 2003. You can choose to apply your GPO according to certain computer criteria, based on information gathered by Windows Management Instrumentation (WMI). We'll discuss this new feature in more detail shortly.

Back in the Group Policy tab of our REDHILLTOWN.com domain properties page, if you highlight the new GPO that you have just created and click either the Up or Down button, you can move the policy up or down in the window. This is an important tidbit to know: When multiple GPOs are linked to one container, as is the case in Figure 9.46, they will be applied from the bottom

up, so the one at the top is applied last. Therefore, GPOs higher in the list have a higher priority. If there are conflicting settings, the higher policy wins.

**FIGURE 9.46**

Increasing the priority of group policy objects

To delete a GPO, or to just remove it from the list, highlight the policy and click Delete. The GP Editor will ask you whether you want to delete it altogether (Figure 9.47) or to remove it from the list while preserving the policy to be linked to another container at another time.

**FIGURE 9.47**

Removing a group policy object

Click the Add button on the Group Policy tab to link an existing group policy object to the desired container. As you see in Figure 9.48, you can look for GPOs that are linked to other domains/OUs or to other sites, or you can just ask for a list of all GPOs. It took me a minute to grasp this simple

operation: double-click the container name (the OU for Brunswick.REDHILLTOWN.com, for example) to view the policies linked to it. Then highlight the policy and click OK to add it to the list back on the Group Policy tab.

**FIGURE 9.48**

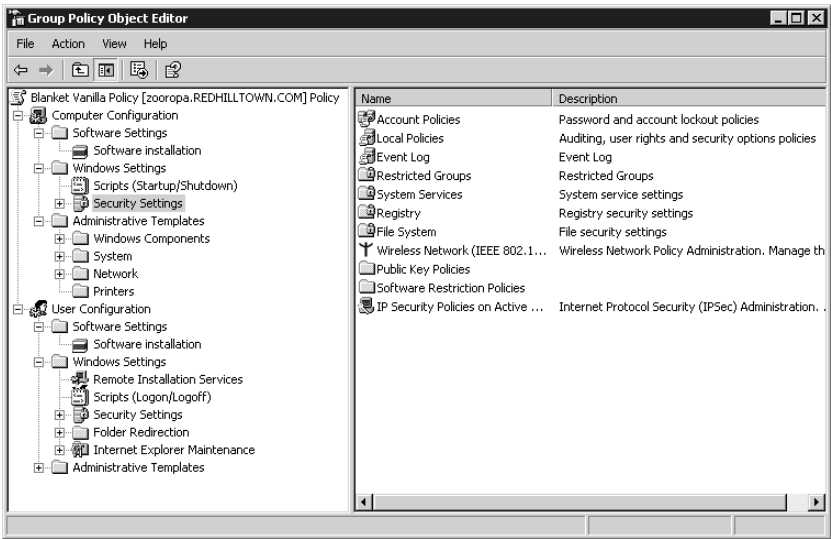

Adding a group policy link

Now let's view and modify our new policy. Back in the Group Policy tab, highlight the policy and click Edit. This will open the Group Policy snap-in in a separate window, and you'll see the policy object name at the root of the namespace, in this case Blanket Vanilla Policy [zooropa.REDHILLTOWN.COM] Policy. This indicates to us what policy is being viewed and edited. Figure 9.49 shows the policy expanded in the console tree to show the major nodes of the group policy object.

**FIGURE 9.49**

Group Policy namespace

There are two major types of settings, as I mentioned earlier. Computer Configuration settings are applied to machines at startup and at designated refresh intervals. User Configuration settings are applied to the users' working environments at logon and at designated refresh intervals.

We'll explore the various policies according to subject matter later, but prepare yourself for the fact that policies are not all configured in a uniform way as far as the interface is concerned. You'll need a few examples to see what I mean:

- ◆ To specify software packages under **Software Settings\Software Installation**, open the folder and choose **New/Package** from the Action menu. An Open dialog box asks for the location of the package. Once it's been located and selected, you configure the package properties.
- ◆ To set the interval that users can wait before changing passwords, go to **Computer Configuration\Windows Settings\Security Settings\Account Policies>Password Policy**. Double-click **Maximum Password Age** in the details pane on the right, enable the setting by clicking the box that says **Define This Policy Setting**, and supply a time interval value.
- ◆ To set a policy that restricts group memberships, go to **Restricted Groups** under **Security Settings in Computer Configuration\Windows Settings** and choose **Add Group** from the Action menu. A dialog box asks you to enter a group or browse for it. Once the group is added to the list in the details pane on the right, double-click the group name to open a dialog box and supply the names of the users who must be or are allowed to be in the group. You can also define group memberships for the group itself.
- ◆ To set up folder redirection, go to **User Configuration\Windows Settings\Folder Redirection** and choose a folder (for example, **Start Menu**). The details pane on the right will be blank. Right-click white space in the details pane (or pull down the Action menu) and choose **Properties**. The properties page appears and you can now specify a location for the Start menu and configure redirection settings.

The point of this wild ride through the Group Policy Editor is not to disorient you, but rather to illustrate the fact that the Group Policy Editor has several nodes to accomplish various tasks, and procedures to specify settings will vary with the node and the task. There is no one way to configure a setting, although many do follow the pattern of the second example. So, when in doubt, right-click or look at the Action menu. It's a strategy to live by.

Once you've configured your Group Policy settings, simply close the Group Policy window. There is no **Save** or **Save Changes** option. Changes are written to the GPO when you choose **OK** or **Apply** on a particular setting, although the user or computer will not actually see the change until the policy is refreshed.

## Group Policy Troubleshooting: GP Application Order

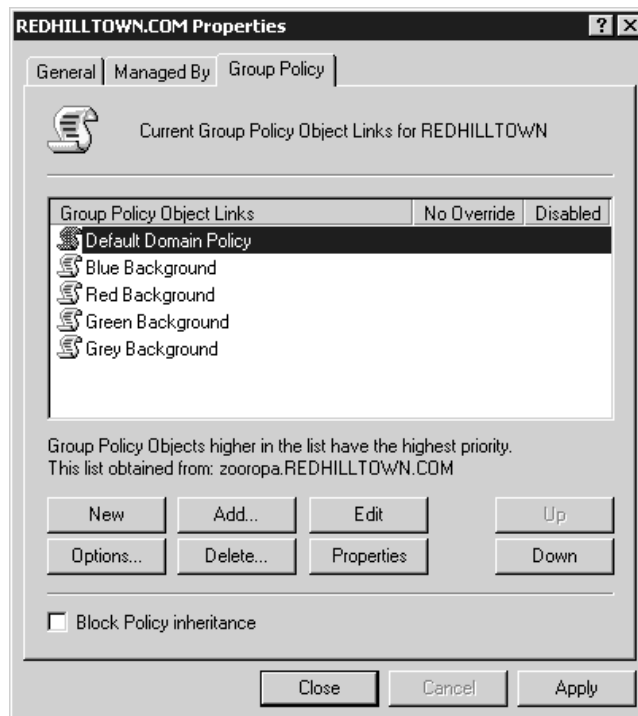

Now that you've got a GPO or two running, you'll soon find the troublesome part of group policies: figuring out what they're doing. Imagine, for example, that a user calls up and says, "Why is my background purple?" You then realize that there are a *lot* of places that your system gets policies from, and they might disagree on things like, for example, background color. So which one *won*?

### POLICIES EXECUTE FROM THE BOTTOM UP, IN THE GUI

Let's start out by just considering a simple situation: just policies on a domain. Suppose I look at my domain in Active Directory Users and Computers. I right-click the domain, then choose **Properties** and click the **Group Policies** tab to see something like Figure 9.50.

**FIGURE 9.50**

Multiple policies in a domain

In this (admittedly fanciful) situation, the domain has five group policies, four of which attempt to set a workstation's background color to gray, green, red, or blue. (The other is the Default Domain Policy, which has nothing to say on the issue.) Who wins? Gray, red, green, or blue? The answer lies in two basic conflict resolution rules for group policies:

**Rule 1** Listen to the last policy that you heard from.

**Rule 2** Execute policies from the bottom up, as they appear in the GUI.

Reading from the bottom of the dialog box up, you see that the system will first see the policy that sets the background gray, then the one that sets it green, then the one that sets it red, and finally the one that sets it blue. As blue is the last one heard from, it wins, and the effects of the previous three are obviated.

But what if you *want* the red background policy to win? Notice the Up and Down buttons in the figure? You can shuffle them around to your heart's content.

#### GROUP POLICY APPLICATION ORDER

That example only considered domain policies. But you can apply policies to different levels:

- ◆ Sites can have policies, and no matter what domain's machines and users are in that site, those policies apply. (That's why you've got to be an Enterprise Administrator to create site policies.)

- ◆ OUs can have policies. And OUs can contain OUs, and OUs can contain OUs that contain OUs, and so on.
- ◆ There are also *local* policies, don't forget.

So, again, who wins? Policies are applied in the following order: local policy, sites, domains, organizational units, then OUs inside of OUs. If the domain policy says, "You must be logged in before you can shut down the machine," and the OU policy says, "Allow shutdown before logon," the OU policy takes precedence because it is applied last. If one policy says, "Lock it down," and the next one says, "Not configured," the setting remains locked down. If one policy says, "Not configured," and the next one says, "Lock it down," then it's locked down in this case, as well. If one policy says, "Leave it on," and the next one says, "Turn it off," it's turned off. If one policy says, "Turn it off," and another, closer one says, "Turn it on," then a third one says, "Turn it off," guess what? It ends up turned off. However, for the preservation of your sanity, it is desirable to avoid these little disagreements between policies.

### **FILTERING GROUP POLICY WITH ACCESS CONTROL LISTS**

But we're not *nearly* finished here. It *could* be that while it looks as if many policies apply to your system, in fact, only a small number do. The reason: group policies have ACLs.

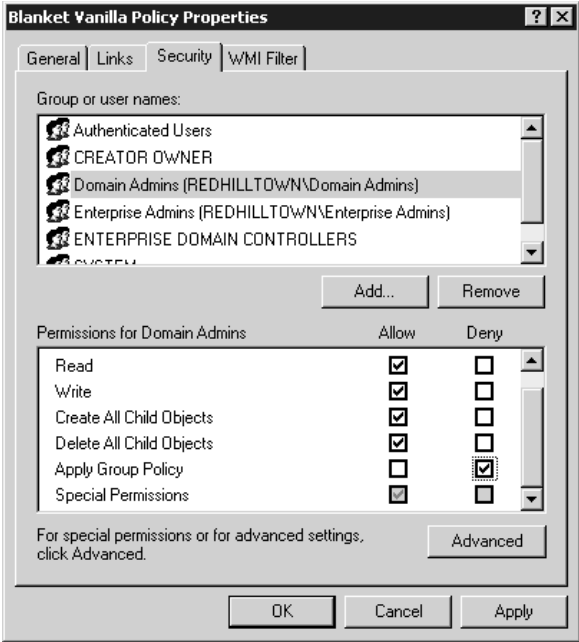

Right-click the container linked to any given GPO (in our example, the domain) and choose Properties. Select the Group Policy tab and highlight the policy you wish to filter. Click the Properties button and go to the Security tab (shown back in Figure 9.45). Now you see the access control list (ACL) for the policy object.

As I pointed out before, Domain Admins and Enterprise Admins have Read and Modify permissions, and Authenticated Users have Read and Apply Group Policy. It may happen that you create a policy to restrict Desktops and you don't wish to apply it to a certain group of people. The group Authenticated Users includes everyone but guests, so by default, the policy will apply to everyone but guests; that means even Domain Admins and Enterprise Admins will receive the policy settings. To prevent Domain Admins and Enterprise Admins from receiving this policy, you must check the box in the Deny column next to Apply Group Policy (Figure 9.51). A member of both groups will only need the Deny setting for one of the two groups, but you'll need to check the Deny box for both groups if the members of Domain Admins and Enterprise Admins are not the same people. To "excuse" others from receiving the policy, put them all in a security group and add that group to the list. It is not enough to "not check" the granted box for Read and Apply Group Policy; the users in your special security group are also members of Authenticated Users, so you actually need to choose the Deny option for them as well. Deny takes precedence over Allow.

If you wish to filter policy for a certain machine (or group of machines), follow the same strategy. Add the computer accounts to a security group, add that group to the ACL for the policy object, then deny the group Read and Apply Group Policy permissions.

There is an alternative to adding a security group to the ACL and denying them Read and Apply permissions. You could also remove Authenticated Users from the ACL altogether, preventing anyone from receiving the group policy. Then you would simply add entries to the ACL for any security groups you *do* want to receive the policy. Be sure, though, to allow them *both* Read and Apply Group Policy. Figure 9.52 shows the permissions list for Blanket Vanilla Policy in which Authenticated Users has been removed and the Domain Engineering group has been added. This is a useful strategy if you don't want the policy to apply to all users and computers in the linked container by default.

**FIGURE 9.51**  
Denying the Apply  
Group Policy  
permission

**FIGURE 9.52**  
Group Policy  
ACL without  
Authenticated Users

By the way, there is nothing to prevent you from adding individual users to the permissions list for a group policy object. Let me stress, then, that policy filtering is incredibly powerful—you might say that it's the tool that lets you oppress individuals or groups. In the real world, however, adding ACLs to a policy can be a nightmare for the poor fool trying to figure out two years later why a policy is attached to a domain but *isn't bloody applying to most of the people in the domain!*

### USING WMI FILTERS WITH GROUP POLICY

Windows Server offers a WMI filtering option for group policies, which it didn't offer in Windows 2000. WMI filters run queries created in WMI Query Language (WQL) to determine whether or not to apply the entire policy. You can't pick and choose among the policy settings. To use WMI filtering, open the properties tab of a GPO and go to the WMI Filter tab (it's adjacent to the Security tab) shown in Figure 9.53. Use the Browse/Manage button to add, edit, or delete WMI filters.

**FIGURE 9.53**

Enabling the WMI Filter option for group policy objects

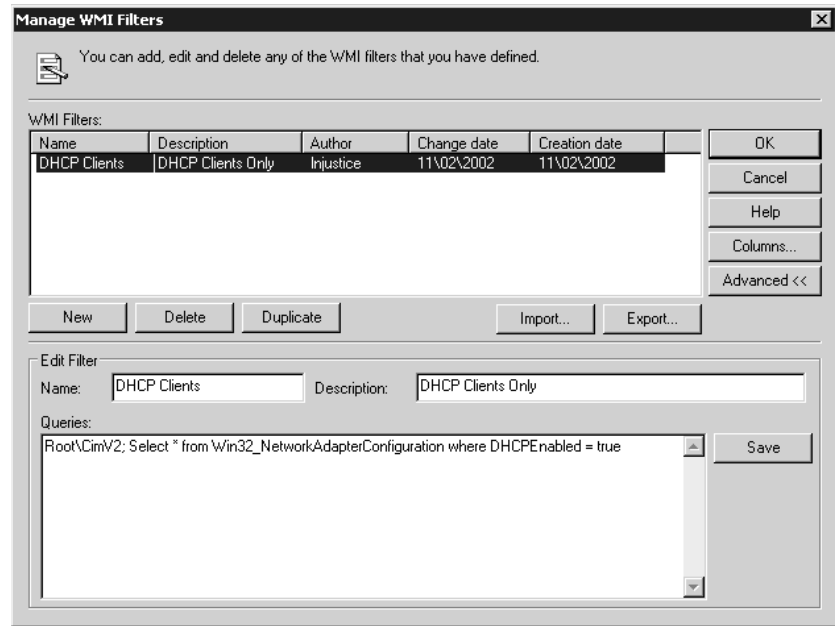

There are literally thousands of WMI-based variables for you to choose from. For instance, you might wish to have a policy apply only to laptops. First, you'd need to determine the make and model of laptops used, and then you could create a query that looks something like this:

```
Root\CimV2; Select * from Win32_ComputerSystem where manufacturer = "Toshiba" and
Model = "Portege 2000" OR Model = "Portege 4010"
```

Other WMI criteria you could use to filter policies are disk space thresholds, version of the operating system, absence or presence of an existing software package, or even network information. Figure 9.54 shows a WMI filter for systems with DHCP enabled.

**FIGURE 9.54**

Managing WMI filters for group policy objects

This WMI filter thing sounds great, right? Well, here's the down side: you can only have one WMI filter per GPO. If you use WMI filters, you'll probably end up creating more GPOs than you normally would. First you would create one or more "generic" GPOs, the ones that apply to the entire site, domain, or OU without any of the hardware or software-dependent settings. Then you would create a bunch of "mini-GPOs" that each use a WMI filter to determine whether or not to deploy.

**TIP** Another disadvantage of using WMI filters is that you have to learn the WMI scripting variables. Or you can cheat and download the unsupported Scriptomatic tool from <http://www.microsoft.com/technet/scriptcenter/wmimatic.asp>. This little hypertext application reveals all the WMI classes, properties, and methods you need to use the WMI filtering capability.

### NO OVERRIDE AND BLOCK INHERITANCE

Just as filtering can be used to counter the blanket application of policies, Block Inheritance is a special setting on a policy to prevent higher-level policies from trickling down. When Block Inheritance is turned on, the settings of higher policies will not be applied to lower containers at all. For example, if you create a GPO for a specific OU, say Brunswick, and set up all the necessary settings for the Brunswick OU, and then you want to prevent the REDHILLTOWN domain GPOs from affecting the Brunswick OU, you'd turn on Block Inheritance. The only policies applied will be the Brunswick OU policies.

There is also a counter to the Block Inheritance counter. (Isn't this becoming like a *Batman* episode? "Robin, they've blocked our transmission. It's time for the block-anti-block Bat-transmitter!") When No Override is turned on for a policy, settings in subsequent policies are prevented from reversing the ones in the No Override-enabled policy. For example, if domain admins have a set of highly disputed settings turned on at the domain level and those renegade Brunswick admins set up their own OU with its own policies and turn on Block Inheritance, the Brunswick OU effectively escapes the disputed settings, but only until the domain admins get wise and turn on No Override. Then the domain

admins win, and the Brunswick OU people have to live with the same restrictions as everyone else. No Override beats Block Inheritance (just like paper covers rock).

Like all secret weapons, No Override and Block Inheritance are best used sparingly. Otherwise, in a troubleshooting situation it becomes rather complicated to determine what policies are applied where. This could be detrimental to the mental health of a network administrator.

Whew! To summarize the factors that can decide which group policy object wins:

- ◆ Examine policies in this order: local policies, then site policies, then domain policies, OU policies, and any OUs inside the OUs, and so on.
- ◆ Within any unit—site, domain, or OU—examine the policies as they appear in the GUI, from the bottom up.
- ◆ If policies conflict, only pay attention to the last one that you examined, *unless* you already saw a policy that said No Override—that means that no matter what policies come afterward, you should ignore them if they conflict with the No Override policy.
- ◆ Before you actually apply a policy, check its ACLs—if you don’t have the Read and Apply Group Policy ACLs, then the policy doesn’t apply.

#### **GROUP POLICY EXAMPLE: FORCING COMPLEX PASSWORDS**

Before leaving this, let’s look at a conflict resolution example that will also offer an example of a useful policy. You may recall that an early NT 4 service pack (either 2 or 3, I forget) included a file called `passfilt.dll` which, if installed on your domain controllers, would force users to select “strong” passwords, where Microsoft’s definition of “strong” (“complex” seems more appropriate to me) is that a password must fit the following criteria:

- ◆ Be at least six characters long
- ◆ Contain three of the four types of characters: uppercase letters, lowercase letters, numbers, or “special” (punctuation, etc.) characters
- ◆ Not contain your username

Under NT 4, you just installed `passfilt.dll` on all of your DCs. To make your Active Directory domain require complex passwords, however, you use a different process.

First of all, you needn’t install `passfilt.dll` and, in fact, you won’t find it anywhere on the 2000 or Server 2003 CD; its functionality is built into Windows 2000 and Windows Server 2003. You need only turn that functionality on with a group policy. The short version of how to do that is to enable the Passwords Must Meet Complexity Requirements policy. Here are some more step-by-step details:

1. Open up Active Directory Users and Computers.
2. In the left pane (the “command pane”) you’ll see a three-computer icon representing your directory. Right-click it and choose Properties, then click the Group Policies tab in the resulting property page. Create a new policy object, called Complex Password Policy and click the Edit button to open the GPO Editor.
3. This policy is a machine policy, not a user policy. (This surprised me, as it seemed as if it should be a user policy—after all, we’re controlling how users set policies, no? But I guess this is a policy that affects any action on this particular machine—i.e., the domain controller.) Therefore, open up the Computer Configuration node.

4. Within that, open Windows Settings and then Security Settings. There may be a bit of a pause here, but don't worry, just give it a few seconds. Then open Account Policies and finally the Password Policy folder.
5. Inside the Password Policy folder, you'll see an entry labeled Passwords Must Meet Complexity Requirements. Double-click it.
6. Check the Define This Policy Setting check box.
7. Click the Enable radio button.
8. Close the GP Editor.

But you're not done yet—don't expect this to take effect immediately. Domain controllers reapply policies every five minutes, but they can only apply a policy that they know about, so you've also got to wait for the policy information to replicate to other domain controllers. (Obviously, if you have only one DC, then replication isn't a problem.)

Now, I *did* all that, and then created a user account and tried to give it a short one-character password, expecting to get an error message. But I didn't; the system accepted the short password despite the new policy. I even opened a command line and typed `secedit /refreshpolicy machine_policy`, hoping that would push the system into seeing the policy. But it still didn't work.

Here's what I forgot. Domains automatically get a policy called Default Domain Policy. When I created my new policy, Complex Password Policy, then the Group Policies user interface placed it below the Default Domain Policy, as the UI does by default—reading top to bottom, you can see the order in which policies were created and/or linked to the domain. I hadn't realized it before, but the Default Domain Policy object *disables* strong passwords!

So there's a conflict in policies here. My Complex Password Policy said to use complex passwords, and the Default Domain Policy said not to. Who wins? Well, by default, a system pays attention to the *last* command that it heard, and the system executes policies from the one at the bottom of the list in the user interface to the top. (It's true, believe it or not.) So the system first got the command to force strong passwords, and then as it worked its way up the UI it came across the Default Domain Policy, which said *not* to force strong passwords. So no strong passwords.

The answer? I could have simply set my Complex Password Policy object to No Override. Instead, I just moved it above Default Domain Policy in the UI. Result: strong passwords.

And one more note, embarrassing as it may be: I thought originally to just try this strong password policy out on an organizational unit, but the policy didn't work. Then I remembered—duh—that account policies don't apply to OUs; you've got to make account policies on domains or they'll be ignored.

## Delegating Group Policy Administration

The ability to delegate creation and configuration of group policies to Administrative personnel (or to others, for that matter) is extremely useful, especially in a large organization. In this section I'll explain how to allow persons who are not members of Domain Admins or Enterprise Admins to create and manage policies for designated sites, domains, or organizational units.

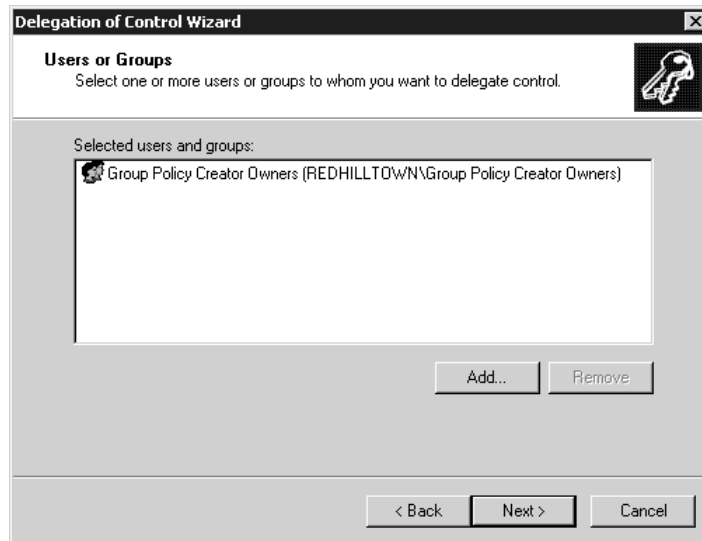

Group policy objects, by default, can be created by a member of the Administrators group for the domain or by members of the global group called Group Policy Creator Owners. However, while members of Administrators have full control of all GPOs, members of Group Policy Creator Owners can only modify policies they themselves have created, unless they have been specifically granted

permission to modify a policy. So, if you put a designated group policy administrator into the security group Group Policy Creator Owners (that's almost as awkward as Active Directory Users and Computers), that person can create new policy objects and modify them.

It's one thing to create a group policy; linking that GPO to a site, domain, or OU is another matter. Administrators have this power by default, but a special permission called Manage Policy Links must be granted on the ACL of the site, domain, or OU before anyone else can create policy links to it. Also, there doesn't seem to be a way to create a group policy without linking it to something, at least initially. So if you want to use the Group Policy Creator Owners security group, you need to go ahead and set permissions on a container object to allow them to manage policy links. You'll need to use the Delegation of Control Wizard to accomplish this.

To allow members of Group Policy Creator Owners to create links to a particular OU (I've created a special OU with no users or groups in it, called GPO Holding Pen), right-click the OU in DSA.MSC. Choose the option Delegate Control from the context menu. Choose Next in the initial wizard screen to go to the part where you add the users and groups to whom you will delegate control. Choose Add and type **Group Policy Creator Owners** in the space provided. Click OK and then Next to return to the Users or Groups window, as shown in Figure 9.55. The Group Policy Creator Owners will appear in the Selected Users and Groups box. Choose Next to proceed to Tasks to Delegate window. Select Manage Group Policy Links from the predefined common tasks to delegate (see Figure 9.56). You should also enable both of the RSOP links, but we'll talk about RSOP in a bit. Now click Next and confirm your choices in the last screen by clicking the Finish button.

**FIGURE 9.55**  
Delegation of  
Control Wizard's  
Users or Groups  
window

Members of Group Policy Creator Owners can now create new GPOs linked to the GPO Holding Pen OU. After they've created the policy objects, you or another trusted admin can actually do the task of linking the GPO to an actual site, domain or OU. They can also modify policies that they have created, but if there are other policies on the OU, members of Group Policy Creator Owners can't edit them by default. You'll have to grant the group Read and Write permission on the policy object's ACL.

**FIGURE 9.56**

Delegating  
management of  
Group Policy links

**TIP** To test GP objects before deploying them, put one or more test environment computer, user, and security group accounts into the holding pen OU you created. This way, you can see the effect the policy will have before linking the GPO to a production site, domain, or OU.

Designating a regular user or junior admin as a member of Group Policy Creator Owners and giving them the ability to manage group policy links, even if it's just at the OU level, is a real exercise in faith and quite taxing for us control freaks (I mean, letting-go-challenged people). If you want finer control when delegating group policy administration tasks, set up a custom MMC console. You may even elect to limit administration to your special GPO Holding Pen by loading the Group Policy snap-in focused on that GPO. Enable only the extensions you want your delegate to use. It's further possible to configure a policy to permit the use of certain Group Policy snap-in extensions and prevent the use of others, just in case the delegate stumbles on to Author mode by accident. See the section "Group Policy Policies" later in this chapter for specifics.

**TIP** See Chapter 3 for a discussion on customizing Microsoft Management Consoles.

That was a lot of information, so let's review the primary requirements for creating and editing GPOs:

- ◆ To create a GPO, you must be a member of either the Administrators group (and this includes nested groups, so membership in Domain Admins is acceptable, for example) or of Group Policy Creator Owners. If you insist on the McGyver approach, however, you at least need access to a domain controller, Read/Write permissions on SYSVOL, and Modify permission on the directory container. When creating an "OU God," then, make sure the would-be OU God is a member of the domain's GP Creator Owner group.
- ◆ To edit a policy, a user must (a) have full Administrator privileges, or (b) be creator owner of the GPO, or (c) have Read and Write on the ACL of the GPO.

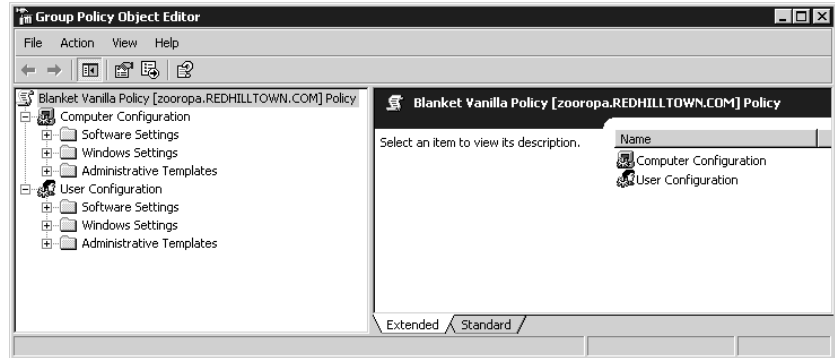

## User and Computer Configuration Settings

Now that you've learned all about creating and linking and delegating administration of Group Policy, we'll explore some of the policy settings themselves in the next few sections. Since you can use various types of policies to configure a range of settings, we won't try to cover every single setting in the pages allotted to this chapter (otherwise it could be a book all by itself!). Rather, think of this section as an overview of what group policies can accomplish to make your life easier as an administrator. To follow along, open the Group Policy snap-in for a GPO by navigating to the Group Policy tab in the container's properties pages, highlight an existing policy, and click the Edit button.

As you see in Figure 9.57, there are two main nodes to the Group Policy snap-in: User Configuration and Computer Configuration. Both nodes have the following subnodes: Software Settings, Windows Settings, and Administrative Templates. The difference between the two is this: Policies set for User Configuration will apply to the user's settings, and those set for Computer Configuration will apply to the machine configuration. For example, if Registry settings are involved, as is the case with **Administrative Templates**, the changes will be written to HKEY\_CURRENT\_USER (HKCU) for User Configuration stuff and to HKEY\_LOCAL\_MACHINE (HKLM) for Computer Configuration settings. Otherwise, the differences aren't so obvious and there is some overlap in the settings, just as HKCU contains some of the same entries as HKLM. You may wish to create separate policies for machines and users, to keep things straight, but be on the lookout for any conflicts. If a value set in the computer settings is also specified in the user policy settings, the User Configuration settings will take precedence by default.

**FIGURE 9.57**  
Group Policy nodes  
and subnodes

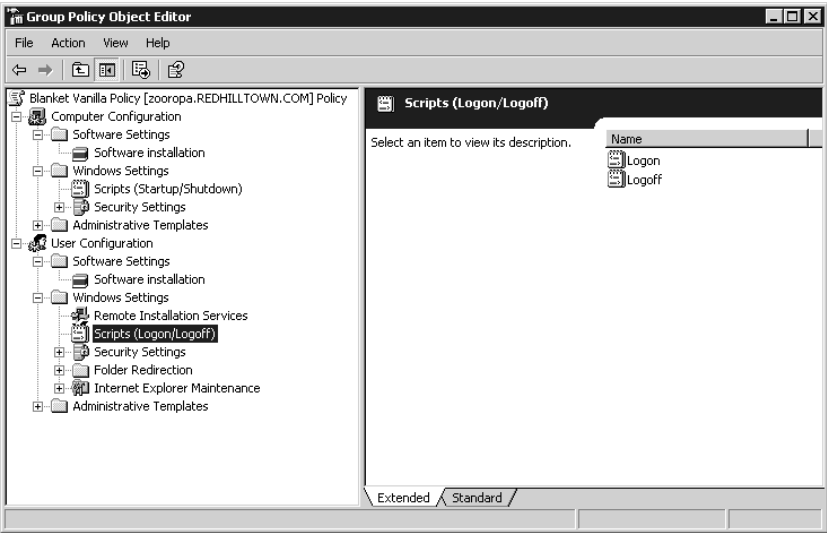

For both User Configuration and Computer Configuration, the **Software Settings\Software Installation** subgroup can be used to publish, assign, update, and even remove applications from a user's Desktop. See Chapter 12 for the full story on using group policies to set up application packages.

### SPECIFY SCRIPTS WITH GROUP POLICY

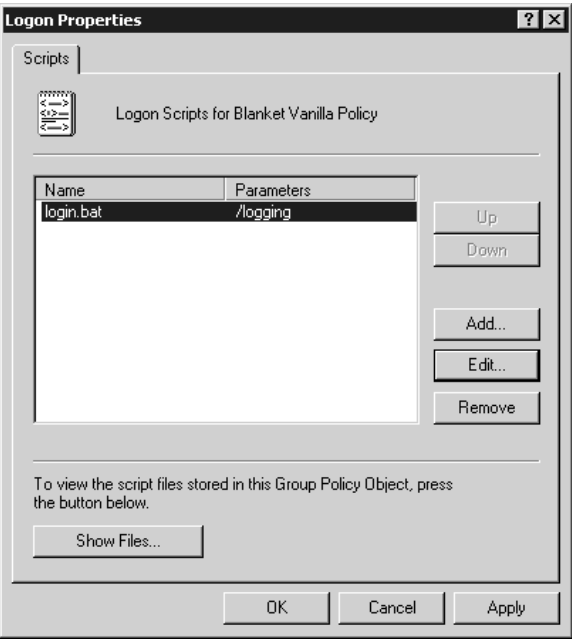

You can specify logon and logoff scripts, as well as scripts to run at system startup and shutdown, using **Windows Settings** in either the User Configuration node or the Computer Configuration node. Expand **Windows Settings** to reveal **Scripts**, then select the script type (Startup, Shutdown, Logon, or Logoff) in the details pane on the right; Figure 9.58 shows the scripts available in User

Configuration. From here, double-click the script type (such as Logon) or highlight it and choose Properties from the Action menu. Add scripts to the list using the Add button (see Figure 9.59). Supply a script name and parameters when prompted. To edit the script name and parameters (not the script itself), choose Edit. If more than one script is specified, use the Up and Down buttons to indicate the order in which the scripts should run.

**FIGURE 9.58**  
Group Policy startup  
scripts

**FIGURE 9.59**  
Adding a script to  
Group Policy

The scripts you create and assign should be copied to the following path in the SYSVOL directory: `\Windows\SYSVOL\SysVol\domainname\Policies\{GUID}\Machine\Scripts\Startup or Shutdown (or User\Scripts\Logon or Logoff, depending on whether you are assigning scripts to the Computer Configuration or to the User Configuration node). The Global Unique Identifier (GUID) for the group policy object is a long string that looks like {FA08AF41-38AB-11D3-BD1FC9B6902FA00B}. If you wish to see the scripts stored in the GPO and possibly open them for editing, use the Show Files button at the bottom of the properties page. This will open the folder in Explorer.`

As you may know, you may also specify a logon script in the properties page of the user account in DSA.MSC. Microsoft calls these *legacy logon scripts* and encourages you to assign scripts with Group Policy for Windows 2000 and XP clients. Of course, Windows 9x/NT clients don't use group policies, so you'll still assign their logon scripts in the account properties. Other than that, the only real advantage to using the Group Policy scripts is that they run asynchronously in a hidden window. So if several scripts are assigned, or if the scripts are complex, the user doesn't have to wait for them to end. Legacy logon scripts run in a window on the Desktop. On the other hand, you might not want the scripts to run hidden (some scripts stop and supply information or wait for user input). In that case, there are several policy settings available to help you define the behavior of Group Policy scripts. These settings are located in the Administrative Templates node under **System\Scripts**. There you'll find settings to specify whether to run a script synchronously or asynchronously and whether it should be visible or invisible. Legacy logon scripts can be run hidden, like Group Policy scripts, by using the setting shown in Figure 9.60. The Computer Configuration settings also include a maximum wait time for Group Policy scripts, which is 600 seconds by default. This changes the time-out period, which is the maximum allotted time allowed for the script to complete.

**FIGURE 9.60**

Policy to run legacy scripts hidden

## FOLDER REDIRECTION

One of the more useful things you can do with User Configuration settings in Group Policy is to arrange for a user's Application Data, Desktop, Start Menu, or My Documents folder to follow her

around from computer to computer. These folders are important elements in a user's working environment. **Application Data** stores application-specific user information (Internet Explorer uses it, for example), and **Desktop** may contain important folders and shortcuts that need to be just one click away for the user. The **Start Menu** folder contains program groups and shortcuts to programs; **My Documents** is the default place to save and retrieve files, sort of like a local home directory. With user profiles in NT 4 and now 2000/XP, you can preconfigure these folders' contents and assign network locations. With the System Policy Editor for 9x or NT, it was also possible to specify a location for these folders. But, unlike the Default User profiles behavior, redirected folders live in one designated place all the time. They are not copied to each machine the user logs in to, causing "profile build-up." Instead of using the folder in the user's local profile, she will be *redirected* to the location specified in the group policy. Group policy folder redirection replaces and enhances those functions offered previously in system policies, with additional options to manage the redirected folder behavior.

There are several good reasons to use folder redirection. For one thing, it's convenient for users who log in from several different machines. Also, if you specify a network location for some or all of these folders, they can be backed up regularly and protected by the IT department. If roaming profiles are still in use, setting up folder redirection speeds up synchronization of the server profile with the local profile at logon and logoff, since the redirected folders need not be updated. Redirecting the **Desktop** and **Start Menu** folders to a centralized, shared location facilitates standardization of users' working environments and helps with remote support issues, because help desk personnel will know that all machines are configured in the same way. Best of all, you can mix and match. It's possible to specify a shared location for the **Desktop** and **Start Menu** folders while allowing each user to have his own **My Documents** and **Application Data** folders. Let's take a look.

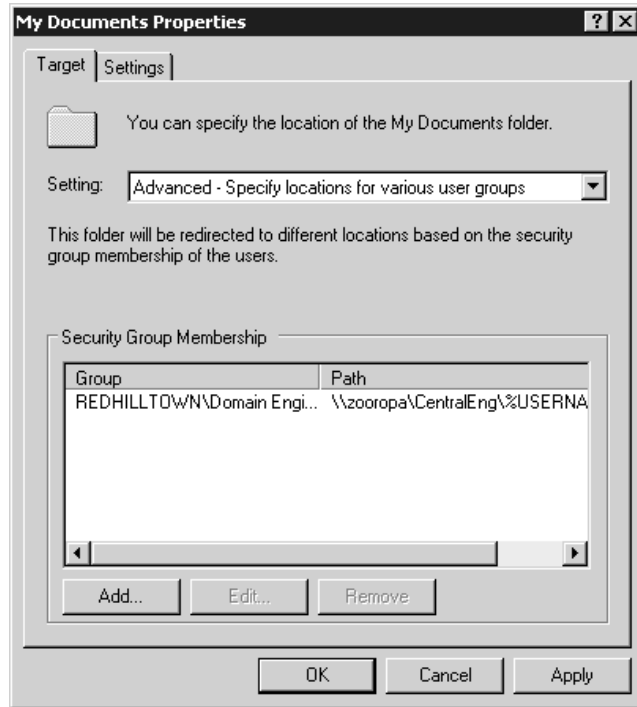

To set a network location for the **My Documents** folder in Group Policy, go to **User Configuration\Windows Settings\Folder Redirection\My Documents**, right-click the highlighted **My Documents** folder, and choose **Properties** from the context menu. The properties page reveals that this setting is not configured by default. Choose **Basic** from the drop-down list to specify a single location for the **My Documents** folder, to be shared by all the users; or choose **Advanced** to set locations based on security group membership. If you want a single location for a shared **My Documents** folder, just fill in the target location with a network path or browse for it. To designate different locations, first choose a security group and then specify a network path. Figure 9.61 demonstrates redirecting the **My Documents** folder for all members of Domain Engineering to the CentralEng share on the server Zooropa. Whether you choose the **Basic** or **Advanced** redirection option, the policy permits you to choose from four different options:

- ◆ Redirect the folder to the user's home directory
- ◆ Create a folder for each user under the root path
- ◆ Redirect to the following location (which you specify)
- ◆ Redirect to the local user profile location

For our example, choose the second option; all of Engineering will use the same root path, but they will have individual **My Documents** folders. When you use this option, the system creates a subfolder named after the user in the path you specify.

**FIGURE 9.61**

Policy to redirect  
the user's My  
Documents folder

Now click the Settings tab to configure the redirection settings. For the sake of completeness, the redirection settings for My Documents are shown in Figure 9.62. The redirection settings for all the other folders are the same except that My Documents has the My Pictures subfolder, so there are a couple of extra items to configure.

The options you see in Figure 9.62 show default selections for the My Documents folder. Notice that the user will have exclusive access to the folder by default. The contents of the corresponding folder will be copied to the new location by default. Even after the policy is removed, the folder will remain redirected unless you say to “un-redirect” it. One notable exception is the Start Menu folder. You can pretty much assume that a redirected Start Menu folder is a shared Start Menu folder (otherwise, why bother?), and making it private or copying over it would generally be a bad thing. Therefore, both the option to grant exclusive rights and the option to move the contents of a user’s Start Menu folder to the new location are grayed out in the Settings tab.

### SECURITY SETTINGS

Security settings, along with administrative templates, make up a large part of Group Policy. The default security settings are purposely open, to keep down administrative headaches and to ensure that users and applications work as intended. As security increases, users and applications have more restrictions and support time goes up. In other words, security is inversely proportionate to convenience. As you start locking down systems, something is bound to stop working. Hey, regular users can’t even install applications on a Windows 2000 or XP system by default. When you start enforcing passwords

that are 8 characters or more, contain both letters and numbers, can't use any part of a user's name, and cannot be reused until 15 other passwords have been used, things get complicated for the everyday Joe. As important as security is, Microsoft judged (wisely, I believe) that functionality had to come first. For organizations that want to increase security, there are tools and guidelines. But there is one problem with this approach. A big problem.

**FIGURE 9.62**

Redirection Settings  
for My Documents

If you've ever "hardened" an NT 4 server according to established military or other high-security guidelines, you know that you have to set particular permissions on particular folders, that you must change the default permissions on certain Registry keys, and change or create other Registry entries as well. All in all, it takes a few hours of work on a single server, even for an efficient admin. What if you have 50 servers and 500 Professional workstations? Some things can be scripted, but others can't. Try as they might, there is no Microsoft or third-party tool that does everything automatically for all machines.

Here's where Group Policy comes to the rescue. Assuming you are going to standardize throughout the organization somewhat, you only have to change those sticky Registry permissions and settings once, using Group Policy. You only have to set the NTFS permissions once. They can even be set up in one policy and copied to another. Whether you need a lot of security or just a little more than the default, chances are you'll want to make at least some standardized changes, and the Security Settings node will certainly make your life easier. The bulk of security settings are found under **Computer Configuration\Windows Settings\Security Settings**, although public-key policies and software

restriction policies are also found in the User Configuration node in the same path. The following summarizes the major categories of settings under Security Settings:

**Account Policies** Specify password restrictions, lockout policies, and Kerberos policy.

**Local Policies** Configure auditing and assign user rights and miscellaneous security settings.

**Event Log** Centralizes configuration options for the Event Log.

**Restricted Groups** Enforce and control group memberships for certain groups, such as the Administrators group.

**System Services** Standardize services configurations and protect against changes.

**Registry** Creates security templates for Registry key permissions, to control who can change what keys and to control Read access to parts of the Registry.

**File System** Creates security templates for permissions on files and folders to ensure that files and directories have and keep the permissions you want them to have.

**Public Key Policies** Manage settings for organizations using a public key infrastructure.

**Software Restrictions Policies** Place restrictions on what software runs on a system. This new feature is designed to prevent viruses and untrusted software from running on a system. It only works on Windows XP or Server machines, though.

### IMPORTING SECURITY TEMPLATES

A full discussion of all these security settings is certainly beyond the scope of this chapter, but you should be aware that several security settings templates are available and installed with the Server to ease the burden of wading through and researching all the settings. It's also safer to configure settings offline and then apply them than it is to play with a live working group policy.

As you read in the earlier section on *local* group policies, the Security Settings templates take the form of INF files and are found in `\Windows\security\templates`. When applied directly or via Group Policy, the templates incrementally modify the default settings. You can view and modify the templates using the Security Templates snap-in, shown in Figure 9.63. As you see in the figure, these settings are the same as those found in Group Policy Security Settings, with the exception of Public Key Policies and IP Security Policies, which cannot be configured with templates. The values for the settings in each template are configured to meet the necessary level of security. These templates, or new ones you create, can then be applied directly to a Windows 2000, XP, or Server machine's local policy by using a command-line program called `SECEDIT.EXE`, or they can be imported into Group Policy.

Every fresh installation of Windows 2000, XP, or 2003 gets a standard set of local computer policies with default security settings. For this reason it's a good idea to export your existing settings to a file by using the Group Policy Editor focused on the local machine (`GPEDIT.MSC` will open that way by default) before making any drastic changes. Security settings for upgraded systems do not have their local policy changed in case the configuration has been customized.

Remember that I promised you when I discussed templates how to apply them with domain-based group policies? This is how: To import a security template into Group Policy, go to

Computer Configuration\Windows Settings\Security Settings and right-click Security Settings. Choose Import Policy from the context menu, and select your policy from the list of templates. Group Policy automatically looks for the template in \Windows\security\templates, but you can tell it to look someplace else if you wish. The INF file will be imported to modify the settings in the selected group policy object.

**FIGURE 9.63**

Security Templates  
snap-in

In the spirit of this template idea, the various subcomponents of Security Settings (like Account Policies or Local Policies) also support a copy-and-paste function, which appears in the context and Action menus when the subcomponent is selected. An admin person can actually copy that part of the template information to the Clipboard and apply it to another policy.

### ADMINISTRATIVE TEMPLATES

Administrative Templates is the part of Group Policy that is most like System Policies in NT. The settings available here are based on template files (ADM files, like those used in NT and Windows 9x System Policies). These settings specify Registry entry changes to adjust various aspects of a user's environment or a machine configuration, including those famous options to restrict a user's Desktop to the point where they can only run a limited set of programs and nothing else.

The user changes specified in Administrative Templates are written to HKEY\_CURRENT\_USER\Software\Policies, and computer changes are written to HKEY\_LOCAL\_MACHINE\Software\Policies. Like the NT 4 System Policy Editor, Group Policy Administrative Templates loads ADM files to disclose collections of configurable settings. These ADM files are in \Windows\inf. Capabilities of Administrative Templates can also be extended with custom ADM files. Right-click the Administrative Templates node and choose Add/Remove Templates to see a list of loaded ADM files (shown in Figure 9.64).

**FIGURE 9.64**

ADM files loaded  
in Administrative  
Templates node

Of the five templates you see in Figure 9.64, the most important are system, which exposes system settings and inetres, which contains settings for Internet Explorer. conf controls settings for NetMeeting, wmpplayer has the Windows Media Player settings, and wuau contains configuration options for Windows Update and Automatic Update.

**NOTE** When you load an Administrative Template, the ADM files are copied to `\SYSVOL\Domainname\Policies\GUID\Adm`.

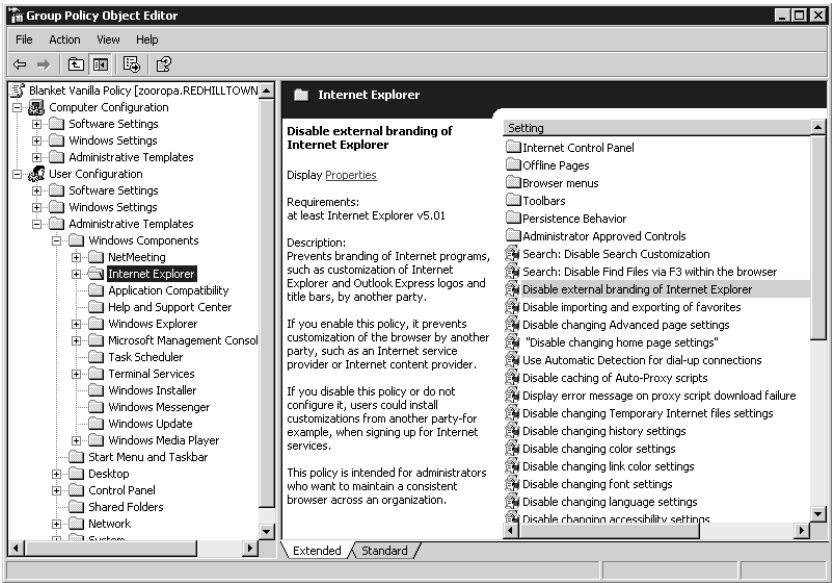

What's the difference between User Configuration and Computer Configuration with regard to Administrative Templates? Good question. Depending on the nature of the configuration settings, some live in the user part of the Registry (HKCU), while others live in the machine part (HKLM). Other settings exist in both places, which makes things really confusing. Settings for Task Scheduler, for example, are exactly the same in both places. So, other than asking yourself, "Which node has the setting I want?" the difference is whether the policy should apply to the machine, regardless of who logs in, or whether the policy should apply to the users and follow them from machine to machine.

One really useful feature about Administrative Templates is that most of the settings include a lengthy description and minimum software or system requirements that display automatically if you are using the Extended View in the tool (see Figure 9.65). If you prefer the Standard View, open the individual item and you'll see the Supported On information at the bottom of the Setting tab. Click the Explain tab to see the description information (shown in Figure 9.66). That beats the heck out of having to stop and look something up in Help every time you have a question.

What can you do with Administrative Templates settings? Among the primary functions is "Keep users from changing X" or "Disable or hide option Y." But mostly it's just a large collection of configuration options loosely organized together to ease our administrative burden and help us achieve the power and control of our networks and users that we crave and feel we truly deserve. An attempt to catalog each subnode and all of its policy settings would be a boring and futile exercise in the Microsoft style of documentation and is best left to those who write the Resource Kits. Besides, many of these policies should not be discussed in a vacuum and are best approached in the context of the particular application or service they configure.

**FIGURE 9.65**

Extended View  
Information in  
Administrative  
Templates

**FIGURE 9.66**

Descriptions of  
settings in the  
Explain tab

Nonetheless, this section would be lacking if it did not include at least a few pointers on individual policies. So the following sections offer a few highly opinionated comments on some of the settings you'll find in Administrative Templates.

### **Restricting Internet Explorer**

For every setting in Internet Explorer, there seems to be policy to disable it. Considering that a good deal of time at work is spent surfing the Web, it's a particularly cruel and clever thing to impose such control over IE settings (unfortunately, many companies use Netscape Navigator instead of Internet Explorer). Here are a couple of settings that I find useful: If you want to prevent users from messing with the security zones you set up, or if you want Internet Explorer to use the same security zones and proxy settings for all users on the computer, then enable the Security Zones and proxy settings under **Computer Configuration/Administrative Templates/Windows Components/Internet Explorer**. To prevent users from downloading offline content to their workstations, enable the policy named **Disable Adding Schedules for Offline Pages** under **User Configuration/Administrative Templates/Windows Components/Internet Explorer/Offline Pages**. To prevent users from making any changes to IE's Security, Connections, or Advanced Properties pages, disable access to these and other IE Control Panel pages in the User Configuration node under **Internet Explorer/Internet Control Panel**. If you want to keep users from downloading any software from the Web, however, that's a little more difficult. There is a policy under **User Configuration/.../Internet Explorer/Browser Menus** that disables the **Save This Program to Disk** option. However, this won't prevent users from installing the software without saving it, and there are probably a couple of other ways around the restriction for a determined power user.

### **Prevent Users from Installing or Running Unauthorized Software**

While I'm on the subject of preventing users from installing software, enable the policy found under **User Configuration/.../Windows Components/Windows Installer** named **Prevent Removable Media Source for Any Install** to keep users from running installations from a CD-ROM or a floppy drive (remember those?). And if you are going to do that, you should also enable the policy to **Hide the "Add a Program from CD-ROM or floppy disk" Option** in **User Configuration/.../Control Panel/Add or Remove Programs**. The Control Panel node includes several options to disable or remove all or part of the Add/Remove Programs applet. Disabling Add/Remove Programs will not prevent users from running setup routines in other ways, however. Anyone who can use a command line can circumvent these restrictions, so you'd need to open the System node of the User Configuration policies and enable the policy to **Prevent Access to the Command Prompt**. If you are looking for that infamous policy to **Run Only Allowed Windows Applications**, it's found in the System node of the User Configuration templates (shown in Figure 9.67). Be careful with this one, though; you have to make a list of all applications that can be launched from Explorer. There is also a setting in the same location called **Don't Run Specified Windows Applications**. For this one, you'd need to make a list of disallowed programs.

**TIP** Figure 9.67 also shows the location of a policy to **Prevent Access to Registry Editing Tools**. Enabling this policy prevents users from running **REGEDT32.EXE** and **REGEDIT.EXE**, although regular users only have **Read** access to the vast majority of the Registry anyway.

**FIGURE 9.67**

Policy to run only  
allowed applications

The same principle applies to the Start Menu and Taskbar option to remove Run from the Start menu. Experienced users will not be prevented from running unblesed programs just because Run is removed from the Start menu, so you have to seek out all the other ways of launching programs and disable them as well (users can also launch programs from the Task Manager unless you disable it in the Ctrl+Alt+Delete options).

**TIP** If you want to achieve a simplified and consistent Desktop and Start menu for your organization or department, you'll probably need to combine folder redirection with the restrictions that are available in the Administrative Templates. You should also look at the last section in this chapter to explore your options for preconfiguring user profiles or the Default User profile.

### **Configure Time Servers and Clients Using Administrative Templates**

Synchronizing time across a big network can be a bit of a headache. Admins often use login scripts to execute the `net time` command, or install a third-party service on NT or 2000 systems. For Windows XP and Server 2003 only, you can use the Computer Configuration Administrative Templates to enable and configure NTP clients and servers and to specify global parameters for time sources. These settings are found in the System node under Windows Time Service.

### **USING GROUP POLICY TO SET PASSWORD AND ACCOUNT LOCKOUT POLICY**

In NT 4, any account policies set in User Manager for Domains applied to domain account and password functions; the audited events, such as restarts, failed logon attempts, and security policy changes, were those occurring on domain controllers. Group policies are much more powerful. If you choose to create a policy at the domain level, the settings will apply to all domain member

machines—servers, workstations, and domain controllers included. Domain controllers receive their settings from domain-level account policies and will ignore the settings in policies linked to OUs. In fact, you'll see an error in the Event Log if an OU-level policy contains these settings. So unfortunately, you still can't make administrator types change their passwords more often than everyone else does (not without a big stick, anyway). Differing Local Policy settings can be applied to OUs, however, so the audit policy can be stricter on "high security" OUs and more lax on others.

**NOTE** Password and account policies should always be set at the domain level; if they are set at the OU level they are ignored. However it is possible for OU policies to override local policy settings such as auditing and user rights.

Password and account lockout policy settings are located under **Computer Configuration/Windows Settings/Security Settings**. Password policy includes the following options:

**Enforce Password History** Enable this option to specify the required number of consecutive unique passwords before a given password can be used again.

**Maximum Password Age** This option sets the amount of time for which a password can be used before the system requires the user to pick a new one. Organizations usually set this interval somewhere between 30 and 90 days.

**Minimum Password Age** The value set here is the amount of time for which a password must be used before the user is allowed to change it again.

**Minimum Password Length** This option defines the smallest number of characters that a user's password can contain. Seven or eight characters is a good minimum length for passwords. Setting this policy also disallows blank passwords.

**Passwords Must Meet Complexity Requirements** In case you are wondering "what requirements?," this setting used to be called Passwords Must Meet Complexity Requirements of Installed Password Filter. A password filter DLL was available as an option for NT 4, but it's built in to Windows 2000 and Server 2003. Password filters define requirements such as the number of characters allowed, whether letters and numbers must be used, whether any part of the username is permitted, and so forth. If you enable this policy, all new passwords and changed passwords must meet the following requirements:

- ◆ They must be at least six characters long.
- ◆ They cannot contain the username or part of the username.
- ◆ They must use three of the four following types of characters: uppercase letters (A–Z), lowercase letters (a–z), numbers (0–9), and special characters (e.g., @, %, &, #).

**Store Passwords Using Reversible Encryption** Yes, this policy is definitely a security downgrade, telling the domain controller that it's OK to store passwords in a reversible encryption. This is one step away from clear text; passwords are normally stored in a one-way hash encryption. If you only need this for individual user accounts (like Apple users) enable the option in the user account properties instead. Reversible encryption is required, however, if you are using CHAP authentication with Remote Access or Internet Authentication Services.

Account Lockout Policy, once enabled, prevents anyone from logging in to the account after a certain number of failed attempts. The options are as follows:

**Account Lockout Duration** This setting determines the interval for which the account will be locked out. After this time period expires, the user account will no longer be locked out and the user can try to log in again. If you enable the option but leave the minutes field blank, the account will stay locked out until an administrator unlocks it.

**Account Lockout Threshold** This value defines how many times the user can unsuccessfully attempt to log in before the account will be locked out. If you define this setting, be sure to specify the number of permitted attempts, or the account will never lock out.

**Reset Account Lockout Counter After** This setting defines the time interval after which the count of bad logon attempts will start over. For example, suppose you have a reset count of two minutes and three logon attempts. If you mistype twice, you can wait two minutes after the second attempt and you'll have three tries again.

### USING GROUP POLICY TO MANAGE MMC

Delegation is a great feature of Active Directory under 2000 and 2003, and the Microsoft Management Console is a big part of that. Many administrators will want to create consoles to accomplish particular tasks and distribute them to the responsible parties. Group Policy offers options to control MMC so that others can't make changes to existing MMC tools or access snap-ins and extensions that are off-limits, not the least of which are the Group Policy snap-ins and extensions.

You see, in NT 4, users could either run the Server Manager tool or they couldn't. If they could run the tool, they might only be able to create machine accounts (if they were members of Account Operators) but not to promote domain controllers. That didn't keep users from seeing the option in the menu or from attempting operations that were not permitted in their security context. Now, not only can you design a tool that includes just the snap-ins and extensions that you want your admins to use, but you can also explicitly forbid any changing of the tool by preventing Author mode. What's more, you can completely forbid access to a particular snap-in, regardless of the tool employed by the user. Please note that this does not actually set a user's security level (that's what security groups and rights are for), but it can effectively limit access to certain administrative tools. Cool, eh?

The Microsoft Management Console policies are found under **Administrative Templates\Windows Components\Microsoft Management Console** in the User Configuration node (see Figure 9.68). The main policies shown in this figure are to restrict Author mode (which prevents the user from creating console files and from adding or removing snap-ins) and to restrict users to an explicit list of permitted snap-ins. These two policies are not exactly mutually exclusive, as you might think; nor does enabling the first policy eliminate the need for the second.

A user who is not permitted to enter Author mode is unable to do any of the following:

- ◆ Run MMC.EXE from the Start menu or a command prompt; it opens, by definition, in Author mode with a blank console window.
- ◆ Open any console with the /a (Author mode) switch.
- ◆ Open any console that is configured to always open in Author mode.

**FIGURE 9.68**  
MMC group policies

All of the prebuilt administrative consoles that are included in Administrative Tools are User mode tools, so they can be used when the restriction is activated. However, if you create a console and distribute it but forget to set it to open in User mode, the user will not be able to access the tool with this policy in effect.

If the policy to restrict users to only the expressly permitted list of snap-ins is enabled, users will not be able to add or remove restricted snap-ins or extensions to console files when in Author mode (they will not even appear in the list of available snap-ins). More importantly, if a console file already contains a restricted snap-in or extension, when a user who is subject to this policy runs the tool, the restricted snap-in or extension will not appear in the console. For example, if you don't have access to the Group Policy tab for Active Directory tools (set this policy in the Group Policy node under **Restricted/Permitted Snap-Ins**), you won't even see the tab in Active Directory Users and Computers (or AD Sites and Services) when you open the properties of the site, domain, or OU.

If you do choose to restrict users to only the expressly permitted list of snap-ins, be sure to filter the policy for exempt admin types. Also, you need to go to the **Restricted/Permitted Snap-Ins** folder and enable those snap-ins that you want to be available. Otherwise, *no snap-ins will be available* to nonexempt users regardless of their power and status on the network. This could be very bad, so think carefully before you disable access to the Group Policy snap-in, or you might not be able to reverse the damage.

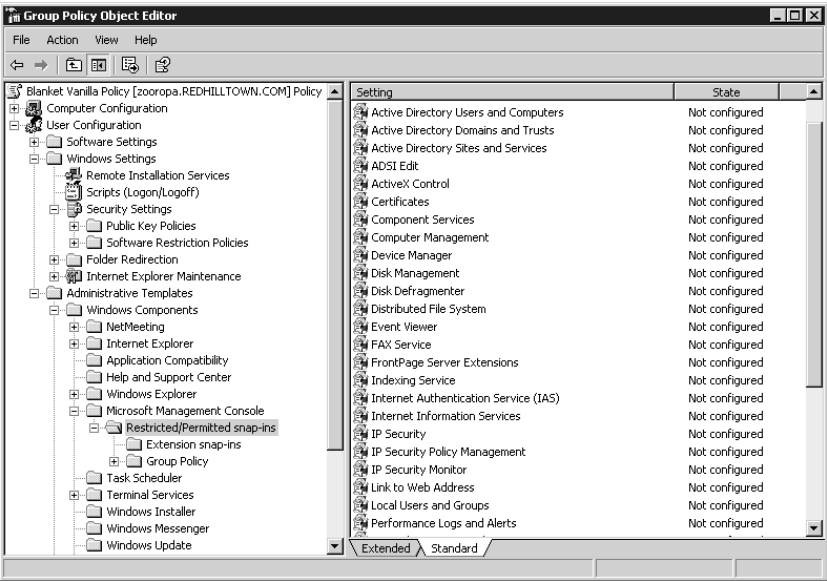

Even if you don't enable the policy to restrict snap-in and extension use, you can still deny access to certain snap-ins. You see, if the policy **Restrict Users to the Explicitly Permitted List of Snap-Ins** is configured, enabling a certain snap-in means that it *can* be used. But if you leave this policy turned off, enabling a certain snap-in means that it *cannot* be used.

Figure 9.69 shows a partial list of snap-ins that can be permitted or restricted. There is a separate list of extension snap-ins that can be restricted/permitted (Figure 9.70). Extensions are implemented

as dependent modules of snap-ins, but sometimes they do the same things as full-blown snap-ins. For example, the Event Viewer is a snap-in and can exist by itself in a console, as it does in the Event Viewer administrative tool, but it is also implemented as an extension in the Computer Management tool. So you'll need to know whether the thing you want to restrict is a full snap-in or an extension. See Chapter 3 for additional information on MMC consoles and snap-ins.

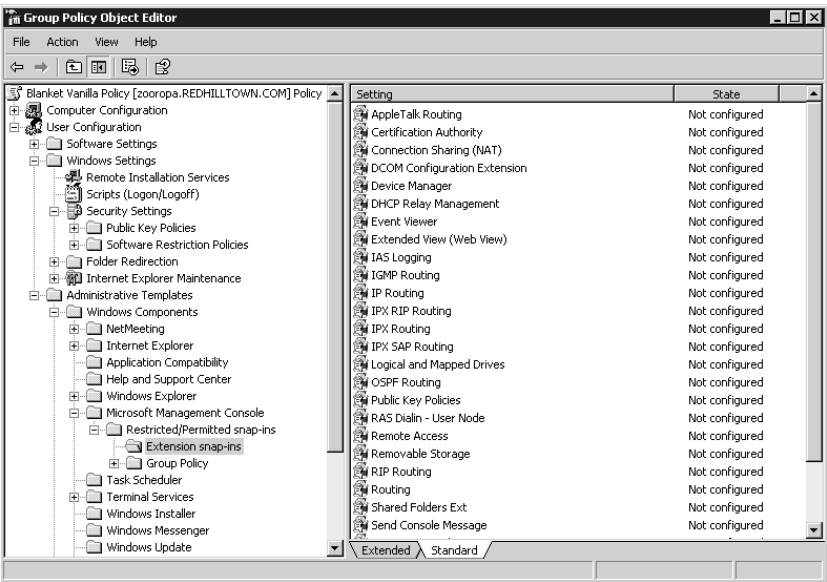

**FIGURE 9.69**

Permitted or restricted MMC snap-ins

**FIGURE 9.70**

Permitted or restricted MMC extensions

There is a separate folder for the Group Policy snap-in and related extensions (Figure 9.71). These allow you to restrict or permit access to the Group Policy tab in DSA.MSC and the GPO Editor) as well as to different extensions within the tool. This could be configured, for example, to permit delegated admin types to assign software for installation without granting access to the Security Settings node. *Be careful when restricting access to the GP snap-ins.* This policy should be filtered for trusted, responsible (and polite) administrators.

**FIGURE 9.71**  
Setting up Group  
Policy snap-in  
restrictions

A final note about MMC policies: If the user doesn't have all the necessary components installed on her machine, the MSC file won't work properly and may not even run. There is a very useful policy called Download Missing COM Components, which directs the system to search for those missing components in the Active Directory and download them if they are found. For some reason, this policy is found in User Configuration\Administrative Templates\System and in the corresponding path of Computer Configuration.

## Managing Group Policies

In the preceding section, we touched on using Group Policy settings to restrict access to certain MMC snap-ins and extensions, including the Group Policy snap-ins. Let's finish up our discussion of group policies with an exploration of the other Group Policy configuration options that are actually included as group policies (Group Policy policies). Then I'll close with a few select observations and suggestions for configuring and managing group policies in your organization.

### GROUP POLICY POLICIES

Policies to control Group Policy are found in Administrative Templates of both the User Configuration and Computer Configuration nodes (Administrative Templates\System\Group Policy). The Computer Configuration node contains most of the policies we'll be discussing. Figures 9.72 and 9.73 show the User Configuration and Computer Configuration options for Group Policy. The following paragraphs summarize the most important configuration options.

**FIGURE 9.72**  
User Configuration  
settings for Group  
Policy

**FIGURE 9.73**  
Computer Confi-  
guration settings  
for Group Policy

**Group Policy Refresh Intervals for Users/Computers/Domain Controllers** These separate policies determine how often GPOs are refreshed in the background while users and computers are working. These parameters permit changes to the default background refresh intervals and tweaking of the offset time.

**Turn Off Background Refresh of Group Policy** If you enable this setting, policies will only be refreshed at system startup and user logon. This might be useful for performance reasons, since having 1500 computers refreshing policies every 90 minutes could cause congestion on an Ethernet.

**Policy Processing Options** These policies, with names such as Registry Policy Processing and Folder Redirection Policy Processing, are available to customize the behavior of the different GPO components. Each policy (see Figure 9.74 for an example) presents at least two of the following three options:

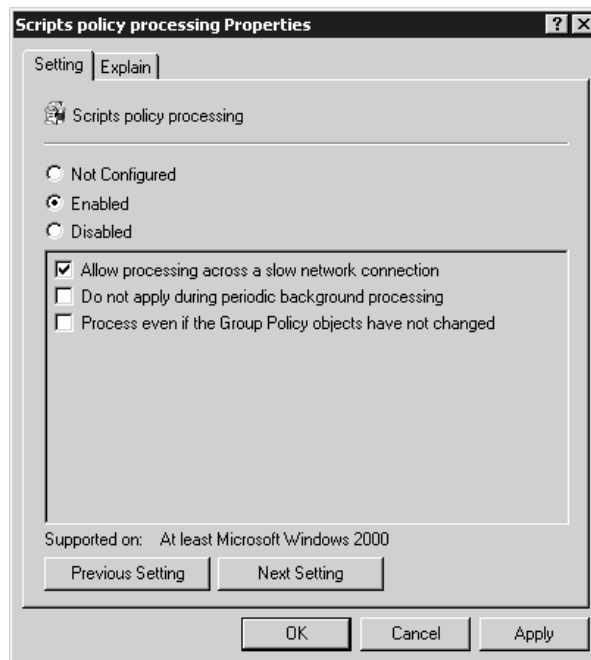

**Allow Processing Across a Slow Network Connection** For slow connections, some policies can be turned off to enhance performance (you can define what a “slow link” is by using the Group Policy Slow Link Detection setting). Security settings and Registry policy processing will always apply, however, and cannot be turned off.

**Do Not Apply During Periodic Background Processing** Specify which components will be refreshed periodically. Software installation and folder redirection policies will never be refreshed while a user is logged in, so the option is not available for them.

**Process Even If the Group Policy Objects Have Not Changed** To conserve network and system resources, GPOs are, by default, not refreshed if there have been no changes. To increase security, however, and guard against a user’s changing a policy setting, enable the policy to ensure that all settings are reapplied at each refresh interval. Please note that enabling this policy may cause noticeable performance degradation.

**FIGURE 9.74**

Scripts policy processing options

**When you want user settings on a particular machine: loopback processing mode** By default, user policies are processed after Computer Configuration policies, and user policies will take precedence if there are conflicts. Also by default, users receive their policy regardless of the machine they use to log in. Sometimes this is not appropriate and policies need to be applied according to the computer's policy objects instead ("loopback processing"). For example, if I log in to a server to do administration, it's not appropriate for my office productivity applications to start installing themselves. Another example of when you would want computer policies to override user policies is if you want to apply more stringent policies for machines that are exposed to the anonymous public (machines in libraries, university computer labs, or kiosks in shopping malls and tourist attractions, for instance). Two modes are used to control this behavior (see Figure 9.75): Merge mode and Replace mode.

**Merge mode** Processes user policies first, then computer policies. Computer policies will therefore override conflicting user policies.

**Replace mode** Disregards user policies and processes only computer policies.

**FIGURE 9.75**

User Group Policy loopback processing mode policy

### GROUP POLICY OVER SLOW LINKS

Group Policy still works over slow links such as dial-up connections. Even better, it's applied whether users log in using Dial-Up Networking or whether they log in with cached credentials and then initiate a connection. However, application of Group Policy over slow links can pose performance issues, so there are also policy settings to define a slow link and to define how policies are applied over a detected slow link.

The default definition of a slow link, as far as group policies are concerned, is anything under 500 kilobits per second. The system performs a test using the Ping utility to determine the speed of the connection. If the Ping response time is under 2000 milliseconds, the connection is fast. You can

change the definition of a slow link, however. This policy setting, called Group Policy Slow Link Detection, is available in both the User Configuration and Computer Configuration, under **Administrative Templates\System\Group Policy** (see Figure 9.76 for the properties page of the policy). To change the default parameter, enter a number in Kbps or enter 0 to disable slow-link detection altogether. If you disable slow-link detection, all policies will be applied regardless of the connection speed.

**FIGURE 9.76**

Group Policy's  
slow-link detec-  
tion properties

As I mentioned in the preceding section, policy processing settings for individual policy components (these have names such as Folder Redirection Policy Processing and are found in the same path as the Slow Link Detection setting, under **Computer Configuration\Administrative Templates\System\Group Policy**) allow you to specify whether a portion of the policy object will be processed over a slow-link connection. Again, this is not an option for Registry-based policies or for security settings; these will always be processed, even over slow links. The other modules will not be applied over slow links by default.

To have logon scripts run over slow links, for example, open the policy called Scripts Policy Processing. Enable the policy and check the box beside Allow Processing Across a Slow Network Connection (shown back in Figure 9.74). Click OK and the policy is set. Repeat as necessary for the other policy processing entries.

## Troubleshooting Group Policies

In case it's not clear by now, group policies are powerful...and also complex. And they can be kind of opaque—sometimes you create a bunch of policies on a domain controller that you intend to control some Desktop, then restart the Desktop, log in, and wait to see the effects of the new policies...but nothing happens.

Windows Server 2003 now includes a couple of decent tools to assist you in troubleshooting group policy issues. The Resultant Set of Policy (RSOP) snap-in and console tool provides a graphical interface, and `GPRESULT.EXE` performs equivalent functions from the command line. `GPOT00L.EXE` is a Windows 2000 Resource Kit tool, and it looks for inconsistencies between GPOs that are stored on domain controllers. This little utility can help you identify replication issues are causing a problem with group policy application.

### THE RESULTANT SET OF POLICY (RSOP) TOOL

Troubleshooting group policies has been, for administrators, a major obstacle to complete control and domination of the network environment. The problem was our inability to view the cumulative policy settings that were in effect for a user or computer. This little capability to display actual policy settings, referred to as the Resultant Set of Policy (RSOP), is built into Windows Server and XP Professional systems. Although RSOP is not supported on Windows 2000 systems, even if you can't see the actual RSOP data, you can run a "what if" scenario using RSOP on a server, and make an educated guess about the problem. Without RSOP, you have to look at the properties of each site, domain, and OU to see which policies and containers are linked. Then you must view the ACLs and WMI info to see if there's any filtering, and check out the disabled, Block Policy Inheritance, and No Override options. Finally, you need to view the settings of the policies in question before you can get to the bottom of things. You'll need to take notes. Personally, I prefer the RSOP tool.

RSOP is a query tool that can retrieve information from individual XP and Server 2003 systems about which policies were applied in what order and with what precedence. When RSOP is retrieving actual information from a system about applied policies, it's running in *logging mode*. RSOP logging mode works by using WMI to create a database called the Common Information Management Object Model (or CIMOM) database, which contains the group policy logging information. When a computer logs on to a network and group policies are applied, the settings and changes are writing to the CIMOM database. It can also run in *planning mode*, where you create a "what if" scenario and manipulate different factors in the group policy application results.

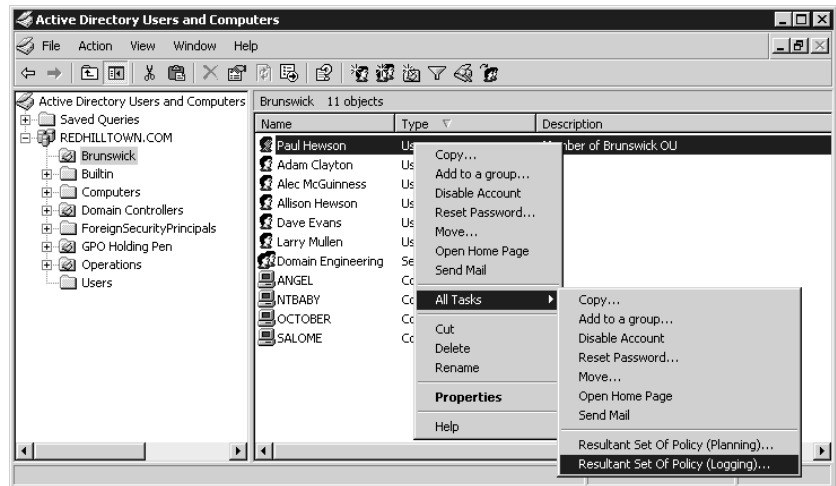

RSOP logging and planning queries can be run for individual users and computers. For sites, domains, and OUs, you can only run planning queries. Apparently Server 2003 doesn't have a place or capability to store a CIMOM database for sites, domains, and OUs. You cannot run RSOP queries for members of a security group. Remember, policies don't apply to security groups.

You can create and run RSOP queries directly from Active Directory Users and Computers, Active Directory Sites and Services (for site-level RSOP queries), or by loading the RSOP snap-in. In my example, I'll use `DSA.MSC` as my starting point. I have three different policies in effect in my REDHILLTOWN.COM domain. The Default Domain Policy applies at the domain level, the Default Domain Controllers Policy applies to domain controllers (unless you remove them from the `Domain Controllers` container!), and my Blanket Vanilla Policy applies only to the Brunswick OU.

My users are not receiving the Desktop restrictions I specified for them, and I'd like to know why. Let's run RSOP in logging mode to see what policies are applying to user Paul Hewson (phewson) when he logs on to his XP computer named ANGEL. From within `DSA.MSC` I find the icon for user Paul Hewson and right-click it to open the context menu. I select `All Tasks\Resultant Set of Policy (Logging)`, as shown in Figure 9.77. The RSOP Wizard starts and asks what computer and user I want to use for the RSOP query. I tell it to use REDHILLTOWN\Angel as the computer, but it's already selected phewson as the user for me. If you haven't already figured this out, you can only run a logging mode query against a user who has actually logged on at that machine. To run a query

involving a new user who has never logged on, I have to use planning mode. If you are only interested in seeing user RSOP settings, you can check a box to not display the computer policy settings (or vice versa, depending on the context). Once I've made my user and computer selections, the wizard displays my choices (see Figure 9.78), and I click Next to start the query. When the wizard is done gathering information, I click Finish to close it. An RSOP console opens in a new MMC window (shown in Figure 9.79). It looks very much like a Group Policy Editor window, except that the root of the console displays the name of the query instead of the name of a policy.

**FIGURE 9.77**  
Start the RSOP  
Wizard from  
DSA.MSC

**FIGURE 9.78**  
RSOP Wizard  
selections

**FIGURE 9.79**

The RSOP results console

If RSOP encountered any warnings or errors while running the query, a yellow flag or a red X will appear over the User or Computer Configuration nodes. To see details of warnings and errors generated while running the RSOP query, right-click the User or Computer Configuration node, choose Properties, and then go to the Error Information tab. The General tab (see Figure 9.80) shows the GPOs that were applied to the computer (or user, as the case may be). The GPOs will display in order, with the last policy applied at the top of the list. In Figure 9.80, you can see that the local policy applied, then the Default Domain policy, and then the Blanket Vanilla Policy had its turn. By enabling the option to display all GPOs and filtering status, you can also see whether any filtering affected the application of these group policy objects. It's a little counter-intuitive, but "applied" means that a filter did not cause the policy to be excused. If it looks like a security filter is the problem, use the handy Security button to view the ACLs on a selected GPO. The Edit button will open the GPO Editor for the policy selected from the list.

Back in the console window, I scroll down to find the problem settings. A nice thing about the RSOP console is that you don't have to look through a trillion undefined settings to see the applied policies. Although you do have to drill down through the tree structure, you should only see the specific settings that were applied by one of the policies in the details pane. Now glance back at Figure 9.79 for a moment. Notice the Start Menu and Taskbar settings in the User Configuration node. Two of the settings were defined by the Blanket Vanilla Policy and two were defined by the default domain policy. My user Paul was complaining that Run and Search were missing from his Start menu, even though the default domain policy explicitly enabled these options. But if the Blanket Vanilla policy removes Run and Search, then it wins, because OU GPOs take precedence over domain-level GPOs. Just to confirm this, I click the Remove Run Menu setting and go to the Precedence tab (Figure 9.81). Just as I suspected, the Default Domain Policy specifically enabled Run on the Start menu, but then the Blanket Vanilla Policy came along and disabled it.

Now that I think I've found the problem, I'll make the appropriate changes and refresh the query to see if the results are different. First I put Paul into a security group with deny permission for Apply Group Policy, thus excusing him completely from the draconian Blanket Vanilla Policy. Then I right-click the query name at the root of the console tree and choose Refresh Query from the context menu. But nothing's changed. Doh! Remember, the query is taking actual logging information from the computer! I either have to log Paul off the workstation and back on again, or wait for the group policy refresh interval, which means Paul will know if it worked before I will. What good is that? Alternately, I can run a query from DSA.MSC in planning mode to see if the policy is reversed.

**FIGURE 9.80**  
The General tab

**FIGURE 9.81**  
The RSOP Precedence tab for a GPO setting

Because it simulates settings and circumstances for group policy results, the planning mode version of the wizard has a lot more options than the logging mode version. You can simulate the effects of loopback processing, a slow network connection, different security group memberships, or WMI filters. Or, if you only want to run a query against a selected user and computer, just choose the option to skip to the final page of the wizard (see Figure 9.82).

**FIGURE 9.82**

The RSOP Wizard  
in planning mode

**Resultant Set of Policy Wizard**

**User and Computer Selection**  
You can view simulated policy settings for a selected user (or a container with user information) and computer (or a container with computer information).

Example container name: CN=Users,DC=REDHILLTOWN,DC=COM  
Example user or computer: REDHILLTOWN\Injustice

Simulate policy settings for the following:

**User information**

☐ Container: [ ] Browse...

☒ User: REDHILLTOWN\phewson Browse...

**Computer information**

☐ Container: [ ] Browse...

☒ Computer: REDHILLTOWN\ANGEL Browse...

☒ Skip to the final page of this wizard without collecting additional data

< Back Next > Cancel

Using the RSOP.MSC tool is not much different from invoking it from DSA.MSC, except that when you open it, it automatically runs a query using the current username and local machine. If that's what you want, fine. If not, you'll need to right-click the query name at the root of the console tree or pull down the Action menu and choose Change Query. This invokes the Logging Mode Wizard, and you can specify a computer and username to use. Apparently, you cannot invoke the Planning Mode Wizard from the RSOP.MSC tool. You can run RSOP in planning mode if you use the snap-in, though.

To use the RSOP snap-in, open an instance of MMC.EXE in author mode and choose Add/Remove Snap-in from the File menu. Add the Resultant Set of Policy to the console. Pull down the Action Menu or right-click the RSOP node in the console root and choose Generate RSOP Data. The RSOP Wizard offers you a choice of logging mode or planning mode before asking you for all of the other usual information. Once a query is created, it can be changed or refreshed, but you can't change it over to the other mode. If you want to create a console for running queries, load more than one instance of the RSOP snap-in into the MMC. For one node, choose to generate a query in logging mode. Choose planning mode for the other one. Save your console, and now you have a placeholder for a logging mode query and a planning mode query. You can change the queries as often as you like. Alternately, you can create several queries and save them all. When you make changes, just refresh the queries to evaluate the ripple effects.

As you can see, the RSOP tool will soon be a valuable asset in the Group Policy administrator's toolkit. The ability to see what policies are in effect, where they came from, and how they are being

filtered makes all the difference in the world. Now administrators can actually start using group policies, instead of just admiring them from a safe distance.

## GPRESULT

GPRESULT.EXE is an RSOP tool that complements the RSOP snap-in by adding command-line and batch file capabilities to the RSOP arsenal. Run without arguments or options, GPRESULT will generate the following RSOP information for the current user at the local machine:

- ◆ The DC that the workstation got the policies from
- ◆ When the policies applied
- ◆ Which policies applied
- ◆ Which policies were not applied due to filtering
- ◆ Group memberships
- ◆ User rights information (if used in verbose mode)

To generate RSOP information for a remote user on a remote machine, use the `/S systemname` and `/USER username` arguments. For instance, to get RSOP information on the remote workstation OCTOBER for the user phewson, type: `gpresult /S OCTOBER /USER phewson`. The targeted remote system must be running Windows XP or Server 2003, though. GPRESULT doesn't work remotely on Windows 2000 systems.

You can get more detailed information with options:

- ◆ `/V` says to give more verbose information: `gpresult /V`.
- ◆ `/Z` says to give even *more* information; it is the “Zuper-verbose” option: `gpresult /Z`.
- ◆ If you know that you're zeroing in on just a machine policy, add `/SCOPE MACHINE`; if you're only interested in user policies, add `/SCOPE USER`. So, for example, to get the maximum information about the user policies applied to this system, add `gpresult /Z /SCOPE USER`. It's also a simple matter to generate a report by redirecting the output of the command to a text file:

```
gpresult /S OCTOBER /USER phewson /Z >gpinfo.txt
```

## GPOTool

Sounds like the Windows 2000 Resource Kit's only Irish program, doesn't it? GPOTool.EXE checks all of your group policies to ensure that they are “whole.” Group Policies exist in two parts: First, there is a text file in Sysvol for each policy, which is called the Group Policy Template (GPT), and second, each policy shows up as a record in the Active Directory called the Group Policy Container (GPC). If one replicates and the other one does not, then the policy won't work.

GPOTool checks each policy and ensures that it has replicated both in the GPC and GPT. But GPOTool has one annoying feature, in fact, a feature shared by many GP tools: it doesn't refer to policies by their English name or “friendly name,” as Microsoft calls it. Instead, it reports on policies by their globally unique ID (GUID), a scary-looking hexadecimal string. You can look up a GUID's friendly name with some techniques outlined in a Knowledge Base article (Q216359) or with this script:

```
set RootDSE = GetObject("LDAP://RootDSE")
Domain = RootDSE.get("DefaultNamingContext")
```

```
wscript.echo "The domain name is: " & domain & vbCrLf
Set GPCContainer = GetObject("LDAP://cn=Policies,cn=System," & domain)
For Each object in GPCContainer
    wscript.echo "Friendly name: " & object.displayname
    wscript.echo "Container GUID: " & object.guid
    wscript.echo vbCrLf
Next
```

(That's from the book *Windows 2000: Group Policy, Profiles, and IntelliMirror*, ISBN 0-7821-2881-5, by Jeremy Moskowitz, from Sybex.) You make the script work by opening Notepad and typing those lines into Notepad. Save the file as `c:\seepols.vbs`, ensuring that Notepad doesn't tack on an extra `.txt`. Then open a command prompt and type `cscript c:\seepols.vbs` and you'll get a list of all policies and their GUIDs and friendly names.

### REGISTRY KEYS TO REVEAL POLICIES

Thankfully, the RSOP tool makes it much simpler to find and resolve issues with group policy application. However, if you want to take the geekiest approach possible to troubleshooting, the Registry can also reveal policies. It actually keeps a record of what policies applied to your computer and your account in `HKEY_LOCAL_MACHINE\Software\Microsoft\Windows\CurrentVersion\Group Policy\History` for the machine settings and `HKEY_CURRENT_USER\Software\Microsoft\Windows\CurrentVersion\Group Policy\History` for user settings. You can also enlist the Registry's aid in logging GP information with a couple of keys.

In `HKEY_LOCAL_MACHINE\Software\Microsoft\Windows NT\CurrentVersion`, create a completely new key—not a value entry, a key—named `Diagnostics`. In that new key, create a value entry `Run-DiagnosticLoggingGroupPolicy` of type `REG_DWORD` and set it to 1. Reboot the computer. You'll get a tremendous amount of information about what group policies applied to this computer. (Turn it off when you no longer need it, or you'll gain new skills, like learning how to make the Event Log larger and how to clear it. Those policies can be a bit voluble!)

`USERENV.DLL` is a DLL that drives much of group policies as well as handles your roaming profiles. It reveals some of what it's doing with a Registry change: Go to `HKEY_LOCAL_MACHINE\SOFTWARE\Microsoft\Windows NT\CurrentVersion\Winlogon` and create a new entry `UserenvDebugLevel` and set it to 1. You'll get an ASCII log file in `WINNT\Debug\UserMode\userenv.log`. It's a log file, so it doesn't reset itself with every reboot; if you're about to do some troubleshooting, then go delete or rename any existing `userenv.log`s, or you'll make the job of picking through its cryptic output even harder.

### TROUBLESHOOTING 101: KEEP IT SIMPLE

I predict that, even with the RSOP tool, working with group policies will not be a walk in the park for most. Here are a few suggestions to help minimize troubleshooting time:

- ◆ Keep your policy strategy simple. Group users and computers together in OUs if possible, and apply policy at the highest level possible. Avoid having multiple GPOs with conflicting policies that apply to the same recipients. Minimize the use of No Override and Block Policy Inheritance.
- ◆ Document your group policies strategy. You may want to visually depict your policy structure and put it on the wall, like your network topology diagrams. That way, when a problem arises, you can consult the diagram to see what's going on before you go fishing.

- ◆ Test those group policies before deployment! This is absolutely essential to conserve your help desk resources and ensure that applications and system services continue to run properly.

### Coming Attractions: The Group Policy Management Console

You probably noticed that it takes several different tools to manage group policies. Microsoft is planning the release of a tool, called the Group Policy Management Console (GPMC) that will simplify management of group policies by providing a single interface to all of its functions. It should be available as a free download shortly after Windows Server 2003 hits the shelves. GPMC can be used to manage Windows 2000 and Server Active Directory domains, plus it adds some much needed management features:

- ◆ Backup and restore of GPOs
- ◆ Import/export and copy/paste of GPOs and WMI filters
- ◆ HTML reporting
- ◆ RSOP information

The tool itself is an MMC snap-in which can only run on a Windows Server 2003 system or Windows XP Professional Service Pack 1 with an additional post-SP1 hotfix (QFE Q326469). Once you install the GPMC snap-in, it replaces the Group Policy tab in the properties of the site, domain, and OU (in `DSA.MSC` and `DSSITE.MSC`). Well, actually the Group Policy tab is replaced by a tab with a button to open GPMC (see Figure 9.83).

**FIGURE 9.83**

GPMC replaces the Group Policy tab in `DSA.MSC`

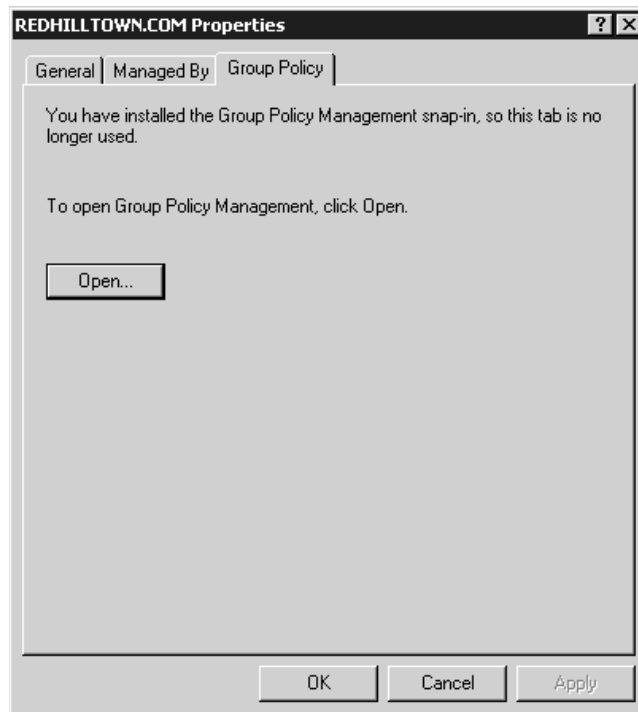

Figure 9.84 shows the GPMC for the REDHILLTOWN.COM forest. The site, domain, and OU hierarchy is shown in the left pane, with separate nodes for Group Policy objects and WMI filters. Group Policy Modeling is what they are calling RSOP planning mode, and Group Policy Results is another name for RSOP logging mode. Select a policy object in the console tree to view its properties in the details pane on the right. The Scope tab has most of the useful information, as you can see in Figure 9.84; it contains information on links, security filters, and WMI filters. The Details tab includes timestamp and version information, and the option to disable either the user or computer configuration settings. The Settings tab is not yet functional, but the final version is supposed to display an HTML-based read-only view of the GPO policy settings. The Delegation tab is the entire ACL for the GPO.

**FIGURE 9.84**  
The Group Policy Management console

GPMC is still missing a few features, like reporting, and you have to actually open the GPO Editor (using a link) to see the policy object's individual settings, but it does provide a sort of one-stop shopping experience in a busy little MMC console.

### A Closing Thought or Two on Group Policy

In the last few sections, I have discussed the concepts of group policies, including local policies. We have created a sample group policy and seen how to turn on the various settings, like No Override and Block Policy Inheritance. We have looked at filtering policies for security groups and delegating policy administration to others. We have explored many of the actual policy settings, including administrative templates for Desktop control, security settings, folder redirection, MMC management, even Group Policy policies. But before you close this chapter and begin to configure group policies on your network, you want to be very aware that group policies affect network and system performance.

The more group policies there are to apply, the longer the logon time. Each time a user logs in (or a computer is restarted), each of the GPOs associated with the user's or computer's containers (SDOUs) is read and applied. This can slow down logons considerably, and users may start calling the help desk to ask, "What's wrong with the network?" Therefore, you should keep the number of policies to a minimum. Another thing that can bog down a machine or a network is the background refresh rate. Refresh your policies too often and you'll see a hit because the machine is always busy asking for policy changes. Think about disabling the background refreshes altogether unless you're worried about users changing their settings to escape policies. With the background refresh disabled, user and computer policies are only reapplied at logon and startup, respectively. The worst thing you could do for performance is have a bunch of different policies in effect and tell Group Policy to reapply at each refresh interval even if there are no changes. Another way to streamline GPO processing is to avoid assigning GPOs from different domains. Just because you can do it doesn't mean it's a good idea.

## Working with Roaming User Profiles

As you use Windows—any version of Windows—and applications, you end up customizing your Desktop and the applications on your Desktop to your particular preferences. Things like your choice of Desktop fonts and color, how an application should start up (e.g., minimized or windowed), and how you want the application to work are all part of something called your *user profile*. You've got one, whether you want it or not, stored on your computer's local hard disk.

But as you move from computer to computer in an organization, it'd be nice to have those settings follow you around. Or, even if you don't use more than one workstation, it'd be nice to be able to wipe that workstation's hard disk clean, reinstall the OS and applications from scratch, and not lose your Desktop and applications settings. You can accomplish that with a variation on a user profile: a *roaming* profile. Not every version of Windows supports roaming user profiles, but NT 3.x and later do. (Although, truthfully, they weren't of much value until NT 4.) In this section, you'll see how they work and what you can do with them.

**NOTE** *Let me stress that NT 4, Windows 2000, XP, and Server 2003 all handle profiles almost identically. Even though this discussion uses XP Professional clients for examples, everything will work the same way if you're supporting Windows 2000 or NT 4 workstations. The main difference is the name of the profile directory. As you'll learn in a page or two, for some incomprehensible reason, Microsoft moved profiles from \WINNT\PROFILES in NT 4 to Documents and Settings in Windows 2000 and XP. Just make that substitution in your head and you'll be able to apply all of this to NT workstations.*

I said that these settings may be configured by a user who wishes to personalize her Desktop, but they can also be set by a system administrator responsible for configuring Desktops, or by a combination of the two. In other words, a user may create shortcuts and select a screen saver, while an administrator may configure special program groups for the user's Desktop. However, the two are not mutually exclusive. By default, every user on an NT, Windows 2000, or XP machine (except members of the Guests group) keeps a local profile directory that the system names after the user ID. Guests are not allowed to keep local profiles.

User profiles can be implemented in several different ways, according to the needs of your organization. In situations where a network-based solution is not feasible or not desirable, there are still several options to keep in mind:

**Local profiles** Users keep only local profiles and create and configure these profiles themselves. User settings don't follow a user around in this case, and a wiped-and-rebuilt workstation won't keep its settings.

**Preconfigured default user profile** Users keep only local profiles, but an administrator preconfigures a "magic," locally stored user profile called the "default" user profile. Anyone who logs onto this system gets that default user profile as a jumping-off point for his or her personal user profile.

**Preconfigured local profiles** Users keep only local profiles, but an administrator preconfigures all or part of the local user profiles. (This can be labor intensive.)

Enabling roaming user profiles, which are of course networked, can exploit the centralizing power of networks and opens up four more possibilities:

**Roaming profiles** Add a profile path to the user's account information to automatically create and maintain a copy of the user profile in a network location (the user can configure her own profile).

**Preconfigured roaming profiles** Add a user profile path to the user's account information and copy a preconfigured profile to the network location specified (the user can make changes to her profile, but the administrator creates the initial state of her profile).

**Network default user profiles** Create a default user profile and copy it to the NETLOGON share of the authenticating domain controller(s). This will hand out default profiles to all new users (users can make changes to their profiles). This option can be used in conjunction with roaming or local profiles.

**Mandatory profiles** Add a user profile path to the user account, copy a preconfigured profile to that path, and use special filename and directory name extensions to specify that this is a mandatory profile. The user must use the profile and cannot make any changes. A mandatory profile can be shared by a group of users.

## Anatomy of a User Profile

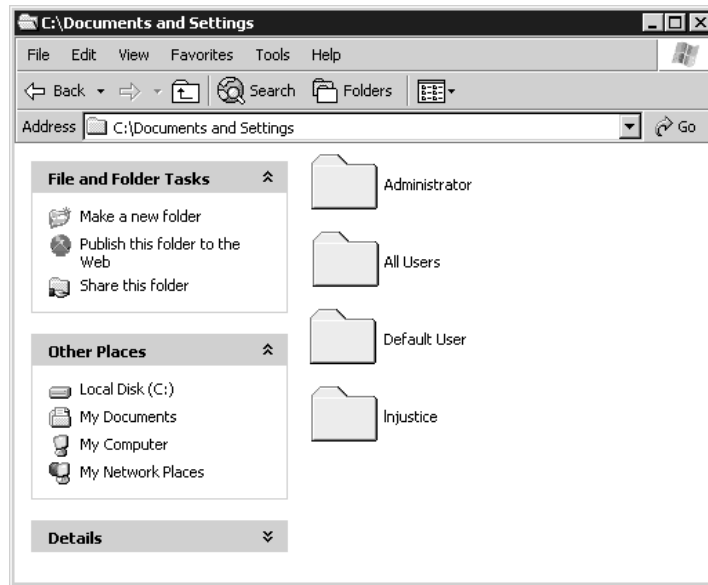

A local user profile is created automatically by the system the first time a user logs in to a NT, Windows 2000, or XP machine. This profile directory is located in %SYSTEMROOT%\PROFILES on an NT 4 machine or a Windows 2000 machine that was upgraded in-place from NT 4. On a cleanly installed Windows 2000, XP, or Server 2003 system, the profiles are stored in a directory called **Documents and Settings** on the same drive as the operating system. (You can change that location if you like, but you've got to do it at setup time by scripting the install.) Figure 9.85 shows the contents of the **Documents and Settings** directory on an XP Professional system.

The **Documents and Settings** directory contains a profile for every user who logs in to the machine (in this case, user **Injustice** and the user **Administrator**), as well as a directory called **All Users** and one called **Default User**. The **All Users** directory stores common program groups (programs

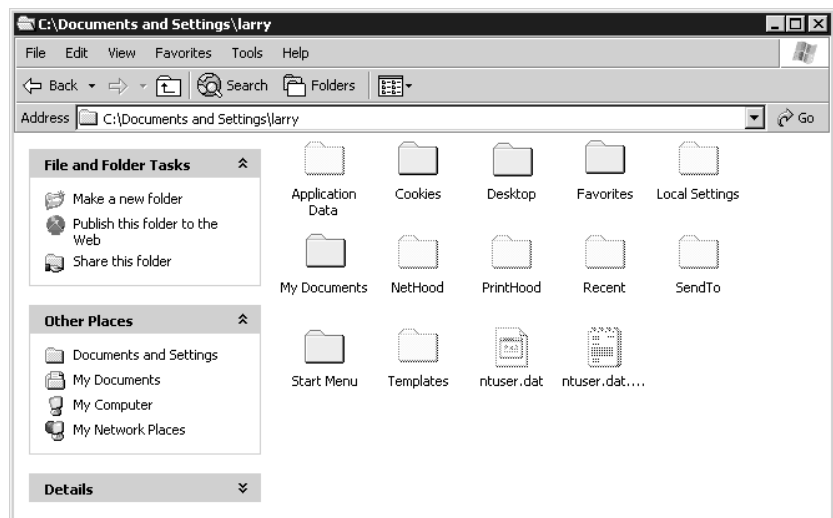

available to all users on a specific machine) and shortcuts that will appear on every user's Desktop on that machine. For example, the Administrative Tools program group is stored in the All Users folder (under Start Menu/Programs), so the programs listed in this group will be made available to anyone logging in to the machine. The Default User folder, which is hidden by default, exists because the operating system uses it as a template for creating individual profiles for new users. Figure 9.86 shows the contents of an individual user profile directory, C:\Documents and Settings\Larry.

**FIGURE 9.85**  
Documents and  
Settings directory

**FIGURE 9.86**  
An individual profile  
directory

Each user’s profile contains several folders with links to various Desktop items plus the NTUSER.DAT file, which contains Registry configuration settings for that user. NTUSER.DAT.LOG is a transaction log file that exists to protect NTUSER.DAT while changes are being flushed to disk (you won’t find an NTUSER.DAT.LOG for the Default User profile directory because it is a template). The other folders store information on the contents of the user’s Desktop and Start menu items, including shortcuts and program groups. Remember that a user’s profile also includes the common program groups and shortcuts indicated in the All Users folder. Table 9.5 describes the various folders in a user profile on a Windows XP Professional system.

TABLE 9.5: FOLDERS IN A USER PROFILE

FOLDER	EXPLANATION
Application Data*	A place for applications to store user-specific information.
Desktop	Any file, folder, or shortcut in this folder will appear directly on the user’s Desktop.
Cookies	Internet Explorer cookies.
Favorites	Shortcuts to favorite Web sites and bookmarks can be stored here.
Local Settings*	A part of a profile that does <i>not</i> roam, even if you make the profile roam. A place for things like temporary files, which can be large and disk-hungry but don’t have a reason to network.
NetHood*	Shortcuts placed here will appear in Network Neighborhood.
My Documents or Personal	You’ll see a Personal folder on NT 4 systems, My Documents on later systems. It’s the place where Microsoft recommends that applications save user data, so that your documents are all in one place. You can change the location of My Documents through policies, so don’t be alarmed if you have a profile that doesn’t have a My Documents.
PrintHood*	Shortcuts placed here will appear in the Printers folder.
Recent*	Shortcuts to recently used files are stored here. Linked to Documents in the Start menu. Windows XP calls this folder My Recent Documents on the Start menu.
SendTo*	The Send To menu is a list of options that appears on the context menu of items on your Desktop and in Explorer. Place additional shortcuts to apps, printers, and folders here to quickly copy an item to a predefined place, to open a file within a specific application (such as Notepad), or even to print a file.
Start Menu	Contains personal program groups and shortcuts to program items.
Templates*	Contains shortcuts to templates created by applications such as PowerPoint and Word.

\*These folders are hidden by default in Windows 2000 and XP. NT also hides the NetHood, PrintHood, Recent, and Templates folders.

In addition to the folders, a user profile includes numerous user-definable settings for Windows Explorer (View All Files and Display Full Path in the Title Bar); the Taskbar (Auto Hide and Show Clock); Control Panel (command prompt, mouse, and display preferences); and Accessories (Calculator, Clock, and the Address Book). Network printers, drive connections, and Help topic Favorites are also saved in the user profile. Virtually any application written for Windows NT-based systems can remember user-specific settings. These settings, which are not directly linked to Desktop items, are contained in the NTUSER.DAT file.

NTUSER.DAT is the Registry part of a user profile. It corresponds to the HKEY\_CURRENT\_USER subtree in the Registry Editor (REGEDT32.EXE).

## Configuring Your Own User Profile

Before you configure user profiles on your network, you will need to master techniques for configuring your own profile. You can then use these skills to configure profiles for other users.

The NTUSER.DAT file for the user currently logged in may be edited using a Registry editing tool such as REGEDT32.EXE or REGEDIT.EXE, although these tools are not particularly intuitive (an understatement if I have ever heard one). The System Policy Editor (POLEDIT.EXE), a tool that originated in Windows 95 for creating system policies (which are covered in an appendix on the CD, in case you've got Windows 9x or NT 4 Desktops to worry about), is more user-friendly and can be used to directly edit several selected settings in the local Registry. The System Policy Editor comes with NT Server and all flavors of Windows 2000, but for some reason it's not installed with XP or Windows Server by default. It's not necessary, though, just convenient.

The System Policy Editor is a "selective" Registry editor and is easier to use, as it does not require any knowledge of Registry syntax or structure. While this application offers several options that are not available in the graphical interface, very little would be of interest to normal users setting up their own profiles, even if they have access to the application. Even though the System Policy Editor can be used to edit the machine's local Registry, as shown in Figure 9.87, most of the Local User options focus on restricting a user's Desktop. Joe User probably would not do that to himself. However, this little piece of information will come in handy when *you* want to restrict other users' Desktops.

**FIGURE 9.87**

Using the Windows 2000 System Policy Editor to change the local Registry

Actually, the best way to configure the NTUSER.DAT part of your profile is simply to configure your Desktop. By using the applets in the graphical interface to change your color scheme, map network drives, and connect to printers, you are making changes to NTUSER.DAT. Use a Registry editor only when you want to make a change that is not offered in the Control Panel. For example, under NT 3.51, the only way to change the icon title font, size, and style was in the Registry, under

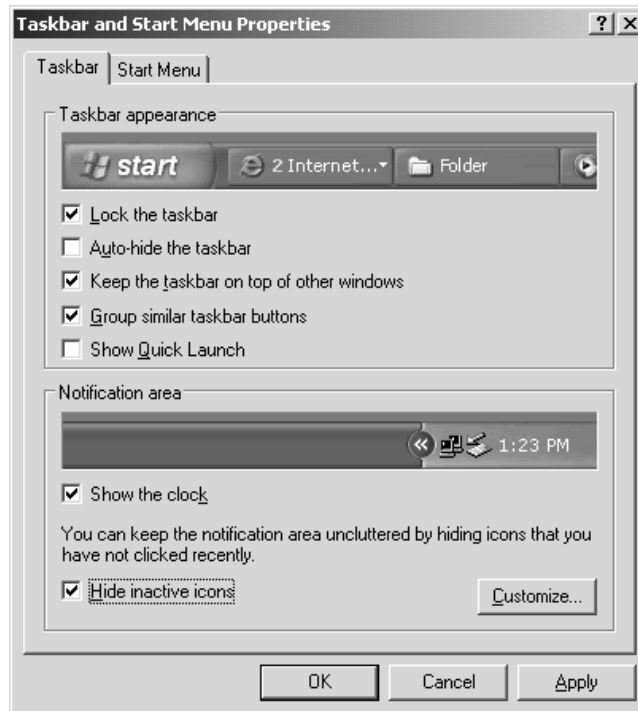

HKEY\_CURRENT\_USER\CONTROL PANEL\DESKTOP. In NT 4, 2000, and XP, however, these and other formerly unavailable options can be adjusted using the Appearance tab in Control Panel/Display.

**WARNING** *As I've warned you before, you're just asking for trouble if you start playing with your machine's Registry for no good reason. Don't edit the Registry if you can make the changes using the Control Panel.*

To configure the Taskbar and customize your Start menu, right-click the Taskbar and choose Properties. The Taskbar and Start Menu Properties dialog box (shown in Figure 9.88) allows you to customize the appearance of these items.

**FIGURE 9.88**

Specifying Taskbar options in the Taskbar and Start Menu Properties dialog box

Toggle the check boxes to see how your display will change. Use the options in the Start Menu tab (Figure 9.89) to select a menu style and customize folders. (An NT 4 or Windows 2000 version of this will look a little different.)

If you choose the Classic Start menu and then click Customize, you can add and remove items from the Start menu using the Add and Remove buttons, or click the Advanced button to be taken directly to your Start Menu folder in Explorer. From there, you can add a folder to create a program group and add a program to add a program item. Folders and shortcuts may be added in Explorer or by double-clicking My Computer on your Desktop. Either way, changes to the folders in your profile directory show up right away on your Desktop. You can also create shortcuts and drag them right over your Start menu button to create a shortcut on the Start menu. For XP Professional systems, you can't use the Customize option to add and remove program groups or items

from the new XP Start menu, because you don't have to. Just add folders and shortcuts directly to the Start Menu folders or subfolders in Explorer, or right-click an executable and choose Pin to Start Menu.

**FIGURE 9.89**

Customizing the Start menu in the Taskbar and Start Menu Properties dialog box

**TIP** Add a few shortcuts to the **SendTo** folder in your profile. If **SendTo** contains shortcuts to your home directory, word processing or spreadsheet applications, and printers, you'll be able to right-click a file to copy it to your home directory, open it in Word, or even print it!

## Birth of a Local Profile

The next step in mastering user profiles is to understand how Windows XP Professional (or Windows 2000 or NT) creates a user profile and how a user obtains one. In short, when a user (we're calling him Larry) logs in for the first time, there is no profile for him yet. So the system creates a new profile folder for him. The Default User profile information is copied to that new directory. This information, along with the shortcuts and program items found in the All Users folder, is then loaded to create Larry's working profile. The new profile now exists in a folder named after the user in the same path as the Default User profile directory, `\Documents and Settings\Larry`. (Again, if this were an NT 4 workstation, the local profile would instead be located in `\Winnt\PROFILES\Larry`. After the system creates the local profile, any user-specific changes made by Larry, to elements such as Desktop color schemes, shortcuts, persistent network connections, or personal program groups, will be saved to Larry's profile.

**NOTE** Contents of the **All Users** folder are not copied to a user's profile directory; the system checks the contents when the user logs on and combines the information in the user's profile directory with the information in the **All Users** folder.

By the way, if that profile is created on an NTFS partition, Larry will be the *owner* of the profile because he created it. Permissions will be set to allow him to modify his own profile. SYSTEM and Administrators will also have full access to the profile. The system sets the permissions like so:

- ◆ SYSTEM gets Full Control.
- ◆ The local Administrators group gets Full Control.
- ◆ The user's account gets Full Control.
- ◆ Other users will be denied access to Larry's profile folder.

Even if an individual profile is created on a FAT partition, the system sets Registry key permissions on the NTUSER.DAT file to prevent other users from using or modifying the Registry hive file. (For more information about ownership and permissions, see Chapter 11.)

If the **All Users** folder is created on an NTFS partition when the system is installed, only users who are members of the local Administrators group may make changes to the folder.

So, to summarize: If you log onto a workstation either with a local or domain account and you don't have a roaming profile, then the workstation needs to find one for you *somewhere*. First, the workstation looks in its profile directory and, if it finds one for your account, then it uses that one. If there *isn't* one for your account, then the workstation needs to create one and uses the "template" profile stored in Default User.

That's how *local* profiles work. Now let's see how things change when we network the profiles, as "roaming" profiles.

## Roaming Profile Basics

A network administrator might choose to specify a path on the network to store a user profile. A profile is a *roaming profile* (rather than a local profile) when the user's account information indicates a profile path, even if that path is local. In the simplest of scenarios, the administrator has simply created a share on the server, set appropriate permissions on the share (and directories), and indicated in Computer Management/System Tools/Local Users and Groups or Active Directory Users and Computers that a copy of the user's profile should be stored there.

Thus far, we haven't given Larry a roaming profile; so far, he's just created a local profile on the workstation that he uses all the time and that workstation keeps the one and only copy of that profile locally, in C:\Documents and Settings\Larry. (Notice that this applies whether Larry has a local account or a domain account; merely having a domain account doesn't confer a roaming profile. But let's say for the sake of the example that Larry's account is on an Active Directory domain.)

Suppose now that Larry is downstairs in Paul's office and wants to get to the domain. Paul logs off, and Larry logs on. Larry doesn't yet have a roaming profile, and so Paul's computer doesn't have a clue about how Larry likes his system set up, so it creates a new profile for Larry by making a copy of the Default Users directory. That means more work for Larry. We'd like his Desktop settings to follow him around. So we'll give him a roaming profile. Here's how to specify a roaming profile path for a user in two easy steps:

1. Create a shared directory. I like to create a share and name it **profiles** or **PROFILE\$** (to hide it from the browse list). Set share-level permissions to Change or Full Control to allow all users

storing profiles to alter their profiles. You do not have to create profile directories for the users. The workstation operating system will create the profile directory for the user and set appropriate permissions.

2. Open Active Directory Users and Computers, navigate to the user account in question, open its properties page, go to the Profile tab, and fill in the path for the user profile directory as shown in Figure 9.90. The figure shows the user's roaming profile located in `\\Z00R0PA\profiles\Larry`. `profiles` is the name of the share, not the directory name, so if you created a hidden share for the profiles, as mentioned in step 1, you'll need to use `PROFILES$` instead. Use `%USERNAME%` in place of the username if you are specifying roaming profiles for more than one user account. You may also specify the user profile path as the user's home directory, as shown in Figure 9.91.

**FIGURE 9.90**

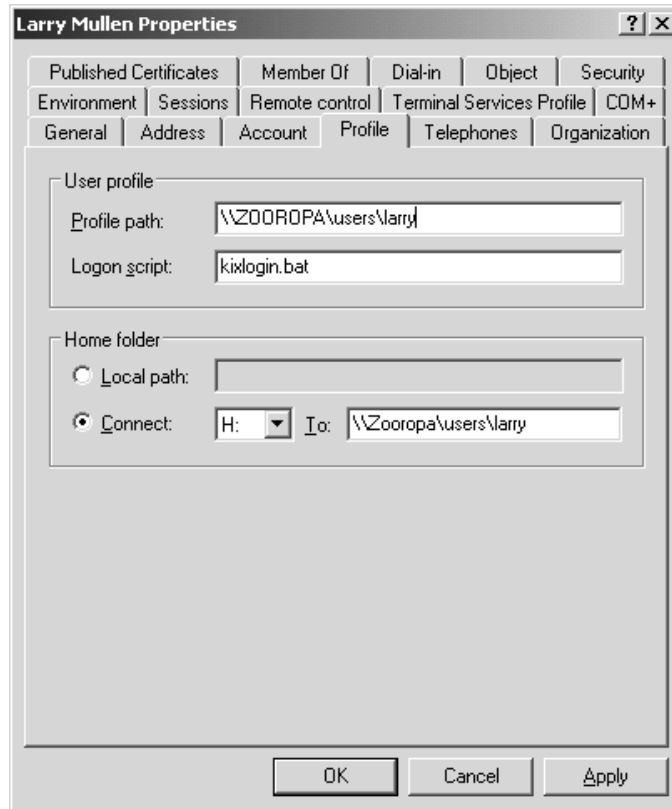

The profile path field on the Profile tab of the user account's properties page

So Larry has logged onto his local system in the past, and his local system has a profile for him. Now that we've specified a profile path, the Active Directory has set aside a place for a roaming profile. But how does AD fill that place—how does it create the user's profile? As it turns out, that can be a bit complex. Let's first consider the case where Larry has been granted a roaming profile, but already has one on his workstation.

**FIGURE 9.91**

The profile path set to the same location as the user's home directory

### CREATING A ROAMING PROFILE WHEN A LOCAL ONE EXISTS

The next time Larry logs in, the workstation will see that there is a network path specified for the profile. Recall that Larry already has a local profile in his workstation. This appears to pose a problem, however—there is no profile on the server yet, but one does exist on the local machine. So, the workstation simply loads the local profile and creates a directory on the server to store the roaming profile. When Larry logs out, the workstation operating system (NT, 2000, or XP) will copy the local profile directory to the network path. In other words, the OS used the preexisting local profile to create the roaming profile directory on the server. From now on, whenever Larry logs in, the workstation operating system will check to make sure that the profiles still match (using a time stamp) and will load the most recent version. The workstation operating system will save any changes Larry makes to both profiles: the local copy and, when Larry logs out, Larry's profile directory on the server.

Okay, why all this rigamarole about saving the user profile to the local path and to the server? The server is the first option, but by default, the workstation operating system will always keep a local profile folder to ensure that the user can access his profile if the network profile is unavailable. This is also useful with slow network connections.

If the profile directory on the server is unavailable for some reason when Larry logs in (perhaps because the server is down), the workstation operating system will simply let him know this and load the local copy. In that case, the workstation operating system will not attempt to copy changes to the server when Larry logs out. The next time he logs in, the workstation will display another dialog box saying, “Your local profile is more recent than your server profile.” Larry can then choose which profile to load. (In case you are wondering, this scenario for Win2K and XP Desktops can be managed with group policies.)

#### CREATING A ROAMING PROFILE WHEN THERE IS NO LOCAL PROFILE

Next, let’s consider what happens if a user logs onto a workstation and a domain for the first time. What if newcomer Adam also has a roaming profile path specified in the Active Directory and he logs in to his workstation for the first time? Like Larry, Adam doesn’t have a profile directory on the server at all. Unlike Larry, he has no local profile on the workstation. In this case, the workstation operating system will use the information in **Default User** on the local machine to create a local profile and will also create a profile directory in the network path. Just as with Larry, when Adam logs out, the workstation will copy his local profile, including any changes, into the newly created directory.

Table 9.6 illustrates the order for loading a user profile, given the two scenarios we’ve discussed.

**TABLE 9.6:** LOADING A USER PROFILE WHEN THE ROAMING PROFILE IS NOT YET CREATED

SITUATION	WHAT THE WORKSTATION OS DOES
A local profile exists.	The workstation OS loads the local profile and creates a roaming profile directory on the server. Changes to the local profile are updated automatically. When the user logs out, the contents of the local profile directory are copied to the server profile directory.
No local profile exists.	The workstation OS uses the Default User profile to create a local profile. The local profile is updated dynamically. A roaming profile directory is created on the server. When the user logs out, the OS copies the contents of the local profile directory to the server.

**NOTE** Although it is possible to specify a roaming profile for a local account on a workstation using the Computer Management tool, it’s not really useful unless you are setting up mandatory profiles for the local machine. And it’s not really a roaming profile at all in this case, because it cannot be loaded when the user logs in elsewhere. Also, do not expect consistent roaming profile behavior if the user is logging in locally and has a roaming profile path specified on the local machine.

Note that if you log onto more than one kind of Desktop—that is, if you sometimes log on to workstations running NT 4, sometimes ones running XP, and sometimes ones running 2000, and if you log on with a roaming profile, then you’ll see some odd behavior. For example, if you have a profile first created on a 2000 workstation and you log onto an NT 4 workstation, then the icons look odd and you’ll get a few error messages. It’s not the end of the world, but it can be unsettling to the nontechnical user. Or it can just be annoying; for example, when I first set up an XP system on my Active Directory domain, I logged on as my normal domain account, which dragged my profile over to the XP system. XP then set my colors to all of the goofy bright XP colors, giving my Desktop a kind of Playskool look.

For performance reasons, some folders in a user profile are configured never to roam, even if roaming profiles are enabled. These include Local Settings, Temporary Internet Files, History, and the user's Temp Directory by default, but you can configure additional non-roaming folders using REGEDT32.EXE or Group Policies (for Windows 2000, XP, and Server systems). In fact, you can use a combination of roaming profiles with non-roaming folders and folder redirection.

## Preconfiguring User Profiles

This idea that people start out from some Default User profile is all well and good, but you'd probably like to gussy that thing up a bit, perhaps customize it to look like a corporate standard or perhaps to simplify the Desktop a bit for your less-techie users or the like. So one way to make things easier for users would be to preconfigure the Default User profile. (It'd be even better to preconfigure one profile that would affect the whole domain, but we'll get there in a minute. For now, let's just see how to make the Default User profile do our bidding on a given workstation.)

To preconfigure the Default User profile, just create a bogus user account, log on as the bogus user, and set up the Desktop and other profile settings just as you want Default User to be. Then log off the bogus user account and log back on as a local administrator. Now you can copy the contents of the newly created profile over the existing contents of the Default User profile on the local machine, using the System applet in Control Panel. On a 2000 or XP system, remember that you must first unhide the Default User folder or set the Explorer folder options to show hidden files and folders.

You can also copy that profile folder to a server location, to implement a preconfigured roaming profile. You can even change the name of the folder and assign appropriate permissions during the process if you use the System applet to perform the copy rather than Explorer or another file management tool. Although a copy from Explorer would work in some scenarios, you would still have to set the directory permissions separately. Also, in certain other procedures regarding user profiles, the operating system needs to know that you are dealing with *profiles* here, not just files and directories. So get into the habit of using the System applet when dealing with user profiles.

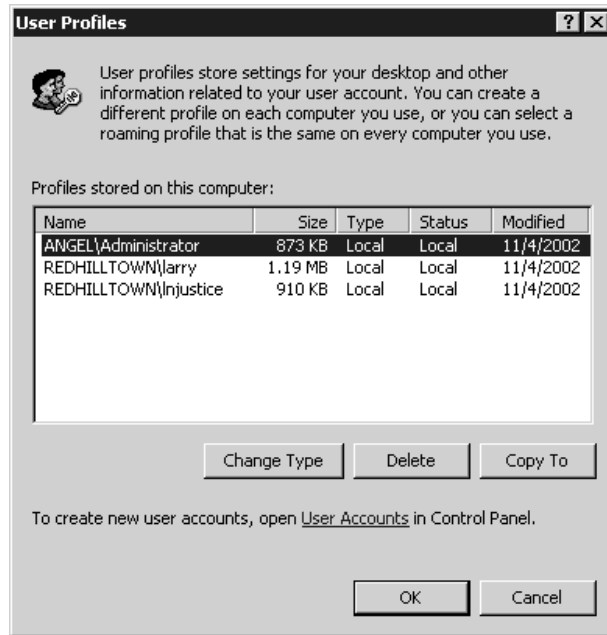

Figure 9.92 shows the User Profiles applet on an XP system. To get there, open the System applet, go to the Advanced tab, and click the User Profile Settings button. For Windows 2000 or NT, open the System Applet and select the User Profiles tab to see the same information. Select the profile you have configured (Larry, in my case) and choose Copy To. Specify the path for the copy as shown in Figure 9.93—remember to change the Permitted to Use information, or only the bogus user will be able to load the profile. Give Everyone, Authenticated Users, or some other appropriate group on your network permission to use the profile.

This procedure can be used for several functions, depending on the Copy To path you specify. On the local level, you can copy the customized profile to C:\Documents and Settings\DEFAULT USER to preconfigure profiles for all new users on the workstation who do not already have a roaming profile stored on a server. It's also possible to copy the customized profile to other workstations if you have administrative rights on them. Take advantage of the fact that the system root directory on all of the workstations is shared as ADMIN\$. Use the path \\MACHINENAME\ADMIN\$\Documents and Settings\DEFAULT USER to preconfigure the Default User profile on other workstations.

You can easily overwrite existing user profiles (although it's a good way to make enemies) by typing in **Documents and Settings\username**, or the appropriate UNC path; but again, don't forget to set permissions. You also need permission to overwrite the user's existing profile, so you should be logged on as an administrator for this.

**FIGURE 9.92**

**FIGURE 9.93**

Copy the profile over Default User

### HOW DO I CREATE AND COPY A PRECONFIGURED DEFAULT USER PROFILE?

1. On a Windows XP Professional workstation, create a new user account using Manage Computer\ System Tools\Local Users and Groups, as you learned earlier in this chapter. For this example, I'll call the new user account Dave. Dave doesn't need any particular user rights or group memberships. While you are logged on as an administrator, either unhide the Default User folder in Documents and Settings or tell Explorer to show hidden files.

*Continued on next page*

**HOW DO I CREATE AND COPY A PRECONFIGURED DEFAULT USER PROFILE? (continued)**

2. Log off and log back in to the workstation as Dave. Windows will create a user profile for Dave using the default.
3. Customize Dave's Desktop. Create any Desktop shortcuts and put those shortcuts into the Start menu. Set up persistent network connections. Using Explorer or by right-clicking the Taskbar and choosing Properties, you can add new program groups or shortcuts to the Start menu folders.
4. When the profile is exactly the way you want it, log out. The system will save the changes in the user's profile directory (\Documents and Settings\Dave). Actually, they are flushed to disk as you make changes to the profile.
5. Log back on to the workstation as a local administrator. Right-click My Computer and choose Properties to get the System applet (also accessed through Control Panel/System). Choose the User Profiles tab. You should see at least a user profile for your administrator account and for Dave. If no one else has ever logged in to the workstation, that's all you will see.
6. Select the template profile from the list, and then choose Copy To. Browse to the location of the target Default User directory, or type in the path. This may be a local path or a network path. The system will create the profile directory where you specify as long as you have permissions to write to that path. Be sure to give Authenticated Users or the Everyone group (or other appropriate users or groups) permission to use the profile; Dave is the only user who has access right now. Click OK to start the copy process. Figures 9.92 and 9.93 show the dialog boxes you will be using in this step.
7. Log off. You're done! When a new user logs on and the system makes a copy of the Default User profile to create a new one for the user, they'll also get all those nice customizations you did for them. Keep in mind, though, that users can still make changes to their own profiles by default.

**PRECREATING ROAMING PROFILES**

You can set up preconfigured roaming profiles by copying a customized profile to the UNC path you specified in the user account properties. In other words, if Adam has never logged onto a workstation before, then you could precreate a profile for him, copy the profile to the path \\MACHINE\NAME\PROFILES\Adam, and specify that path as the user profile path for Adam's domain account.

Preconfigured local profiles may also be set up this way, but you must specify a path in the user's local account information. Do not try to just put the directory into the Documents and Settings directory: NT, 2000, or XP have no way of linking that profile with the new user, so the machine will just create a new directory (for example, Adam001).

**PRECREATING A DEFAULT ROAMING PROFILE**

If you want to precreate roaming profiles for a lot of users, then you don't want to have to put a precreated profile into each user's directory. And you needn't. You can copy the profile to the NETLOGON share on a domain controller to set up a domainwide Default User profile. You see, if a user is logging in to a domain, the machine first looks for a Default User directory in the NETLOGON share of the authenticating domain controller (recall that XP and Win2K provide a NETLOGON share in \WINNT\SYSTEM32\sysvol\domainname\SCRIPTS to support Windows 9x and NT clients). Only if no Default User directory is found in the NETLOGON directory does the machine use the local Default User information. If a Default User directory exists in this network path (where logon scripts and

system policies are also stored), all new domain users with NT, 2000, or XP workstations will use this directory as the domain-wide Default User template, instead of using the local Default User directory. Copy the folders to \\MACHINE\NAME\SYSVOL\domainname\Scripts\Default User. Alternatively, you can save the profile directly to the NETLOGON share (\\MACHINE\NAME\NETLOGON\Default User) if you are in the Administrators group (by default, the Everyone group has Read permission only to the share, while the Administrators group has Full Control permission). Be sure to name the directory Default User and grant permissions to Everyone (or another appropriate group) to use the profile. Users will need Read, Execute, and Read List of Folders permissions in order to access the profile.

In any of the scenarios described above, users can still modify their own profiles once they are created. A variation of this procedure is used to set up mandatory profiles; it will be discussed later.

### EDITING THE NTUSER.DAT HIVE FILE

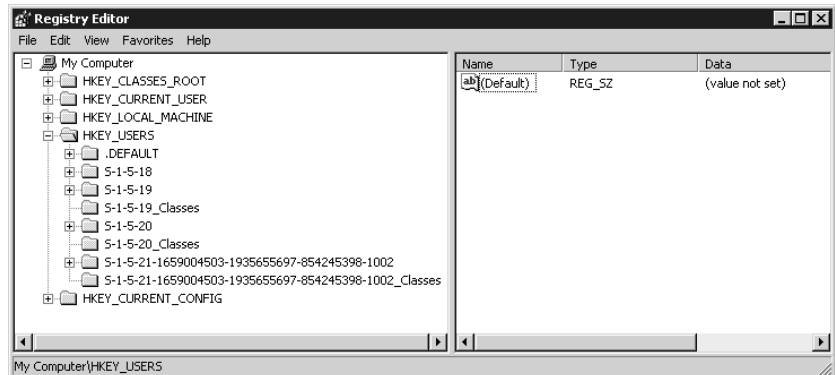

You can change many user profile settings by editing the contents of the folders or by configuring the Desktop. However, if you want to place restrictions on the preconfigured Default User or roaming profile to protect the system from inexperienced users, you will need to edit the hive file (NTUSER.DAT) of the template profile. To do this, you will need a Registry-editing tool.

**WARNING** *As always, do not edit the Registry unless you really know what you're doing. Editing the Registry can have disastrous consequences: you could ruin your system configuration and have to reinstall your whole operating system. Be careful!*

### USING REGEDT32.EXE

To edit user profiles using REGEDT32.EXE, open HKEY\_USERS, as shown in Figure 9.94. The hive file for the active profile (the one for the currently logged on user) is the one with the long SID number. The key .DEFAULT is not the Default User hive file, as you might think. That is located in \Documents and Settings\PROFILES\DEFAULT USER\NTUSER.DAT. The .DEFAULT hive file is loaded from C:\WINNT\SYSTEM32\CONFIG\DEFAULT and is known as the *system default profile*. Microsoft describes it as the profile in effect when nobody is logged in. This seems to be a dangling chromosome from NT 3.51 profiles, when profiles were nothing more than individual hive files.

**FIGURE 9.94**  
HKEY\_USERS  
subkey

The system default and Default User profiles are independent of each other. That is, changing the color scheme in the Registry for the .DEFAULT hive will not affect the Default User profile hive in Documents and Settings. Otherwise, when I set the system default (.DEFAULT) profile to use some neat (I mean practical and informative) bitmap wallpaper, any user who logged in without an already established profile would also get stuck with my wallpaper.

**NOTE** Have you ever wanted to change that default Windows bitmap you see on the screen when nobody is logged in? Well, that bitmap is the wallpaper for the SYSTEM profile (also known as the system default profile). Since SYSTEM is a user (or at least an entity), it makes sense that SYSTEM should have a profile, right? The SYSTEM default profile is the profile in effect when no one is logged in (you see the Ctrl+Alt+Del login dialog box). Simply use a Registry editor such as REGEDT32.EXE or REGEDIT.EXE to specify different wallpaper. The entry is found in HKEY\_USERS\ .DEFAULT\CONTROL PANEL\DESKTOP. Edit the value entry for Wallpaper, specifying the full path of the bitmap that tickles your fancy as the value of the string. You will be editing the hive file %SYSTEMROOT%\SYSTEM32\CONFIG\DEFAULT. Screensavers in effect when no one is logged in can be specified in the same way. This works for NT, Win2K, and XP systems as well.

You can use REGEDT32 to edit a user profile other than the system default and the profile that is actively loaded. If you aren't doing this on an XP machine, be sure to use REGEDT32—REGEDIT can't do this job! On Windows XP, REGEDT32.EXE and REGEDIT.EXE point to the same program. This upcoming example is from XP, but it works the same in 2000 or NT. And one more point: You don't have to do the following Registry hacks to control how a profile gets loaded. System and group policies can handle all of that stuff; look back to the group policies section for more info or read the section on NT 4's system policies on the CD if you're using NT 4 Desktops.

Load the hive file using the Load Hive option from the Registry menu (Figure 9.95). This may be the NTUSER.DAT file from the Default User profile directory or any NTUSER.DAT file; you can browse for it (Figure 9.96). NT will prompt you for a temporary key name (Figure 9.97) and will then load the hive into the Registry Editor, as shown in Figure 9.98. Now make your changes to the Registry settings of the Default User profile. To finish up, select the loaded hive and choose Unload Hive from the Registry menu to save changes and clear the hive from the Registry Editor.

**FIGURE 9.95**  
Loading the hive in  
REGEDIT.EXE

**FIGURE 9.96**

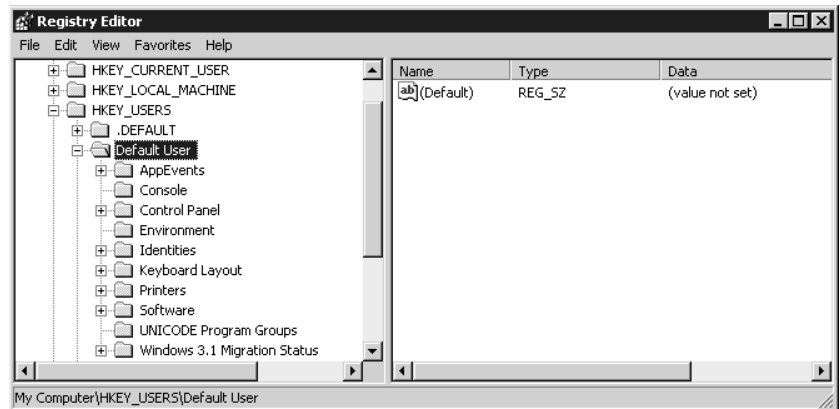

Browsing to find the hive file

**FIGURE 9.97**

Assigning a temporary key name

**FIGURE 9.98**

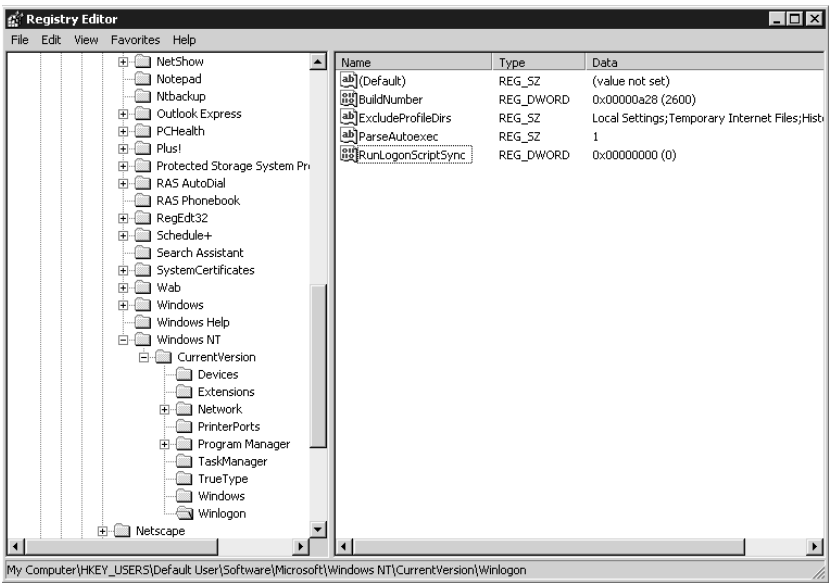

The hive is loaded.

So which changes do you make once the hive is loaded? Ah, that is the real question. You might configure all profiles to wait for logon scripts to execute before starting the user's shell. That way, any drive mappings or environmental variables specified in the logon script will take precedence over those in the user's profile. This entry is called `RunLogonScriptSync` (run logon scripts synchronously)

and is found in HKEY\_USERS\KEYNAME\SOFTWARE\MICROSOFT\WINDOWS NT\CURRENTVERSION\WINLOGON (Figure 9.99). Although I could suggest a couple of other Registry entries to modify, the fact is that REGEDT32.EXE and REGEDIT.EXE are not all that user-friendly. Without spending copious amounts of your time reading Registry documentation (which is not always helpful) and experimenting, you do not know what is possible. You need a GUI Registry Editor. At this point, the System Policy Editor steps back onto the scene.

**FIGURE 9.99**  
The RunLogon-ScriptSync entry

**SYSTEM POLICY EDITOR TO THE RESCUE**

Instead of trying to hack everything out in REGEDT32.EXE, use group policies Administrative Templates settings to make changes on a Windows 2000, XP, or Server 2003 system. If you are still supporting NT 4 machines, the System Policy Editor (POLEDIT.EXE) can be used to make changes to the current profile.

Run POLEDIT.EXE while logged in as your template user (Larry, in my case). Choose File/Open Registry/Local User, as shown in Figures 9.100 and 9.101. Now you can actually read about your options in English (Figure 9.102). Apply your restrictions. You'll notice that you can take away the Run, Find, and Settings in the Start menu, as well as many other built-in options on the Desktop. You'd better be careful, though: changes will apply immediately to the open profile you are configuring, so you might want to make that the last thing you do when configuring the profile. Also, don't touch Local Computer or you will be making changes to your other local hive files (like the System hive). These restrictions are written to the Registry, in HKEY\_CURRENT\_USER\SOFTWARE\MICROSOFT\WINDOWS\CURRENTVERSION\POLICIES\EXPLORER.

**NOTE** The examples in this section are based on Version 5 of the System Policy Editor, which comes with Windows 2000 Service Pack 3. NT 4 Service Pack 6 includes Version 4, so some of the options may vary from Version 5.

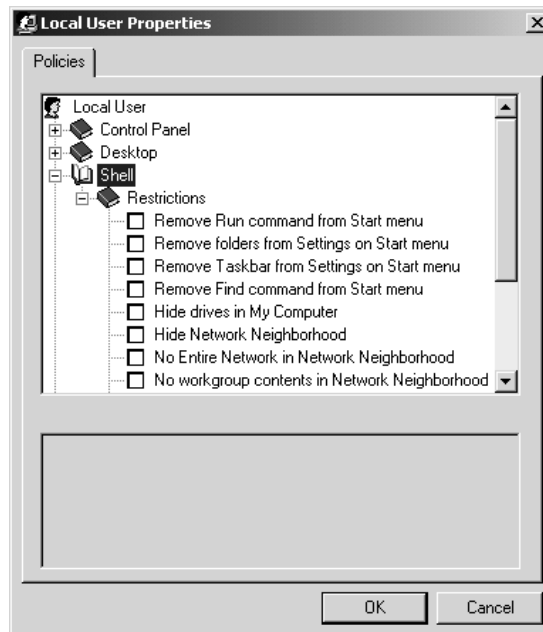

**FIGURE 9.100**  
Open local Registry

**FIGURE 9.101**  
Local User/Local  
Registry

**FIGURE 9.102**  
Local User  
properties in  
POLEDIT.EXE

**NOTE** *Windows XP and Server 2003 do not include POLEDIT.EXE. However, profiles that are modified on a Windows 2000 system using POLEDIT can then be distributed to XP users, as long as the modified Registry entries are common to Windows XP systems. So you can build a profile and set restrictions on a 2000 Professional system, then deploy that profile with reasonable success to XP users and 2000 users alike.*

When you finish, close POLEDIT.EXE, log out, log back in as an administrator, and follow the steps outlined earlier to copy the profile, restrictions and all, to the Default User folder or roaming profile path.

If you are configuring a domain-wide default profile, test your work by logging in to the domain as a new user; you should get the preconfigured default profile and any restrictions you built in. This will be a good opportunity to look for any loopholes or problems. And remember to create your own profile or an administrator profile before doing this stuff, or it will apply to you as well!

### **THE BAD NEWS ABOUT PRECONFIGURED DEFAULT PROFILES**

The problem with a “powerless, preconfigured” Default User profile becomes apparent when a new administrator or some such person logs in for the first time. Your new administrator’s profile will be created from this template, and she will be the irritated but unintentional recipient of a highly restricted Desktop (oops). In this case, you would need to keep a stash of unrestricted profiles in reserve somewhere (make a copy of an untouched Default User profile, for instance). Users who should not get these powerless, preconfigured profiles must have unrestricted profiles specifically assigned to them. Furthermore, these profiles will have to exist in the profile path specified in the user account options before the user ever logs in. If she has already logged in and received the altered Default User profile, you have to delete her profile from the local machine and from the server to remedy the situation. In other words, the user will need to start over with a new profile and will lose any changes made to customize her Desktop. (That’s why people tend not to use profiles to restrict user behavior—these days they use group policies instead.)

### **PROBLEMS WITH PRECONFIGURED AND ROAMING PROFILES**

As you create profiles for users or simply allow users to have roaming profiles, keep in mind that a user profile includes settings on screen placement, window sizes, and color schemes. The display adapters and monitors on the workstations should be taken into consideration. If Larry has a 21-inch monitor with the latest and greatest AGP card and sets up his Desktop accordingly, he may get an unpleasant surprise when he logs in to Adam’s machine equipped with lesser video capabilities. When preconfiguring a profile for a user, sit at a computer that has the same video capabilities as the user’s primary workstation. If you are configuring a Default User profile or one that will be used by multiple users, those workstations must have the same video capabilities. Alternately, you can use the lowest common denominators to ensure that the settings will work on all platforms.

### **A Special Note about Shortcuts and Link Tracking**

Video problems are not the only issue. If you are installing applications on the Desktop, always use default installation directories so that shortcuts created will resolve more smoothly. Also, keep in mind that shortcuts will first attempt to resolve using the link tracking method, which is the absolute path for the shortcut. Failing that, the shortcut will try to resolve with the search method, which means it will search the local drive. In other words, if you created a shortcut to Notepad on \\OCTOBER, saved the profile as a roaming profile, then sat down and logged in at \\SALOME, the shortcut would

first try to resolve to \\OCTOBER\\WINDOWS\\SYSTEM32\\NOTEPAD.EXE. If the user cannot connect to \\OCTOBER, the system will supposedly search for the program in %Systemroot%\\SYSTEM32\\NOTEPAD.EXE. But if \\OCTOBER exists, the user is prompted for a username and password to access \\OCTOBER\\C\$, the hidden drive share that's reserved for remote administration. This leaves users scratching their heads, saying, "What did I do?"—or worse, calling the help desk to ask, "What did you do?" To prevent this problem, when creating shortcuts, use expandable variables (such as %WINDIR%, %SYSTEMROOT%) whenever possible. Luckily, shortcuts work just fine when they point to a shared directory on the server, as long as they are created properly and permissions are appropriate.

Another consideration to keep in mind is that when users on your network regularly move from one profile-creating workstation to another, every machine they use will store a copy of their local profile. These will eventually add up and consume a chunk of disk space. An administrator can delete local profiles periodically, using the Delete option in the User Profiles tab of the System applet. You may also use System Policy Editor or Group Policies to compel the workstations to delete cached copies of roaming profiles when the user logs out. This is a machine-specific setting that is implemented in the Registry in HKEY\_LOCAL\_MACHINE\\SOFTWARE\\MICROSOFT\\WINDOWS NT\\CURRENTVERSION\\WINLOGON. If you are doing a direct Registry edit, the name of the value entry should be DeleteRoamingCache, with a data type REG\_DWORD and a value of 1; it should read

```
DeleteRoamingCache:REG_DWORD:1
```

**NOTE** For Windows 2000 and XP/Server systems, use Active Directory's group policies settings instead of the System Policy Editor to remove copies of roaming profiles. In the Group Policy Editor, look in Computer Configuration\\Administrative Templates\\System\\Logon, and there's a policy named Delete Cached Copies of Roaming Profiles.

Finally, using roaming profiles across a WAN link is not recommended. Whenever possible, load profiles from a server locally. Besides eating up network bandwidth (when the profile is sucked off the server at logon and copied back to the server at logoff), time-out intervals for slow connections will cause numerous problems in synchronizing the local and server copies of the profiles.

### **"CACHED" PROFILES: A TIP**

Talking of mandatory profiles reminded me of a peculiar behavior, one that may bedevil you if you're extremely security conscious.

Suppose I've given you a workstation (again, NT, 2000, or XP will all work the same way) named \\ANGEL, but I've not created a local account for you. Instead, I've given you a domain account on the SONGBIRDS domain and told you to log in from that. Thus, every morning you sit down at your workstation and tell your machine that you want to log in from a SONGBIRDS account, not an ANGEL account. That is, you want your workstation's Local Security Authority *not* to look in your workstation's SAM but rather to use NETLOGON to communicate with one of the DCs in SONGBIRDS, and then to ask one of those controllers to look up your user account in the domain SAM.

Sounds good—but what about those times when you get that dratted "No domain controller found" error message? If your workstation's NETLOGON can't find a DC, it seems that there's no way for your local LSA to establish your credentials. That seems to mean also that if there's no DC around, you can't get on your workstation, doesn't it? Or does it?

*Continued on next page*

**“CACHED” PROFILES: A TIP (continued)**

The first time this happened to me, I was somewhat taken aback to see that my workstation logged me in *anyway*, using “cached credentials.” The idea is that, if you got in all right *yesterday*, we’ll give you the benefit of the doubt *today*, even if the local LSA *can’t* find a DC. Cool, eh? Well, yes, it might be cool for many—but the more security-conscious among us might be quite unhappy about the idea that if a network administrator modifies or deletes your account on Tuesday, by Wednesday your workstation might not know about it.

Fortunately, there’s a Registry setting that you can use to make a workstation require a domain logon before providing access to the local machine. Just go to HKEY\_LOCAL\_MACHINE\Software\Microsoft\Windows NT\CurrentVersion\Winlogon and create a value entry called `CachedLogonsCount`, of type `REG_DWORD`, and set its value to 0. Make this change on every NT workstation on which you want to require strict logons. Use group policies to limit cached logons for Windows 2000, XP Professional, and Windows Server systems.

**NOTE** `DELPROF.EXE` a command-line utility included in the NT Workstation and NT Server Resource Kits, allows administrators to delete user profiles on a local or remote computer running any version of Windows NT through 4, but not Windows 9x. Of particular interest is the utility’s ability to delete profiles that have been inactive for  $\infty$  number of days.

**Mandatory Profiles**

So far in this discussion, all types of user profiles allowed users to make changes to customize their own profile (assuming you did not set up System Policy Editor to discard changed settings at logoff). Another option for controlling user profiles is to assign a *mandatory profile* to the user or to a group of users.

**NOTE** I don’t really recommend using mandatory profiles. Their goal is to lock down a user’s Desktop and, as I’ve indicated before, the better tool for that is policies, not profiles. But I include information about them for the sake of completeness.

A mandatory profile is a read-only profile that the user must use. Mandatory profiles are a tad more work than roaming profiles. The profile must exist ahead of time and it must exist in the path you point to, or else the user cannot log in. Remember, with roaming profiles, we could just let the workstation copy the profile to the network path unless we wanted Larry to use a profile we created for him.

The mandatory profile is a type of roaming profile, in that you must specify a profile path in the user’s account information. To create a mandatory profile directory, name it with the extension `.MAN` (for example, `\\ZOOPOPA\PROFILES\LARRY.MAN`). This tells the operating system that the profile is mandatory and that the user will not be able to log in if the profile is unavailable. In that case, the user will see a dialog box that says, “Unable to log you in because your mandatory profile is not available. Please contact your administrator.”

Also, rename the `NTUSER.DAT` file to `NTUSER.MAN` so that the user cannot save changes to the profile. Once the local profile is created on the workstation, the locally created copy of the profile will also be read-only. This does not set permissions on the profile per se, so it works on both FAT and NTFS. Nor does changing the name to `NTUSER.MAN` set the read-only attribute on the file. It’s just a special extension for the profile that tells NT not to save changes at logoff (changes will apply while the user is logged in but will be lost when the user logs out). This feature is useful if you want to assign one profile to a group of users and you do not want these users to be able to save changes. In other words, everybody shares a copy of the same profile, and it is protected against users’ “personal touches.”

The following are your options for setting up mandatory profiles:

**Use a read-only profile** Simply rename the file NTUSER.DAT to NTUSER.MAN before you assign the profile to the user or users. Keep in mind that when a user first logs in, the workstation does not know that this user's profile is a mandatory profile (because the directory name is *USERNAME*, not *USERNAME.MAN*). If the profile is unavailable, the system will load a local or default profile. However, once the system loads the mandatory profile from the profile path, the System applet on the workstation shows the profile as mandatory. The user or users will not be able to save changes to the Desktop. At this point, if the network profile becomes unavailable, the system will load the local profile, but because the system now considers it a mandatory profile, changes will not be saved.

Incidentally, renaming the NTUSER.DAT file to NTUSER.MAN can be done as an afterthought, as well. In other words, if a user formally has a local and configurable profile, you can go to the *\Documents and Settings\Username* directory and rename the hive file. It will be read-only from that point on.

**Force the user to load a particular profile** If you specify the directory path on the domain controller or server as *DIRECTORYNAME.MAN* but you do not rename the hive file to NTUSER.MAN, the operating system will not see it as a mandatory profile. If the hive file is not named NTUSER.MAN, the workstation will classify it merely as a roaming profile. In this scenario, users can make changes to their Desktops. At logon, however, the user will not be able to log in if the profile directory does not exist in the specified path.

**Create a read-only profile that must be used** Specify the directory name as *DIRECTORYNAME.MAN* and rename the NTUSER.DAT file to NTUSER.MAN. This is ideal if you want to force users to load a profile off the network and you want to prevent them from making any changes to it.

## HOW DO I CONFIGURE A MANDATORY PROFILE?

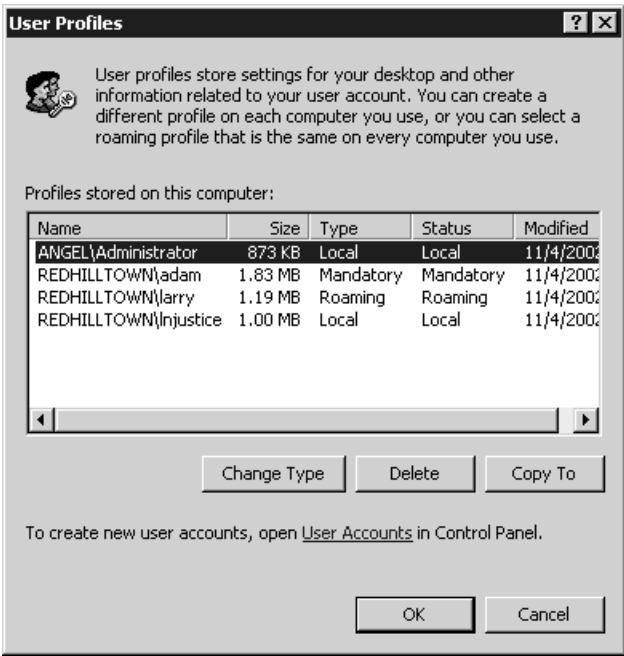

Mandatory profiles are created in much the same way preconfigured profiles are created. Mandatory profiles can be assigned to individual users or to groups. Here is how to create a shared mandatory profile and assign it to everyone in a particular group (Engineering):

1. Create a user, log in as that user, and set up the Desktop, network and printer connections, and so forth.
2. Apply any restrictions you want, as described earlier. Log off.
3. Log back on to the machine as an administrator.
4. Use the System applet (under Control Panel/System/User Profiles) to select the profile and copy it to a shared directory on the network, naming it *SOMETHING.MAN*. Remember to set permissions to allow your user (or a group) at least Read and Execute access to the profile and its contents. I named the directory *Engineering.man* and assigned permissions to the group Domain Engineering.
5. Rename the copied NTUSER.DAT file to NTUSER.MAN.
6. In the properties sheet for the user account, fill in the profile directory path, pointing to your mandatory profile directory. DSA.MSC now allows you to select multiple accounts and change the profile path field to the same value for all of them, so it's easy to select a number of user accounts and assign them all to use the same mandatory profile.
7. You are now ready to have users log in and receive their mandatory profiles.

*Continued on next page*

**HOW DO I CONFIGURE A MANDATORY PROFILE? (continued)**

You can see what profiles are saved on a local machine, and what type they are, in the System applet—the same place you go to copy profiles. The following properties sheet shows all three types on a machine:

**Setting Up a Group Template Profile**

As you can see, it's relatively easy to assign “shared” profiles to users and groups. However, any time two or more users are pulling their profiles from the same profile directory, they should be pulling a mandatory (and read-only) profile. Otherwise, changes made by each user to the group profile directory on the server will be saved. Larry and Adam will have to deal with Paul's Eggplant color scheme or Ninja Turtles icons.

What we really need is to provide profiles with elements in common, like network connections and any corporate-wide security settings, but also allow users to make customizations. Group Policy is the real answer to this dilemma, but for your NT workstations (or just for the sake of argument), how much more trouble is it to preconfigure and assign profiles based on, say, group membership, which will then be under the control of the individual user? This would not be a mandatory profile but just a point of departure for the user. Actually, it's a lot more trouble. Sure, you can make profile templates for groups, but how do you assign them and still let users customize the Desktop according to their own preferences or needs? Let's see how to do this.

### ASSIGNING USER-CONFIGURABLE PROFILES TO GROUPS

If you use the standard preconfigured user profile procedure, follow these steps.

First, make group template profiles by creating three security groups (CLEAVERS, ADAMSES, and CLAMPETTS). Then create three template group member accounts, naming them, for instance, Wally, Tuesday, and Granny (you were getting pretty tired of Larry and Adam, weren't you?). Log on as each template user in turn, and configure a group profile for each one. When you are finished, log off and log back on to the system as an administrator.

When you are creating user accounts, before adding Ward or June user to the CLEAVERS group, open the System applet and copy the CLEAVERS group template profile to a shared profile directory, renaming it after the new user you are about to create. Don't forget to give the new user permission to use the profile. Then create the user, specifying his or her profile path as `\\MACHINE\NAME\SHARENAME\USERNAME`, indicating the directory where you copied the profile.

This process is not complicated overall, but you do have to remember to copy a new profile to the shared directory and assign the profile to that specific user each time you create a new account. This permits the users to start off on the right foot with all the settings you want them to have, but also to make changes as needed to their own profiles.

### How Does a Client Choose between Local, Roaming, and Mandatory Profiles?

In all of this discussion about locally cached profiles, roaming profiles stored on a server, and mandatory profiles, it's important to understand the order in which NT, 2000, or XP looks for a profile and how the system chooses among the three. Plus, there are a couple of considerations that I haven't yet explained. To make this simple, let's view the scenarios from two perspectives: that of a user who has never before logged in to that workstation (Morticia), and that of a user who has logged in to the machine already (Gomez).

Morticia logs in to her newly assigned Windows 2000 workstation. Assume that there is no profile path specified for Morticia in her account information. She only has a local profile. The workstation must create a profile for her from a `Default User` directory. If Morticia is logging in to an Active Directory domain (Windows 2000 or Server), the operating system will first look in the `NETLOGON` share of the authenticating domain controller for a `Default User` profile (it has to look there anyway for the logon script; why not just kill two birds with one stone?). There's no `Default User` directory in the `NETLOGON` share? Oh well, the system will just have to use the `Default User` info from the local machine.

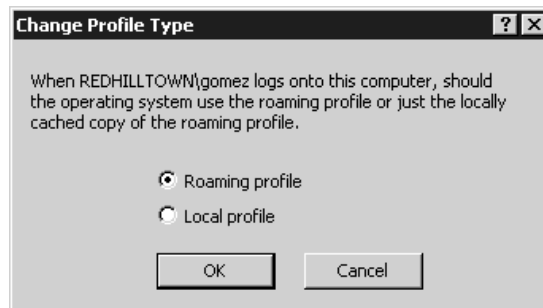

If there *is* a profile path specified for her account, however, the system looks in that path for the profile directory. If the profile exists, the Desktop loads it and uses it to make a local copy. This may be a roaming or a mandatory profile. If there is no profile in the specified path and a roaming profile is specified (`\\SERVERNAME\SHARENAME\USERNAME`), the workstation will make one using a copy of the `Default User` folder. Again, for a Win2K/Server domain logon, the system first checks in `NETLOGON`. If no `Default User` directory is found there, the system creates Morticia's profile from the local `Default User` directory. If no profile exists in the path and the path was indicated as mandatory, the user will not be allowed to log in at all!

So far, so good. Now let's tackle Gomez, who has been using his workstation for a few weeks already. If no profile is specified in his account information, nothing changes for Gomez. He continues to use his locally stored profile.

On the other hand, if by chance you decide to implement roaming profiles one evening or weekend and Gomez comes in the next morning and logs in, his workstation has to check a few things. First, if a profile path exists in the account info, his workstation must first check to see if Gomez has changed his roaming profile type back to local. Aha! You see, Gomez might have grown tired of waiting for his roaming profile to load off the server and decided to tell his workstation not to bother, to just use the local copy all the time. He can do this by opening the System applet and the User Profiles tab, selecting his own profile, and choosing Change Type. Gomez then sees the dialog box shown in Figure 9.103. Gomez could not do this if the profile was mandatory, and of course, you cannot change a local profile to a roaming profile unless you are changing it *back* to a roaming profile.

**FIGURE 9.103**

Changing a user profile from roaming to local

Any user may change an unrestricted roaming profile back to a local profile. On NT 4 systems, the user may also choose the option to automatically Use Cached Profile on Slow Connections. If Gomez checks that box, he's saying to his operating system, "If there is a slow network connection, just go ahead and load my local copy and don't bother me." What qualifies as a slow connection? That depends on an interval set in the Registry, called `SlowLinkTimeout`. The default interval is two seconds. Generally, if the two-second interval is exceeded, Gomez will see a dialog box stating that a slow network connection has been detected and asking whether to load the local or the roaming profile. By default, Gomez has 30 seconds to choose (that value is determined by a Registry entry called `ProfileDlgTimeout`), after which time the system will load the local profile. But if Gomez enables the Use Cached Profile on Slow Connections option, the workstation will automatically load the local profile without asking Gomez. Hmmm.

The Registry entries affecting detection of slow network connections are found in `HKEY_LOCAL_MACHINE\SOFTWARE\MICROSOFT\WINDOWS NT\CURRENTVERSION\WINLOGON`. All of the following values can be set using the System Policy Editor and Group Policy Administrative Templates:

**SlowLinkDetectEnabled** Has a data type of `REG_DWORD` and possible values of 0 (disabled) or 1 (enabled). Slow-link detection is enabled by default, and the system is told to be aware of slow network connections.

**SlowLinkTimeout** Has a data type of REG\_DWORD and a default value of 2000 (2 seconds expressed in milliseconds). Possible values are 0–120,000 (up to 2 minutes). When this threshold is exceeded and **SlowLinkDetectEnabled** is set to 1, users can log in by using a local profile instead of the roaming profile.

**ProfileDlgTimeout** Has a data type of REG\_DWORD and a default value of 30 (expressed in seconds). This value determines how many seconds a user has to choose between a local or server-based profile when the value of **SlowLinkTimeout** is exceeded.

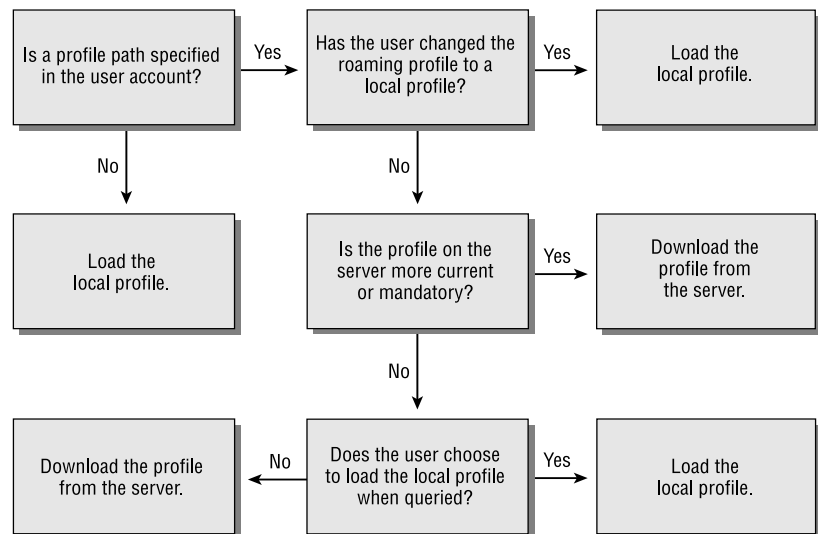

Assuming that there is no slow network connection and assuming Gomez has not changed his roaming profile back to a local profile (he hasn't had a chance yet, right?), the system will check to see whether (1) the profile is mandatory or (2) the profile on the server is more current.

If either (1) or (2) is true, the system will load the server copy. If neither is true, then Gomez gets a pesky dialog box. You see, if (2) is not true, then the profile on the server is not more current than the local copy. This implies that there was a problem in synchronizing the profiles the last time Gomez logged out. So the operating system will announce that the local profile is more recent than the network profile and will ask if Gomez wants to load the local instead.

Whew! That was a bit complex, so maybe the following flow charts will help. Figures 9.104 and 9.105 describe Morticia (new user to the workstation, with local profile and roaming profile), and Figure 9.106 follows Gomez (an existing user with locally stored profile). Finally, I've thrown in Figure 9.107 to show how a user's profile is saved at logoff.

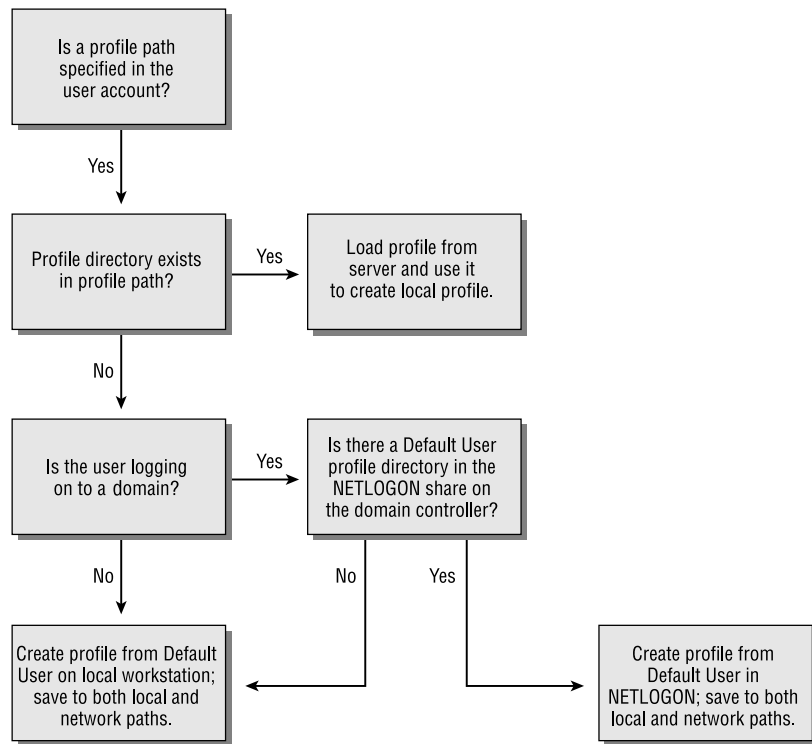

**FIGURE 9.104**

How a new user gets a local profile

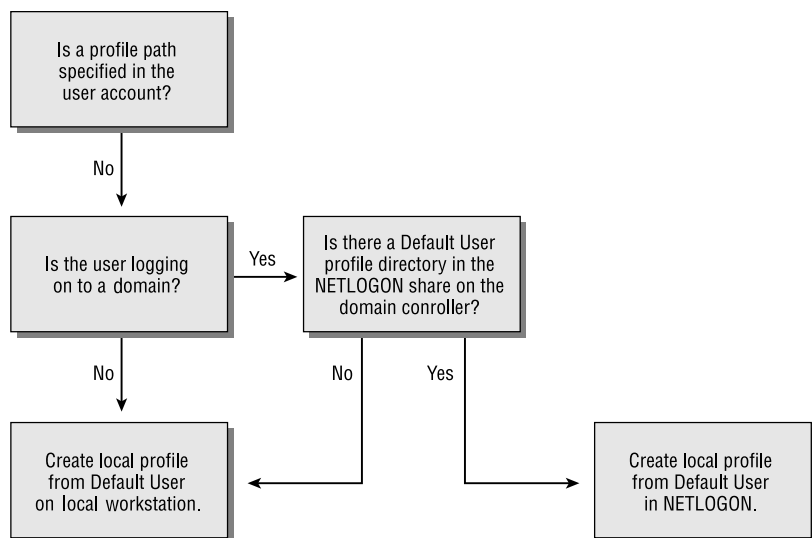

**FIGURE 9.105**

How a new user gets a roaming profile

## Which Type of Profile Is Right for My Network?

Now that you are a Microsoft user profile guru, you'll need to decide what kind of profiles to implement on your network. Even if you do nothing, you are still making a choice to let users just keep local profiles. To help you decide, the following paragraphs summarize the pros and cons of the different types of profiles:

**Local profiles only** Local profiles may be the best choice in a mixed client environment or where users don't need to roam. Windows 9x profiles are not interchangeable with NT/2000/XP Workstation profiles, though the Desktop is similar, so users moving from one client OS to another need *either* local profiles only *or* two roaming profiles. (Do you feel a migraine coming on?) This option has the lowest administrative overhead and offers the fewest options for preconfiguring profiles and controlling Desktops. However, you can still use System Policy Editor and group policies (for 2000 and XP systems) to configure Desktops and impose restrictive policies without implementing roaming profiles.

**Roaming profiles** A roaming profile has two major benefits: mobility and fault tolerance. Not only can users move from Desktop to Desktop and have their preferred settings follow them, they

also have a “backup” of their profile stored on the server. If you have to reinstall the workstation, the user doesn’t necessarily have to reconfigure the Desktop. Plus, you can let the workstation create the profile for you as long as there are no special settings to hand out to users.

This is also the option to use if you want profiles to be centrally located and controlled. The downside is that roaming profiles may follow you to another machine but may not work flawlessly once they are downloaded. Shortcuts to applications that exist only on the user’s “home workstation” and different display capabilities are only two of the possible problems users may encounter. Also, roaming profiles shooting across your Ethernet every time a user logs in or out will generate more traffic and slow down user logons. If it’s a consideration at 10 and even 100Mbps, think of the problems if you have an ISDN connection at 64Kbps.

Finally, remember that NT, 2000, or XP will store a local copy of the profile for every user that logs in to a given machine. If users roam and roam and roam, they leave copies behind, taking up hard drive space as well as presenting a security issue (my Desktop may have a few items on it I don’t want to leave behind). To address this problem, set up the machines to delete cached copies of roaming profiles.

**Mandatory profiles** Mandatory profiles, because they are also roaming profiles, have the benefit of being mobile and fault tolerant. They can also be centrally located and controlled, like roaming profiles. Plus, mandatory profiles are the only way you can force a user to load a particular profile. Because it is read-only, users can share a profile; you keep fewer profiles stored on the server instead of one for every single user. While mandatory profiles offer more control than roaming profiles, they also require more setup on your part. You must manually create a mandatory profile and place it in a network path; the operating system can’t create a mandatory profile for you. Finally, if a user attempts to log in and the mandatory profile is unavailable, NT, 2000, and XP systems will not allow the user to log in. This prevents a malicious user from logging in with the Default User profile and running amok, but it can also be a drawback if a legitimate user cannot log in and perform their job.

**Network default user profile** One of the best things about a domain-wide Default User profile is that it can be implemented in conjunction with roaming profiles. This offers a great way to preconfigure all new user profiles, and although it does not help you hand out special program groups to, say, the accounting department, it can be used as a point of departure. You can use the NT or Windows 2000 System Policy Editor and group policies to hand out custom Start menu items to group members. However, if you place heinous restrictions on the Default User profile in the NETLOGON share, you’ll have to create a special roaming profile and assign it to folks who shouldn’t get the restrictions (such as new MIS employees).

### IMPLEMENTING USER PROFILES: AN EXAMPLE

Let’s see what you’ve learned by looking at a sample situation and determining the best way to use profiles.

Suppose you manage several computer labs at a university, and each lab has 35–100 NT 4, 2000, or XP workstations. Up to 10,000 students at the university, who all have accounts on the university-wide system, visit various labs using various machines. A few students cause problems in the network. Some of these students are malicious, while some are just inexperienced. If you stand by and do

nothing, users will leave profiles behind when they log out. You'll have to periodically delete profiles. If you allow users to have access to all possible tools on the Desktop, administrative overhead increases as you troubleshoot problems and reinstall the OS on the workstations.

### **Solution #1: Preconfigure a Domainwide Default User Profile**

With this solution, you may have to create more than one Default User profile if user accounts are in multiple domains. Restrict profiles as necessary, assign roaming profiles, and configure systems to delete cached copies of roaming profiles using System Policy Editor, the Resource Kit utility `DELPROF.EXE`, or Group Policies.

***TIP** Actually, there is a very simple solution to the local profile detritus problem. Rather than going to the trouble of setting up a policy to delete cached copies of roaming profiles, editing the Registry of every machine, or running `DELPROF.EXE` at regular intervals, you can make every user a guest at the local machines in the lab. Although this approach has several other implications that might make it unfeasible for your situation, it would take care of profile buildup. Members of the Guests group are not allowed to keep local profiles unless they are also members of the Users group.*

This solution poses one very big problem. Even if users have restrictions placed on the profile, with roaming profiles for every user, the network servers will hold thousands of copies of the very same profile. Not only that, but savvy users may be able to change their own Registry settings and break free of restrictions.

### **Solution #2: Create a Shared Mandatory Profile**

A better solution is to create a restricted profile directory, name it `USERS.MAN`, rename the hive file to `NTUSER.MAN`, and assign this as a shared mandatory profile to all users. You'll still need to delete cached copies of roaming profiles, but this way, even if a user manages to edit the Registry settings to remove the restrictions, changes will be discarded at logoff. You also save space on the network servers.

***WARNING** There is one possible problem with this solution, if you're still using NT 4: If many students try to download the mandatory profile at exactly the same time, they may experience sharing violations (NT 4 Service Pack 2 fixed this problem, though).*

### **DISTRIBUTING USER PROFILES**

You may also want to keep several copies of the mandatory profile (for example, one on each domain controller) for load balancing. There is a way to distribute user profiles across domain controllers using the environment variable `%LOGONSERVER%`: create a share of the same name on each DC, copy the mandatory profiles into each of the shared directories, and then indicate the profile path in account properties as something like `\\%LOGONSERVER%\PROFILES\USERS.MAN`. To prevent major profile synchronization problems, don't use this approach with regular roaming profiles; use it only with mandatory profiles.

If you don't want to store profiles on the DCs, you can tell the workstation where to look for the mandatory profile by creating a new environmental variable on each of the workstations. The new environmental variable will be `%PROFILESERVER%` and will point to the local lab server keeping the mandatory profile.

### HOW DO I MAKE USERS LOAD PROFILES FROM LOCAL SERVERS?

Use the System applet's Environment tab to set a system variable pointing to the local server, as shown in the following System properties sheet. Fill in the information as shown. In this case, the local lab server will be LAB01UMDCP. (Do not include % signs or \\ as part of the variable.) Choose the Set button and click OK. The new variable will be set, but you will need to restart the computer before these settings take effect (since the operating system reads the system variables at startup).

Once you have defined the %SERVERNAME% variable on each of the workstations (REGINI.EXE, a command-line Resource Kit utility, can be pretty handy for that type of thing), created a share of the same name on each profile server, and copied the mandatory profiles to those shared directories, you can then indicate the profile path in the user's account properties as \\%PROFILESERVER%\PROFILES\USERS.MAN.

### Comparing Windows NT 3.51, NT 4, and 9x Profiles

As described in the preceding sections, there's a lot that can be done with NT 4, Windows 2000, and XP user profiles in an NT/Win2K/Server 2003 environment. However, in case you are still managing legacy client systems, let's round out our discussion with a quick rundown of the differences between NT 3.51, NT 4, and Windows 9x user profiles. The important thing to keep in mind is that Windows 9x, NT 3.51, and NT 4 profiles are not cross-platform profiles. In other words, a user who requires a roaming profile and customarily sits at several types of legacy workstations would need a separate profile for each type of client.

### NT 3.51 PROFILES

In NT 3.51, each user profile is a single hive file (found in %SYSTEMROOT%\SYSTEM32\CONFIG), and profiles are stored with the rest of the systems' Registry hive files. Instead of a bunch of folders and a hive file, everything is included in the one file. NT 3.51 supports per-user profiles (equivalent to roaming profiles) and mandatory profiles. The profile path for an NT 3.51 personal profile would be specified as \\SERVERNAME\SHARENAME\USERNAME.USR in the user account properties, and for a mandatory profile it would be \\SERVERNAME\SHARENAME\FILENAME.MAN.

Because there was no System Policy Editor under NT 3.51, options for restricting profiles were very limited. NT 3.51 did provide a tool called User Profile Editor (UPEDIT.EXE), which allowed you to log in as your bogus user, configure the Desktop, and save a configured profile with a skimpy set of restrictions to the current user or system default. This was also the tool used to save the profile to a specified path when implementing per-user or mandatory profiles.

NT 4 profiles are entire directories, like the Windows 9x profile structure. NT 3.51 per-user profiles were simply files. NT 3.51 profiles will be converted to NT 4 profiles when upgrading from 3.51 to NT 4. NT 3.51 profiles formerly named USERNAME.USR, for example, will be converted to a directory called USERNAME.PDS. Likewise, mandatory profiles named USER.MAN will be converted to a directory called USER.PDM. New profile directories created on upgraded machines will not carry this special extension. If a user is working in a mixed environment, however, she will have a separate profile for each OS, and they will not be synchronized (changes made to one won't show up in the other) if changes are made after the initial migration.

### Windows 9x Profiles

In Windows 9x, individual profiles are not created by default but must be enabled in Control Panel/Passwords. If roaming profiles are enabled on the Windows 9x machine, they will be stored automatically in the user's home directory. You need not specify a profile path for the user in Active Directory Users and Computers. Otherwise, Windows 9x profiles operate in the same way as NT/2000/XP profiles.

Individual mandatory profiles can be used in Windows 9x, but shared mandatory profiles cannot. For this reason, the administrator must create a profile for each user and copy it to that user's home directory.

The structure of a Windows 9x user profile contains differences from an NT, 2000, or XP user profile. Instead of an NTUSER.DAT file, Windows 9x has a USER.DAT file. Instead of NTUSER.DAT.LOG (the log file that stores changes to the NTUSER.DAT file), Windows 9x uses a file called USER.DA0. These two files are not exact equivalents. Windows 9x uses USER.DA0 as a "backup," writing a copy of USER.DAT to USER.DA0 every time the user logs out. NT 4 (and 2000 and XP) uses NTUSER.DAT.LOG as a transaction log file to protect the hive file while it is being updated. To create a read-only mandatory profile, rename the 9x USER.DAT file to USER.MAN. NT 4 and Windows 9x use basically the same folder structure, except that the Application Data folder does not exist in Windows 9x.

Additional differences in Windows 9x profiles include the following:

- ◆ Not all Desktop items will roam; only LNK (shortcuts) and PIF (program information) files will.
- ◆ Common program groups aren't supported in Windows 9x.
- ◆ Windows 9x can't use a centrally stored Default User profile.

**NOTE** If you're still supporting NT 4 and Windows 9x clients, then don't skip the chapter on the CD about system policies for NT and 9x clients!

## Chapter 10

# Managing Windows Server Storage

WHAT IS “STORAGE,” YOU ask? Well, if terms like *pagefile*, *master file table*, *partition table*, and *clusters* make you shudder because they remind you of how much you *don’t* know about what goes on beneath the operating system, stick with me through this complex but incredibly important chapter. Here, I hope to make the concept of storage one more piece of the puzzle that you *do* know.

Basically, when someone refers to storage in a computer environment, they are talking about hard drives, the file systems on those drives, and what you can do with those file systems to organize your data so that it is easier to manage. In this chapter, I’ll cover everything you need to know about how Server 2003 views and uses the physical hard drives that you put into your servers, and what you can do to help manage the files that you store on those drives.

Remember that whether your Server 2003 is a print server, an e-mail server, a Web server, or any kind of server you can think of, it’s still in many ways a file server. No matter what kind of resources a server is providing to the network, the server has to store a lot of files to support those resources.

Having lots of files means a lot of storage, and a lot of storage means maintaining it. In this chapter, I’ll talk about the tools Server 2003 includes to help you manage and maintain your disks and other storage media. With NT 4, this mostly meant the Disk Administrator. I’m going to start with The Tool Formerly Known As The Disk Administrator (which became the Disk Management tool in Win2K), but there’s a lot more to it than that. Encryption, new disk formats, disk quotas, and Remote Storage were introduced in Win2K, and some of these features have even been improved upon in Server 2003. There are also some useful new features that Server 2003 gives us to make our lives even easier.

One of these new features, Volume Shadow Copy Service, which was introduced in XP and is available in Server 2003, could make the sysadmin’s task of restoring users’ lost files a thing of the past. You can now extend basic disks in Server 2003, and Microsoft has made the job of recovering from a failed mirrored system disk much easier. No more editing the `boot.ini`! Server 2003 now offers support for Storage Area Networks (SAN) and has added open file backups to complete the package. You can also now defrag the master file table in Server 2003, and there is a really cool new command-line utility that will allow you to manage your disks as well as—in some ways, even better than—the GUI will allow, including the ability to script disk management for your unattended installs. If your eyes are glassing over and you are thinking that this might be the chapter to skip, stay tuned as I make all these terms part of your sysadmin vocabulary. My hope is that you’ll be a storage expert by the time you get to Chapter 11.

## The Basics of Disk Management

Let's start off with some of the basics of disk management and a little history. I'll begin by defining some of those terms you may not be familiar with, like partitions and logical drives, and once you have the vocabulary, I'll begin to show you how you can manage your storage issues with Server 2003.

### Disk Management Terminology

Before we get into the discussion of how you can use the Disk Management tool to arrange and protect your data, you need to know some of the terms that I'll be tossing around. These terms will be explained further in due course, along with how to use the tools in Server 2003 that relate to them, but this section will give you a basic level of understanding until then.

#### PHYSICAL DISKS VERSUS LOGICAL PARTITIONS

To understand disk management, you must understand the difference between physical disks and logical drives or partitions. A *physical disk* is that contraption of plastic and metal that you inserted in your server's case or have stacked up next to it. The Disk Management tool identifies physical drives by numbers (Disk 0, 1, 2; CD 0, 1, 2) that you cannot change.

**NOTE** *If you have multiple disks in your computer, they're numbered by their status on the drive controller. For example, in a SCSI chain, the disk with SCSI ID 0 will be Disk 0, the drive with the next SCSI ID will be Disk 1, and so on. The SCSI ID and the disk number are not directly related and will not necessarily match—the only correspondence lies in the disk's priority in the system.*

You cannot change the size of a physical disk. The size given to it when it was low-level formatted (something you almost certainly don't have to worry about if you're installing Server 2003 on the disk—you can't low-level format an EIDE drive and don't need to low-level format a SCSI drive—it's done before you buy it) is the size the drive will remain. So, in short, a physical disk is a solid piece of hardware with a fixed size and, once physically installed, the Disk Management tool will recognize it and allow you to assign it a drive letter or mount it to a path on an NTFS volume. Wondering what it means to mount a drive to a path? I'll cover that in a moment.

In contrast to a physical disk, a *partition* or *volume* or *logical drive* is a method of organizing the available space on the physical disk (or disks) that the Disk Management tool has identified in your system. Once you have created these partitions using the Disk Management tool, they will act as if they are separate physical disks. Even if you want the physical disk to be one big partition, you still have to create *one* partition on the disk in order for it to be utilized by the operating system. You can change drive-letter assignments and adjust the size of these logical partitions (since they have no physical presence) with the Disk Management tool. A logical partition can be part or all of a physical disk or even, in the case of volume sets, mirror sets, and stripe sets, can extend across more than one physical disk. I'll talk more about these sets when I talk about RAID. For now, let's look at how you actually create these logical partitions.

#### WHAT IS AN EXTENDED PARTITION, ANYWAY?

When I talk about *partitions* or *volumes* or *logical drives*, I am really talking about the same thing from about a thousand feet in the air. When you zoom in and look more closely though, there are differences in how you can divide up your disks. There is a file that resides on the physical disk called a disk

partition table, which is where the OS keeps track of how the physical disks are logically divided. For now, we'll stick with the basics and say that the partition table can only describe four partitions, because each description is 16 bytes and the partition table file is 64 bytes. Since you only have four partitions, there are a limited number of ways in which you can divide up this logical structure. Only one of these four can be designated as "active" at any time. This is the partition to which the OS will boot. You can have up to four primary partitions or three primary partitions and an extended partition, which itself can have multiple logical drives; this helps to overcome the four-partition limit. Now that you have an idea of how you can logically divide disks, let's talk about the way you look at the available space on the disk.

### FREE SPACE VERSUS UNALLOCATED SPACE

The definition of *free space* seems obvious: "Free space on a disk is just space that's free, right?" It's not. Free space does not refer to unused areas within established drives. Rather, *free space* means an extended partition that doesn't yet have any logical drives in it, or that the space within that partition is not yet divided into a logical drive.

This definition of free space is different from the one used in NT 4 and previous versions, where free space was space on a disk that was not part of a volume. Disk space formerly called free space is now called *unallocated space*. It's not committed to be part of any volume or partition. Both basic and dynamic disks may have unallocated space. I'll talk more about basic and dynamic disks, a new way to look at storage that was introduced in Win2K, once we get through the basics.

### MASTER BOOT RECORD

Each disk needs to share a "starting point," a place where critical information about the disk can be found. Information such as the number of and type of logical divisions that exist on the disk needs to be relayed to the system when it boots. And, of course, there must be a place in which the BIOS can store the initial boot program that actually begins the process of loading the OS. This is called the *master boot record* (MBR).

### PARTITION TABLE

Located within the MBR, this file describes the logical divisions on the disk. It has enough room to account for four partitions, only one of which can be *active*, which means that the OS can boot from that partition.

### MOUNTED DRIVES

The Disk Administrator you used with previous versions of NT identified each logical disk volume by a drive letter. This method is simple and has the advantage of making a really short way of leaping to that partition: you type the letter representing it. The disadvantage, of course, is that so long as Server 2003 insists on using the Roman alphabet, you're limited to a total of 26 letters for all local drives and mapped network connections. It also means that it is not possible to add more space to an existing logical drive. To get around these limitations, Server 2003 supports mounting volumes to empty folders on NTFS volumes. Mounted volumes work *only* with NTFS, because they depend on some attributes not found in FAT or FAT32. However, they work with both basic and dynamic disks.

The basic idea of mounting a partition to a folder is that you're redirecting to the partition all read and write requests sent to that folder. Mount a new partition to X:\Mounted Fo1der and every file I/O

request you send to `X:\Mounted Folder` will be rerouted to the new partition, even if the original drive X: is on a different physical disk entirely. You can mount a volume to as many paths as you like. The only restrictions are that the folders must be empty at the time of mounting, not mapped to any other volumes, and on NTFS volumes on the local computer. NTFS 3.1 is the only filesystem format that Server 2003 supports that can use the reparse points that redirect path information.

The mounted volumes show up as drives in the path you mounted them from, instead of folders, as you can see in Figure 10.1. The User Data folder you see here is actually mounted to a different drive. The user doesn't know where the data is actually being written once he saves his files to User Data.

**FIGURE 10.1**

Mounted volumes within a folder

Why bother with mounting volumes to NTFS folders? There used to be three reasons, but improvements in Server 2003 leave us with two. First, it means that you're in no danger of running out of drive letters for local and network partitions. Mounted drives render the 26-letter limitation irrelevant.

Second, you can use this technique to create a fault-tolerant area on a non-fault-tolerant volume. That 2GB volume you created can be a stripe set with parity or a mirror set, even if the disk containing drive X: is a basic disk and therefore does not support fault-tolerant volumes. For example, you could create a new folder on drive X: called `Home Directories`, then mount a RAID volume to that folder. Whenever someone saves a file to any subfolder of `X:\Home Directories`, it'll go to the RAID volume even if the rest of drive X: is *not* fault tolerant. Don't worry if you are unclear about the definition of fault tolerance—I'll cover that concept in a minute.

**NOTE** Until recently, mounting a volume to an NTFS folder was the only way that you could effectively enlarge a volume on a basic disk by creating a little breathing room elsewhere, since a limitation in Win2K meant that there was no way to actually enlarge a basic disk. Until the release of XP (and now with Server 2003), you could only do that with dynamic disks. For example, say that drive X: was running short of room on a basic disk using Win2K. You couldn't make drive X: any bigger. Instead, you could add a new disk, create a 2GB volume on that disk, then map the new 2GB volume to an empty folder on drive X:. Drive X: would now be, in a circuitous kind of way, 2GB larger. It was okay for a workaround, but life is much improved with the advent of the cool and slightly dangerous command-line tool called *DiskPart*. I'll go into more detail on it once I fill you in on the concepts of using basic disks in Server 2003.

Incidentally, volume mappings are transparent to the user. The user doesn't have to care whether drive X: is on the computer where he's working or on a file server in a different physical location or whether the folder he's saving to is located on the same physical disk as the rest of drive X: or on another disk altogether. You can also mount a drive to multiple paths or both mount it and assign it a drive letter.

Experiment with mounting drives to NTFS paths. Although this feature was introduced in Win2K, I am amazed at the number of people who haven't started using them. They are a really cool addition to Windows storage capabilities.

### FAULT TOLERANCE

I read recently that on the space shuttle there exist two pairs of identical computer systems. As long as the first pair is communicating and performing according to programmed expectations, the other pair is never used. If, however, some stray cosmic ray affects the performance of the first pair, the other pair automatically chimes in and takes over the job of the original, faulty pair. And, just in case, there is a fifth computer on board which is programmed to the exact specifications of the first two pairs but by different programmers who work for a different company, using different code. That fifth computer doesn't failover automatically though. It has to be done manually by the astronauts. Now, *that* would have to be a tense moment! Knowing this, I have to say I will no longer feel quite the same tension when undergoing what I, until now, had classified as a *dangerous operation* in the machine rooms that I have worked in. This is a great example though, of what I'll be referring to as *fault tolerance* in this chapter. What fault tolerance really means is the ability for either software or hardware to withstand some amount of failure and still persist in doing its job, like flying our astronauts home safely.

Now that you have the basic idea of what fault tolerance is all about, I'll get a bit more specific. In this chapter, I'll be going over the details of software fault tolerance available in Server 2003. Server 2003, like its parents, and even its grandparents in the Windows Server family, has the ability to provide a certain level of software fault tolerance. Of course, software fault tolerance has its limitations, which I'll discuss soon.

### SLED

An acronym for *single large expensive drive*, SLED is a way of arranging your data on one very large, very (I hope) reliable drive. SLED was, as history has it, a popular method of arranging data for two reasons:

- ◆ It's simple. You only have to buy one disk and store your data on it.
- ◆ Dedicated RAID hardware was expensive in the past. And even though it's not nearly as expensive as it used to be, it still reflects an added cost.

Trouble is, if that one very large and very reliable drive fails, then your data goes with it. That's where RAID comes in.

### RAID

"Apply a shot of RAID, and all those nasty data problems will be gone!" No, it's not really a household product. RAID (Redundant Array of Independent Disks) is a method of protecting your data by combining or copying the space on hard disks to improve disk fault tolerance and/or data throughput.

As I said before, fault tolerance can be provided through both hardware and software solutions. Here I'll concentrate on the software side, but the RAID definitions are the same either way.

There are many levels of RAID implementation, each of which works in a different way and has different applications and benefits. Most of the discussion of RAID in this chapter will focus on its fault-tolerance attributes. Server 2003 supports levels 0, 1, and 5, also known as striping without parity, disk mirroring, and striping with parity, respectively. I'll talk about exactly what these *mean* in the next section.

**NOTE** RAID isn't always redundant (another word for fault tolerant). RAID level 0 (disk striping without parity) isn't fault tolerant because it contains no redundant data to help you re-create lost data, as you'll see in a minute.

## Understanding RAID in Server 2003

Server disks must be faster, more reliable, and larger than their workstation-based cousins. How do you achieve those goals of speed, reliability, and size? Well, there's always the simple answer: Spend more money for a drive with more of those three characteristics. But there is another solution: a group of drives can band together and, acting in concert, provide speed, capacity, and fault tolerance. This solution is called *Redundant Array of Independent Disks (RAID)*. Until relatively recently, putting RAID on your server required buying an expensive hardware-based RAID system. However, this changed with Windows NT, was improved in Win2K, and the improvements continue in Server 2003. With the Disk Management tool in Server 2003, you can take a bunch of hard disks and "roll your own" RAID system. This doesn't make hardware-based RAID obsolete by any means, since hardware RAID is still both more flexible and reliable than its software cousin. (And it's a heck of a lot easier on your computer—some software RAID can be ruinous to computer performance.) Software RAID just offers a less expensive option for those who want this kind of data protection but can't afford hardware RAID solutions. Let's talk a bit more about the differences between software and hardware RAID.

### HARDWARE OR SOFTWARE RAID?

Software RAID is simple to set up and, if you own an operating system that supports it, you can experiment with RAID at no additional cost other than for the drives needed to support your chosen RAID model. However, for serious applications it's wanting. Here's why:

**Accessibility** Server 2003 RAID volumes are invisible to any operating system other than itself. Even NT can't read these RAID volumes, since they require the use of dynamic disks, which Windows NT has never heard about.

**Recovery time** You've got a mission-critical system up and running, and one of the four drives in a stripe set with parity goes to The Land Where Hard Drives Are Eternally Blessed. Your next move is to bring the server down, replace the bad drive with a new good one, and then reintegrate the new disk into the stripe set in order to keep the data fault tolerant. You must do this as quickly as possible, because the data is no longer fault tolerant and, according to Mark's Law of Disk Injustice, the more you are dependent on those disks, the greater the likelihood that one of them will fail. To do this, however, you must bring down this mission-critical server while you take out the old drive, install a new drive, and put the stripe set back together. We're not talking about a two-minute fix here. Imagine this happening on the space shuttle *Atlantis*!

In contrast, you could buy a *hardware* RAID system: a box containing several drives that are coordinated by a separate controller to act as one, which looks to the Server 2003 system like just one drive. An external RAID box costs a bit more, but a hardware-based RAID system can rebuild itself faster than software RAID. And best of all, most hardware-based RAID systems allow you to hot-swap the bad drive—that is, you can replace the bad drive without bringing down the server.

**Management** Software RAID volumes use individual disk partitions grouped to create a single RAID partition, which can complicate management—with software RAID and three disks, you can set up three parallel RAID 5 partitions, each requiring its own parity calculations that stress the server. Hardware RAID generally treats disks as single-partition entities and the separate controller does the calculations, which takes the stress off of the main processor.

Most people who use Server 2003's built-in RAID use its mirroring capability, since the processing required to support RAID 5 seriously degrades server performance. However, if you're serious about data protection for Server 2003, you'll probably consider using hardware RAID, preferably one of the more advanced sorts, which offers its own processor and the ability to hot-swap failed disks.

## Basic Disks versus Dynamic Disks

Server 2003 supports two kinds of disk storage: dynamic and basic. Aside from the structural differences in the way that information about the disks is stored on the disk itself, there are some pretty large differences with regard to software support and the amount of disk flexibility that each has to offer. In terms of support, any OS can detect a basic disk, even if it can't read the logical volumes on that disk. Only Win2K and Server 2003 can detect dynamic disks, however, and although there are strict limitations on how you can install the OS on a dynamic disk, you must use the new disk structure if you want to use multidisk volumes like RAID.

For logical volumes, Microsoft uses the term *partition* when you are using basic disks and *volume* when you are using dynamic disks, but if I say “partition” or “volume” or “logical drive” throughout this chapter, I'm speaking of generally the same thing: a way of making some logical sense out of physical disk space.

### BASIC DISKS

When you install Server 2003 and create the first partition on which you will install the operating system, the disk defaults to a basic disk. Basic storage is the kind of storage that has been around since the DOS days, allowing for primary and extended disk partitions and logical drives. Basic disks use a partition style called master boot record (MBR). The MBR lies in the first sector of a basic disk, as does the partition table. These files hold critical information relating to the disk structures on that disk, including the starting and ending sectors, total number of sectors, and partition and RAID information. This is the kind of storage that I have been talking about throughout this chapter. Server 2003 still supports this kind of storage, although some of the functionality of Server 2003 can only be garnered if you are using dynamic disks, which I'll talk about in the next section.

If you're upgrading from NT 4 to Server 2003, then the basic disks which currently reside on your NT 4 system may include the mirror sets, volume sets, and stripe sets that you created using NT 4 Disk Administrator, using a basic disk type of storage available in the former OS. Unfortunately, there is no support for these outdated structures in Server 2003, so any mirrored, volume, or stripe sets that exist on an NT 4 server must be wiped out before you upgrade to Server 2003. If you don't

do this, Server 2003 will render them unreadable during the upgrade and you will lose your data. The only way you can utilize mirror sets, volume sets, or stripe sets in Server 2003 is by using dynamic disks, and they have to be created after the install. Yes, there *was* limited support for upgrading these structures from NT 4 to Win2K, but that ability has been removed in Server 2003.

**TIP** *Of course, if for some reason you end up having to come face to face with an angry ex-NT 4 system which has been upgraded to Server 2003 before the old disk structures were removed, there is a handy tool that will at least allow you to recover the data from those drives. It is a command-line tool called `ftonline`, and it's available in the Support/Tools folder on the Server 2003 CD.*

Basic disks have their limitations. For compatibility reasons, they conform to the four-partition limit imposed by the structure of the disk partition table. Remember? It has a 64-byte file in the first sector of any disk that lists the physical locations of any logical partitions on the disk, but it can only describe four partitions because each description takes up 16 bytes. Of course, this type of storage will probably remain the most commonly used storage because, since an installation or boot of the OS requires the old-fashioned partition table entries in the MBR disk style, it is not always the best decision to upgrade to dynamic disks, nor is it always possible.

### DYNAMIC DISKS

Dynamic disks were first introduced in Windows 2000 and are not supported by any Windows operating system prior to Win2K. They are still present in Server 2003, so if you want to use any kind of fault-tolerant or multidisk volumes, then you'll need to use dynamic disks.

Dynamic disks work together in Server 2003 in logical units called *disk groups*. You'll learn more about disk groups later, when we start really playing with dynamic disks in the section called "Using Dynamic Disks." For now, let's talk about what *dynamic disk* really means. Remember the partition table and the master boot record? When you make a disk dynamic, you are replacing the contents of the partition table (you know, all that critical disk information about the disk and the partitions) with a single entry which basically means, "Go read the dynamic disk database to get my partition information because *I* am a dynamic disk."

When you create a dynamic disk, you're writing a 1MB database of information at the end of that disk volume. This database contains all the partition information for each of the dynamic disks in the server. One of the nicer features of dynamic disks is that the information in that 1MB file is replicated to all the other dynamic disks in the system. The contents of the database on each disk are identical. (The changes are time-stamped, so that if a disk happens to be missing for a while, the newer changes will be automatically replicated to the disk when it returns, without any intervention on your part.) This is a big advantage over basic disks, which have a real single point of failure when it comes to all that critical information needed to maintain the integrity of the disk. If anything happens to the first sector of a basic disk, you will be hard pressed to recover from it. "Ah, *now* I know what they mean when they talk about a corrupted boot record," you'll say! If you import a "foreign" disk (a disk belonging to another dynamic disk array on another computer) to the mix, then the database entries in the existing array are copied to that new (foreign) disk, and any entries on the foreign disk are copied to the database of the disk array you're importing the disk into. In other words, importing the foreign disk merges the two databases because, if the task of importing a disk simply overwrote that foreign disk's database, it'd lose any existing volumes, and that wouldn't be very effective.

When you upgrade a basic disk that already has partitions on it (as the system disk will) to a dynamic disk, you'll have the original partition table to deal with. The contents of that table are copied to the database. The rest of the disk is then reserved for new volumes that will be recorded *only* in the database, not in the partition table. What that means is that there is a difference in the way volumes on a dynamic disk are viewed, depending on whether they were created *before* or *after* the conversion to dynamic.

When you boot a computer with dynamic disks in it, the BIOS reads the partition table, looks for the active partition, and reports the boot partition to work from. Finding the operating system, it goes through the boot process described in Chapter 19, "Preparing for and Recovering from Server Failures." The drivers for supporting dynamic volumes—DMLoad, DMAAdmin, and (if the volume is a boot volume) DMBoot—are loaded early in the process of loading all Server 2003 drivers.

Remember how I said that you will need to use dynamic disks in order to use multidisk volumes with Server 2003? Does that mean that you should *always* upgrade disks to dynamic? The answer is no—not even Microsoft thinks dynamic disk are the right answer all of the time. In multidisk systems, dynamic disks can be very useful, but think hard about upgrading a disk before doing it. Dynamic disks are visible only to Windows 2000 and later versions of Windows. They're incomprehensible—in fact, invisible—to any locally installed operating system other than Win2K, XP Professional and Server 2003. Additionally, although you can revert a dynamic disk to a basic disk, you can only do this if the dynamic disk doesn't have any volumes on it. If you upgrade a basic disk that already has data on it to a dynamic disk, you'll have to delete the volumes on which that data is stored (and thus delete the data) before you can revert the disk to basic.

In short, to create new fault-tolerant volumes or multidisk volumes, you'll need to upgrade your disks to dynamic. If you need local compatibility with other operating systems, then stick with basic disks. If you've only got one disk in the server and don't plan to add more, you might as well leave it basic and save yourself the 1MB of space that the dynamic metadata would use, because dynamic disks have no benefits in single-disk computers.

**NOTE** *Dynamic disks are not supported on laptops. See the later section "Not All Disks Are Upgradable" for the details.*

## **DIVIDING BASIC DISKS**

The ways in which you can arrange the space on a physical disk are dependent on whether the disk is basic or dynamic. Basic disks support three kinds of organizational divisions: primary partitions, extended partitions, and logical drives.

### **Primary and Extended Partitions**

Earlier in this chapter, I gave you a general idea of what partitions, logical drives, and volumes are—now I'll go into a little more detail about partitions and logical drives. I'll discuss volumes when we get to the topic of dynamic disks.

A *partition* is a portion of a hard disk set up to act like a separate physical hard disk, rather like splitting a single physical hard disk into several logical drives. There are two kinds of partitions: primary and extended.

A *primary partition* is a portion of a physical hard disk that the operating system (such as Server 2003) marks as bootable. Under DOS, you can only have one primary partition. Under Server 2003, Win2K, NT, XP, or Windows 9x, you can have multiple partitions on a drive, but only one partition at a time is marked active, which means you can boot from it. You can't break primary partitions into subpartitions,

and you can create only up to four partitions per disk because that's all there's room for in the partition table. You might partition your hard disk so one primary partition is running Win2K and another is running Linux, but only one disk is marked Active at a time.

Four logical divisions on the disk aren't enough? You can create an *extended partition* from unallocated space on a physical disk. Once you do, you'll see a new area of free space on the drive, with a dark green border. The dark green border identifies the extended partition's area (the brilliant, neon green inside is the free space within that extended partition until you carve it up). You can only have one extended partition on a physical disk, but you can supplement it with up to three primary partitions, for a total of four blocks, which is all the partition table can manage.

You can't put any data into an extended partition or assign it a drive letter until you create one or more logical drives in that extended partition. Until then, it's just free space.

### **Logical Drive**

A *logical drive* is a logical division of an extended partition that behaves like an entity unto itself. You can divide an extended partition into as many logical drives as you like if you make each partition the minimum size required (this minimum size will be shown in the wizard that helps you create the partition).

Logical drives are indicated in the Disk Management tool display with a royal blue stripe. Because they're part of an extended partition, they'll have a dark green border that encompasses all drives in the partition and any neon green free space left in it after you create the drives.

### **DIVIDING DYNAMIC DISKS**

I hate to keep hammering this home, but it's important and, I've found, not intuitive: You'll use dynamic disks any time you want to use any kind of logical divisions of disk space that use multiple disks. Forget RAID, forget fault tolerance... the key point to dynamic disks is their support for storage areas that may extend over more than one disk. Of those areas, remember that dynamic disks support volume sets, mirror sets (RAID 1), stripe sets without parity (RAID 0), and stripe sets with parity (RAID 5).

### **Volume Sets**

Although historically, the word volume has been used to generically refer to any logical disk division, for Server 2003's purposes, a *volume* is a logical division of the unallocated space on a dynamic disk. Since the advent of dynamic disks in Win2K, Microsoft has used this term to differentiate a dynamic disk from a basic disk. A volume in Server 2003 works like a logical drive or primary partition except for one major difference: Whereas logical drives and primary partitions in Server 2003 must be confined to a single disk, volumes using NTFS may either exist on a single disk or on more than one. This makes volumes much more flexible—and potentially more space efficient—than partitions or drives. As you can see in Figure 10.2, it's much easier to figure out how to fit 30MB of data into a 35MB volume set than it is to fit it into one 20MB logical drive and one 15MB logical drive. Especially if that 30MB is a single database.

Win2K supports two kinds of volume sets: simple volumes, which take up space on one disk, and spanned volumes, which take up space on multiple disks. You can extend either kind of volume; if you extend a simple volume onto another physical disk, it becomes a spanned volume. You cannot make the volume set smaller unless you delete it and create a new one.

**FIGURE 10.2**

How a volume set works

In this figure, 65MB of free space is available, but no more than 20MB of this space is contiguous. To get the most efficient use of this space, you could combine it in a volume set so all of the data is considered in one large chunk. Once this free space has been made into a volume set, you could store a 65MB chunk of data in it, even though the largest contiguous space is only 20MB in size.

**NOTE** At one time, you could only extend NTFS-formatted volumes created on a dynamic disk. Volumes made from converted logical drives or partitions could not be extended. This is no longer true, with the help of the command-line tool called *DiskPart*. I'll go into more detail in the "Extending a Basic Partition: *DiskPart*" section.

Volume sets do not protect your data; they are not fault tolerant. They only let you use available drive space more efficiently. If something happens to one of the hard disks used in a volume set, that volume set is dead, even if the other hard disks are fine. The more hard disks you have, the more likely it is that one will fail at any given time, so be sure to back up volume sets regularly.

### **Mirror Sets: RAID 1**

Mirror sets are the simplest form of Server 2003 fault tolerance. They write two copies of all data onto volumes on two separate disks so that if one disk fails, the data is still available on the other. If anything happens to the disk storing your original data, you still have an identical copy on the disk which stores the other half of the mirror set.

Collectively, the two volumes are called a *mirror set*, or RAID 1. They have a couple of advantages:

- ◆ You can mirror an existing simple volume set, making it fault tolerant.
- ◆ You only need two physical disks to create a mirror set, instead of the minimum of three that RAID 5 volumes require.

Disk mirroring is simpler to use in Server 2003 than it was in NT 4. You can create mirrored volumes without rebooting, and you don't have to regenerate data to recover it if one of the disks supporting the mirror crashes. The data will remain available—it just won't be fault tolerant until you mirror it again.

If you've ever heard of disk mirroring, you've probably also heard the term *disk duplexing*. As shown in Figure 10.3, disk duplexing is much the same as disk mirroring, except that duplexing generally refers to mirroring information on two separate disks—each with its own disk controller—so that the data is not vulnerable to controller failures. When Server 2003 talks about disk mirroring, it is referring to both duplexing and mirroring. Server 2003 can't tell whether you have multiple controllers or not.

**FIGURE 10.3**

Disk mirroring  
versus disk  
duplexing

When compared to RAID 5, this level of RAID has relatively good performance, especially with two controllers, but they're not very space efficient because every piece of data that you record has an identical twin on the other half of the mirror set—so you need exactly twice as much storage space as you have data. Remember that the two halves must be of equal size.

### **Stripe Sets: RAID 0**

Volume sets are useful because they allow you to combine many differently sized areas of unused disk space into a single volume. However, they don't offer any performance benefits. To use space on multiple disks and decrease read and write times, consider using disk striping without parity, also known as RAID 0.

When you create a stripe set from free space on your disks, each member of the stripe set is divided into stripes of equal size. Then, when you write data to the stripe set, the data is distributed over the stripes. A file could have its beginning recorded onto stripe 1 of member 1, more data recorded onto stripe 2 of member 2, and the rest on stripe 3 of member 3, for example. If you're saving data to a stripe set, a file is never stored on only one member disk, even if there is room on that disk for the entire file. Conceptually, striping looks something like Figure 10.4.

If you take free space on your disks and combine it into one stripe set with its own drive letter, the disk access time for that drive will be improved since the system can read and write to more than one disk at a time. To do striping without parity information included, you need at least 2, but not more than 32, disks.

Disk striping has a speed advantage over volume sets, but consider this:

- ◆ You cannot extend a stripe set as you can a volume or extend it over more disks once it's created. The size that you make the stripe set is the size it will stay.
- ◆ You cannot mirror a stripe set with software, although you *can* mirror a simple volume. There is simply no way to make a stripe set fault tolerant other than backing it up.

**FIGURE 10.4**

Stripe set without parity

Different data files are represented here with different shades of gray. As you can see, an entire data file is never all put onto one member of the striped set. This improves read time since, if Data A is called for, the disk controllers on all three members of the set can read the data. With a SLED data arrangement, only one of the members could read the data.

If you're looking for performance, use stripe sets without parity. If you're looking for flexibility and expandability, use simple or spanned volume sets. If its fault tolerance that you're after, use mirror sets or stripe sets with parity.

### **Stripe Sets with Parity: RAID 5**

For data protection, or to decrease your disks' read time, you can select areas of unallocated space on your disks and combine them into a *RAID 5 volume*, also known as a *stripe set with parity*. RAID 5 volumes are the most cost-effective form of RAID that Server 2003 supports because they require less space for redundant data than mirroring does. The catch is that they're also very processor intensive.

How does disk striping with parity work? Every time you write data to a RAID 5 volume, the data is written across all the striped disks in the array, just as it is with regular disk striping, RAID 0. Parity information for your data is also written to disk, always on a separate disk from the one where the data it corresponds to is written. That is, there isn't a separate "parity" disk, although RAID 4, which is not supported in Server 2003, organizes data that way. Rather, each disk supporting the RAID 5 volume may contain a piece of original data or the parity information needed to reconstruct that original data, but not both the original and its parity information. That way, if anything happens to one of the disks in the array, the data on that disk can be reconstructed from the parity information on the other disks. This is shown in Figure 10.5.

If you think about it, writing parity information every time you save a document could turn into a big waste of space and time. Take, for example, the document I'm creating for this book. If I've protected my data with level-5 RAID and parity information is stored to disk every time this file is saved, does that mean that there is parity information for every incarnation of this document from the time I began writing? If so, how can all the parity information and data fit on the disks?

The answer is, of course, that it doesn't, and this is what produces the performance degradation that's unavoidable in striped disk writes. Every time a document is saved to disk, its parity information

must be updated to reflect its current status. Otherwise, you would have to keep backup parity information for every version of the document that you ever saved.

**FIGURE 10.5**

Disk striping with parity information

As you can see, no single member of the stripe set keeps all the original data or all the parity information. Instead, the data and parity information are distributed throughout the stripe set so, if one member disk fails, the information can be reconstructed from the other members of the stripe set.

There are two ways to update the parity information. First, since the parity information is the XOR of the data, the system could recalculate the XOR each time data is written to disk. What is an *XOR*? On a *very* simplistic level, the XOR, or *exclusive OR arithmetic*, is a function that takes two 1-bit inputs and produces a single-bit output. The result is 1 if the two inputs are different or 0 if the two inputs are the same. More specifically:

$$0 \text{ XOR } 0 = 0$$

$$1 \text{ XOR } 0 = 1$$

$$0 \text{ XOR } 1 = 1$$

$$1 \text{ XOR } 1 = 0$$

When you're XORing two numbers with more than one bit, you match the bits up and XOR each pair individually. For example, 1101010 XOR 0101000 equals 1000010. The result you get from this function is the parity information, from which the original data can be recalculated.

Having to recalculate all the data stored in the volume each time you write to disk would take quite a while. A more efficient way of recalculating the parity information, and the one that Server 2003 uses is to read the old data to be overwritten and XOR it with the new data to determine the differences. This process produces a *bit mask* that has a 1 in the position of every bit that has been changed. This bit mask can then be XORed with the old parity information to see where *its* differences lie, and from this the new parity information can be calculated. This seems convoluted, but this second process only requires two reads and two XOR computations rather than one of each for every drive in the array.

RAID 5 volumes are great in theory, but in Server 2003's implementation they don't work so well. First, needing to generate parity information for every write to disk slows down the write process. Second and more important, RAID 5 represents a serious drain on processor time. In high-end hardware RAID, the system is configured with a separate processor that handles all the calculations necessary. Software RAID, such as what we're discussing in this chapter, relies on the server's processor to do all that calculating. You almost certainly won't use software RAID 5 much on a production server because of the performance toll it extracts, especially on processor-intensive applications.

## Using the Disk Management Tool

The Disk Management tool made its debut in Win2K and offered significant improvement over the Disk Administrator offered in NT 4. Whereas the Disk Administrator required you to reboot after any change to the partition system, or possibly if you breathed too hard on the hard disk, Win2K's version allowed you to create and delete volumes without rebooting. You could mount partitions to paths on other NTFS volumes instead of just assigning drive letters to new volumes. You could format volumes while creating them rather than having to format them from the command prompt or from Explorer as was necessary in the past. All in all, it was a good tool and a great improvement over previous iterations of the Disk Administrator. With Server 2003's new and improved version of the Disk Management tool, you can do even more. You can make changes to disks on-the-fly with no shutdown required, you can expand volumes, configure software RAID, add and remove disks and, generally, do just about anything you need to manage the physical and logical storage on your system. More specifically, with the Disk Management tool, you can do the following:

- ◆ Create and delete partitions on a hard disk and make logical drives
- ◆ Get status information concerning these items:
  - ◆ Disk partition sizes
  - ◆ Free space left on a disk for making partitions
  - ◆ Volume labels, their drive-letter assignment, filesystem type, and size
  - ◆ Disk health
- ◆ Alter drive letter and volume mounting assignments
- ◆ Enlarge disk volumes
- ◆ Create, delete, and repair mirror sets
- ◆ Format any volume
- ◆ Extend volumes
- ◆ Create and delete stripe sets and regenerate missing or failed members of stripe sets with parity
- ◆ Create volume shadow copies

The Disk Management tool is the GUI way of managing your storage and is a very effective tool for seeing the logical disk layout on your disks, complete with shiny colors that help identify the kind of disk and the various flavors of logical volumes or sets contained on those disks. But, if the puke green color of the volumes on your dynamic disk doesn't turn you on, you can use the cool new command-line utility DiskPart, which can do everything that the Disk Management tool is capable

of and more, and is installed by default when you install the OS. In fact, if you want to extend a basic disk, this tool is your *only* option. I'll cover this tool in more detail in the section "Extending a Basic Partition: DiskPart." Let's move on to another basic, but important, disk management topic, installing physical disks.

## Installing a New Physical Disk

When you first add a new hard disk to your computer, Server 2003 will not recognize the new disk even if it shows up at boot time (SCSI or IDE). You must add support for the new drive, either manually or by following the Initialize and Convert Disk Wizard, which was known as the Write Signature and Upgrade Disk Wizard in Win2K. The wizard will start up automatically when you open the Disk Management tool in the Computer Management interface and have new physical disks attached to the system.

There are two steps to setting up a new hard disk: writing a disk signature and choosing whether the disk should be basic or dynamic. Server 2003 writes disk signatures as part of the Initialize and Convert Disk Wizard.

To add a new disk, follow the wizard. The disks you just added are already selected for initialization, although you have the option of unselecting one or more. The next screen allows you to choose whether you would like to convert your disk or disks to dynamic disks, something you should think through before doing because, as you'll see, you can't always undo it very easily. This is unchecked by default. Server 2003 will write a signature to the disks so that they are ready for you to begin logically dividing them.

## Using Basic Disk Features

Basic disks, recall, are the default in Win2K and Server 2003. A basic disk is a normal disk, available from any operating system, and uses primary and extended partitions to divide up physical disk space into logical units. You'll need to stick with basic disks if you want to make disks available to operating systems other than Win2K or Server 2003. This will keep you from using RAID, but then again, even before Win2K introduced dynamic disks you couldn't access mirrored or other RAID volumes from any operating system other than NT anyway. On basic disks, you can create primary partitions, extended partitions, and logical drives.

### USING PRIMARY PARTITIONS TO STORE OPERATING SYSTEMS

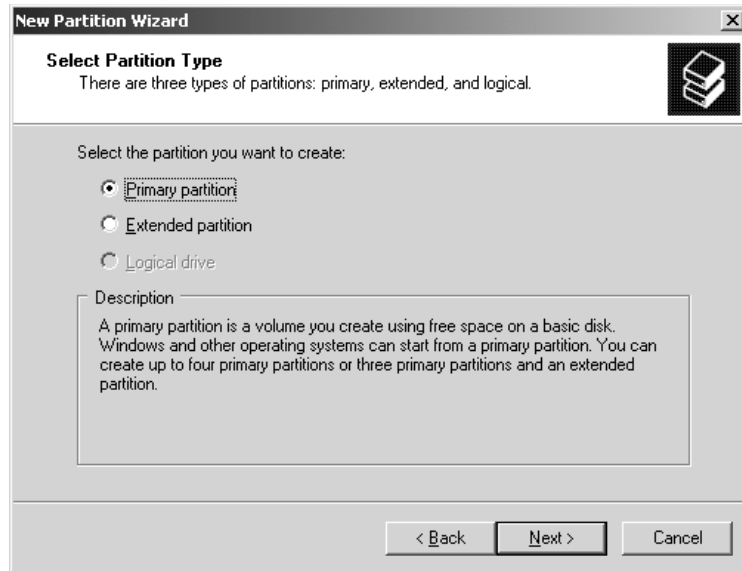

Although you'll set up at least the initial disk partitioning for your system/boot partition when you install Server 2003, you can use the Disk Management tool in the Computer Management section of the MMC (Computer Management is in the Administrative Tools program group) to edit the logical divisions of your disk after you've installed Server 2003.

Forgetting dynamic disks, you normally boot a computer from a primary partition. When you install Server 2003, the Setup program will automatically create a primary partition to put the OS on. Once Server 2003 is installed, you can create more bootable partitions or partitions to store data that's separate from your system partition. Right-click any area of unallocated space on the hard disk and choose New Partition to start the New Partition Wizard. Click through the welcome screen, then choose the type of partition you want to create (see Figure 10.6).

In the next screen of the wizard, specify the size of the primary partition. It can be anywhere from the minimum specified in the wizard to the full size of the unallocated space.

**FIGURE 10.6**

You can create primary partitions from unallocated space.

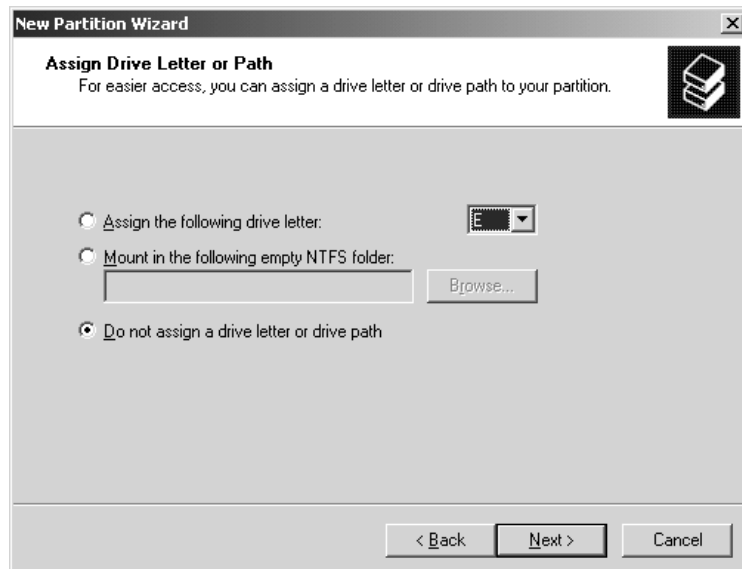

**NOTE** In Win2K, you had to make sure that you made the partition as big as it would ever need to be, because you did not have the ability to extend primary partitions. With the new DiskPart command-line tool, you can now extend basic partitions. I'll show you how in the section "Extending a Basic Partition: DiskPart."

In the next wizard screen (see Figure 10.7), you have three options: choose a drive letter for the new primary partition, mount it to an empty folder on an NTFS volume, or do neither.

**FIGURE 10.7**

Pick an identifier for the partition.

**NOTE** At some point, you'll have to assign the partition a drive letter or path if you want to use it. You can't save data to an area of the disk that isn't named and you can't format it—there's no way to get its attention, so to speak.

Next, you'll be prompted to choose a format for the disk (see Figure 10.8). Server 2003 supports NTFS (the default file format), FAT, and FAT32. You'll only have the option to compress the volume if you format with NTFS. Quick formats, which just wipe the disk without checking it for errors, are available with any format type.

**FIGURE 10.8**

Choose a disk format.

You don't actually have to format the partition now—you can format a volume at any time by right-clicking it and choosing Format from the shortcut menu—but you'll have to format it before you use it.

When you've finished, you'll see a finish screen like the one in Figure 10.9. Review your choices to make sure the new partition is set up the way you want it, and click Finish.

### USING LOGICAL DRIVES TO ORGANIZE INFORMATION

Even if you rely on the SLED model for your data storage, you may want to divide that single large physical drive into smaller logical ones. You could, for example, keep all the accounting information on logical drive C:, the engineering information on logical drive D:, the personnel information on logical drive E:, and so on. As discussed earlier, you can also mount logical drives to NTFS folders on other local disks. Although you can also do all this with primary partitions, logical drives have an advantage: no four-division limit per physical disk.

To create a logical drive, you must first take unallocated space and convert it to an extended partition. Creating an extended partition is much like creating a primary partition, except for the different partition type that you'll choose in the first page of the wizard and the fact that you won't be asked to format or label the new partition. The new extended partition will be labeled Free Space.

**FIGURE 10.9**

Review your choices before finishing the logical drive.

## WHAT FILESYSTEMS ARE AVAILABLE?

I'll talk about the benefits and drawbacks of the filesystems Server 2003 supports shortly, but when experimenting with creating partitions, you might wonder why some filesystems are available for some partitions but not for others.

The filesystems available will depend on the size of the partition you're formatting and the tool you're using to do it. If you format with the Disk Management tool as described here, you can format a partition smaller than 4GB (4096MB) with any filesystem that Win2K and Server 2003 support: FAT, FAT32, or NTFS. For volumes larger than 4GB, the Disk Management tool will only offer the formats of FAT32 or NTFS. For partitions larger than 2GB but smaller than 4GB, FAT will be an option, but when you choose that filesystem you'll see a message warning you that the partition you're formatting will not be compatible with previous versions of Windows, since the filesystem will use clusters bigger than 32KB.

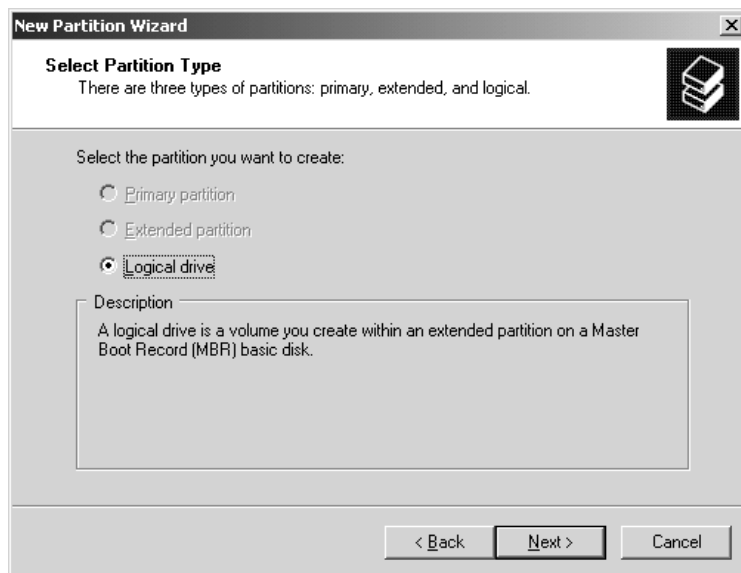

In Win2K, if you were formatting partitions with Explorer, then all three filesystems appeared in the list of available file formats regardless of the size of the partition. If you formatted a partition 4GB or larger, then FAT would still appear in the list of available file formats; when you clicked the OK button to begin the format, Win2K would chug away as though formatting the volume. However, when it finished you'd see an error message saying that the format couldn't be completed. The partition you tried to format would be unformatted, in its original condition, and any data on the volume before the intended format would still be there. This is fixed in Server 2003. The option to format with FAT is no longer there if the partition is larger than 4GB.

Once you've created the extended partition, you're ready to create a logical drive so that you can store data. To do so, right-click free space in the extended partition and choose New Logical Drive

from the shortcut menu. This will start the New Partition Wizard that you've seen before. Click through the first screen, and you'll see the one shown in Figure 10.10.

**FIGURE 10.10**

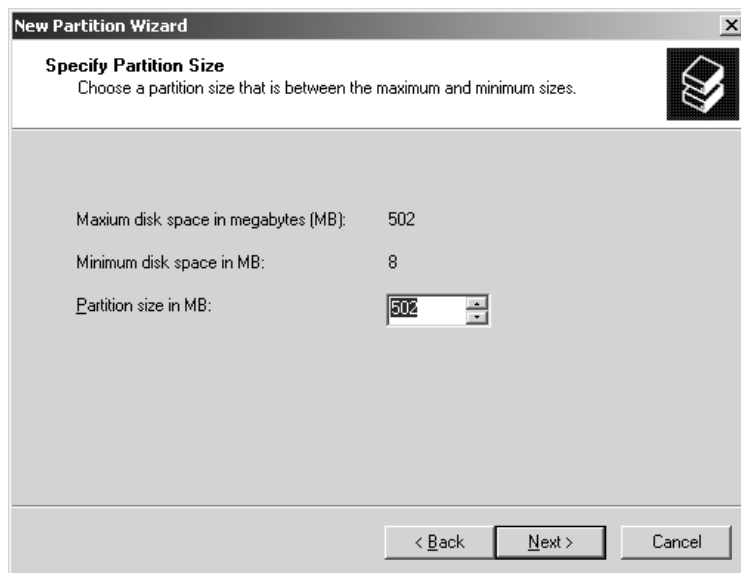

Choose to create a logical drive.

Notice that you only have one option here; you can't create partitions within an extended partition. Click Next to open the next page of the wizard and choose the size of the drive you want to create (see Figure 10.11).

**FIGURE 10.11**

Specify the size of the new logical drive.

In the next screen of the wizard, you can once again choose to either mount the drive or assign it a drive letter. Format the drive with the filesystem you want, and you'll arrive at the finish screen showing you the options you picked. Click Finish, and the logical drive will appear in the extended partition.

#### DELETING A BASIC DISK PARTITION OR DRIVE

To delete any basic disk partition, right-click it and choose the Delete Partition or Delete Logical Drive option (whichever applies). A dialog box will pop up and warn you that any information in the volume that you're deleting will be lost and ask if you're sure you want to continue. Click Yes to delete the volume.

The deleted basic disk volume will revert to whatever it was before you created the volume. Primary partitions and extended partitions revert to unallocated space on the drive; logical drives revert to free space.

#### EXTENDING A BASIC PARTITION: DISKPART

I mentioned before the inability in Win2K to extend basic partitions and the new command-line tool called DiskPart that now makes that possible. What's more, DiskPart has all of the functionality of the Disk Management tool in a command-line utility, which means that—you guessed it!—you can now script your disk management chores. Imagine how useful this will be when you are rolling out machines by the dozens, or hundreds, or even thousands using an unattended setup or Sysprep, which offers support for only one boot volume. Be careful though: DiskPart is a *very* powerful tool. Compare it with the Registry editor with which, without careful attention to detail, you can completely destroy your OS. If you are lucky you'll have your data stored on a separate disk and will still be able to recover it. With DiskPart, you can destroy the logical organization of those disks and delete disks, volumes, partitions, and volumes sets with the same ease as editing the Registry. Imagine trying to recover from a mistake like that. Of course, you can also do a great deal of good with this tool. Right now, I'll show you how to use this tool to expand your basic disks which, as I said before, you cannot do with the Disk Management GUI.

From the DOS prompt, type the command **diskpart**. DiskPart is a command-line interpreter, which means that once DiskPart is called with the command you just typed, it will be ready to accept additional commands at the **DISKPART>** command prompt. To perform any action on a specific disk, volume, or partition in your system, you must first select it, which shifts the focus of the DiskPart tool to that specific structure. Of course, in order to select a disk, volume, or partition, you'll want to list those structures so you can ensure you are making the correct selection. To do this, you use DiskPart's **list** command. Type **list** and then follow it with either **disk** or **volume** in order to view those structures. For example, in the following you can see the effects of listing the disks contained in the system.

```
C:\Documents and Settings\Administrator>diskpart
```

```
Microsoft DiskPart version 5.2.3663
Copyright (C) 1999-2001 Microsoft Corporation.
On computer: STORAGE
```

```
DISKPART> list disk
```

Disk ###	Status	Size	Free	Dyn	Gpt
-----	-----	-----	-----	---	---
Disk 0	Online	6142 MB	8033 KB	*	
Disk 1	Online	6142 MB	8033 KB	*	
Disk 2	Online	6142 MB	6142 MB		

Listing the disks shows you the basic details about the disks, including the size, whether it is dynamic or basic, and any free space not allocated to volumes or partitions on the disk. The GPT detail is used for the Itanium platform, as the partition style of the Itanium differs from both the MBR style and the dynamic disk style; I won't cover that here.

When you use the `list volume` command, DiskPart shows you a list of *all* of the volumes on every disk in the system. To get a list of the partitions, though, you have to first `select` a single disk onto which DiskPart will shift its focus. Then use the `list partition` command for each disk separately by first selecting a specific disk and then running the command for that particular disk, as shown here:

DISKPART> list disk

Disk ###	Status	Size	Free	Dyn	Gpt
-----	-----	-----	-----	---	---
Disk 0	Online	6142 MB	8033 KB	*	
Disk 1	Online	6142 MB	8033 KB	*	
Disk 2	Online	6142 MB	1137 MB		

DISKPART> select disk 2

Disk 2 is now the selected disk.

DISKPART> list partition

Partition ###	Type	Size	Offset
-----	-----	-----	-----
Partition 1	Primary	1004 MB	32 KB

Now that you know how to view the structures on the disks using DiskPart, let's pick a basic disk and try to extend it. You can tell that Disk 2 is a basic disk as it does not have a checkmark in the `Dyn` column. Since Disk 2 has already been selected (you just viewed the partitions on it, remember?) all you need to do to extend the disk is use the `extend` command. The syntax for the command is as follows:

`extend [size=N] [disk=N] [noerr]`

The `size=N` parameter allows you to select the amount of unallocated space (in MB) that you want to add to the partition. If you don't specify a size, the disk is automatically extended using all of the room in the next contiguous unallocated space.

You can use the `disk=N` option to pick a disk that you want to extend. (If you have already selected a disk, you don't need to use this option.) It will extend the disk you currently have selected, so make sure you know which disk you have selected before you use the `extend` command.

If you are using DiskPart to script the disk management for your unattended installs, you can use the *noerr* parameter to ignore errors and continue executing commands. Without this option selected, when DiskPart encounters an error, it will cease to run and will exit with an error code.

## EXTENDING THE BASIC DISK

Before actually extending the basic disk, you'll need to remember a few things:

You cannot extend the system or boot partition on a basic disk.

If the partition is already formatted with NTFS, when you expand the disk the new space is automatically formatted with NTFS. Without NTFS, the command will fail.

The unallocated space you want to use must be on the same disk as the partition on which you have focused DiskPart.

For basic disks, the unallocated space has to be located immediately after the partition you want to extend on the disk. It can't jump a partition and use the unallocated space available at the end of the disk.

Okay, remember that you first selected Disk 2 and then selected Partition 1, and thus you are ready to execute the *extend* command. Here's what it looks like:

```
DISKPART> extend
```

```
DiskPart successfully extended the volume.
```

That's it. Quick as a flash, what was once an impossible task has been completed in seconds with little effort. Remember, extending basic volumes can only be done using the DiskPart tool—it can't be done with the GUI (not yet, anyway).

I have to admit to really liking this new tool, especially its scripting capabilities, although at the time of this writing, I was getting some kind of flaky results using the *size=N* parameter. Any time I tried to expand a basic disk using that option, the command would fail with an error, but it seemed to expand the disk using my size specifications anyway. And any time I received an error, DiskPart seemed to forget whatever disk, volume, or partition I was working on and I'd have to go through the process of reselecting all of those structures to refocus DiskPart on the job at hand. It would be okay if I knew the command really worked, but this isn't the kind of tool where a "maybe" is okay. Of course, I am working with a Beta version of Server 2003 as I write this, so maybe it will be fixed before the final release. Other than my difficulties with the *size=N* parameter, I find DiskPart to be a very handy tool.

I recommend learning this tool whether you are planning to use it for its scripting functionality or not, as it has fixed issues for me that could not be fixed using the Disk Management tool. But, as I said before, if you fear editing the Registry (and you should), you should fear using DiskPart even more—it's the dragon's breath in terms of potential for damage, so beware.

I'll go into some more detail about DiskPart in the "DiskPart For Disk Management" section. But first, you need to learn more about the basics of managing disks using Server 2003's Disk Management tool.

### CONVERTING A BASIC DISK TO A DYNAMIC DISK

Even after you partition part of the disk, you can convert a basic disk to a dynamic disk so that any new volumes you create in the remaining space can span multiple physical disks. Before you start converting, however, here are a few things you should consider.

#### ***You Can't Easily Undo This!***

If you don't read another word in this section before skipping to the instructions, read this. If you upgrade a disk to dynamic, then you cannot make that disk a basic disk again without deleting every volume on it. There is no way to preserve a dynamic disk's organizational structure when making it a basic disk.

#### ***Not All Disks Are Upgradable***

These instructions will not work on every disk. If you don't see an option to upgrade a basic disk, there may be a reason:

- ◆ Only fixed-disk drives may be dynamic disks. Removable disk drives such as Jaz drives can only be basic disks. The reasoning is simple: A dynamic disk volume may extend over more than one physical disk. A removable disk might not always be present.
- ◆ If the disk has a sector size larger than 512 bytes, then you won't be able to upgrade it. Notice that that's the *sector* size, not the *cluster* size. I'll get into the difference more in the later section on formatting, but for the moment just understand that (a) this is a problem you're unlikely to encounter, and (b) you can't change the sector size of your disks with a Server 2003 format. Cluster size, yes; sector size, no.
- ◆ You can't make disks on a laptop computer dynamic—Server 2003 doesn't support this. The logic is that laptops normally only have a single physical disk. First, this means that they can't reap any of the benefits of dynamic disks, since those benefits are all tied into RAID. Second, if a laptop has a second hard disk that's available when the laptop is in a docking station, then the database containing information about the dynamic disks in the computer would easily become out of date if the two dynamic disks only sometimes worked together.
- ◆ For those using Windows Server 2003, Enterprise Edition or Windows Server 2003, Datacenter Edition, you can't make the shared storage system in a cluster dynamic.

#### ***What's Happening to My System and Boot Partitions?***

Before upgrading a basic disk, consider what effects the change will have on existing system data—both for Server 2003 and for any other operating systems on the computer:

- ◆ You will *not* be able to install Server 2003 onto a volume on a dynamic disk unless the volume was upgraded from a basic disk. That is, the volume must have existed on the physical disk before you upgraded it to dynamic. Although Windows Setup can “see” a native dynamic volume—i.e., it will appear in the list of available partitions for installation—if you select it, Setup will not be able to recognize the partition and will ask you to pick another one, as the original partition table must be there to be able to boot from it.
- ◆ You can (usually) upgrade the disk with the system partition on it, but the upgrade will not take effect until you restart the computer. (Actually, this is true for any disk that has files open

during the upgrade, not just the system partition.) This is one of the few times that you'll need to restart the computer for a change in the Disk Management tool to take effect.

- ◆ You will not be able to access the dynamic disks from any locally installed operating system other than Win2K or Server 2003. That is, you'll be able to get to them from across the network, but in a dual-boot computer, the other operating systems will not be able to see the dynamic disks. That, by the way, includes *booting* from those dynamic disks, so don't convert a disk with other operating systems on it.
- ◆ You can't use dynamic disk or volume sets on clustered storage devices, although there are some third-party products that allow for dynamic disks to be clustered.

### Keep in Mind What You Have

You may not *want* to upgrade a basic disk to dynamic. Seriously. You'll need to do it to get the full benefits of Server 2003's multidisk volumes and software RAID support, but upgrading can be hard to reverse and a pain to resolve if you can't. Keep the following in mind:

- ◆ You cannot extend the volumes on the converted disk if the volumes were originally created on a basic disk. Only volumes originally created on a dynamic disk may be extended to other disks or made larger with unallocated space on the same disk.
- ◆ Although you always have the option of converting dynamic disks back to basic disks, you must delete any volumes on the disk first.

### Upgrading the Basic Disk

Now that you're thoroughly intimidated, let's go through the process of doing the conversion:

1. In the Disk Management tool, right-click the gray area on the left side of the physical disk you want to convert (see Figure 10.12).

**FIGURE 10.12**

You must start from the physical disk, not from one of the logical volumes on the disk.

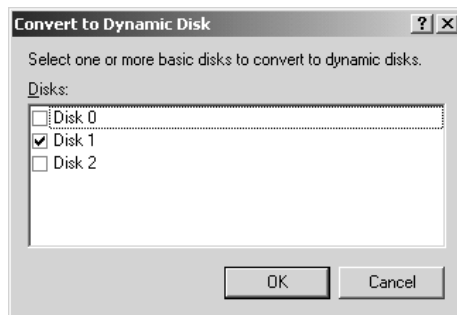

2. From the context menu that appears, choose **Convert to Dynamic Disk** to open the dialog box in Figure 10.13. All basic disks on the computer that are available to be converted (recall, this includes only fixed-disk drives) will be listed and identified by number.

**FIGURE 10.13**

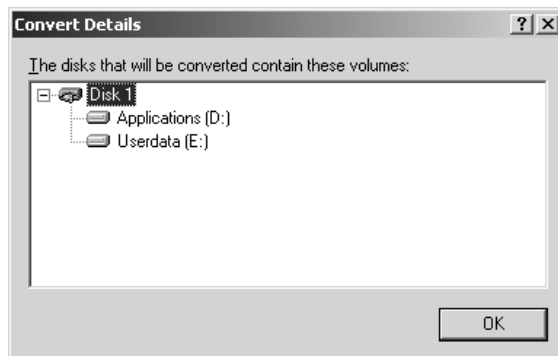

Choose the basic disk(s) you want to convert.

3. Click **OK**, and the Disk Management tool will then display a list of the disks it's going to convert. This dialog box is much like the preceding one except for a **Details** button. Click this button, and you'll see a list of the logical drives on the physical disks (see Figure 10.14).

**FIGURE 10.14**

The Disk Management tool will show you what logical drives are on the disk to be converted.

4. Exit the Details box and return to the Disks to Convert box by clicking **OK**. If you're still sure you want to upgrade, click the **Convert** button. You'll see a message like the one in Figure 10.15, warning you that other versions of Windows will no longer be able to boot from this disk. Click **Yes**, and you'll get *another* message warning you that all mounted file paths will be dismounted. (If you regret upgrading a disk to dynamic, it's not going to be Microsoft's fault.) Click **Yes** to get through this message box.

**FIGURE 10.15**

Be sure not to convert any basic disks that other versions of Windows will need to access.

Once you've clicked Yes, the hard disk will grind away for a couple of minutes. When the operation is completed, any partitions or logical drives that had previously been on the disk will now be simple volumes. If the disk had open files—as with the system disk—then you'll need to reboot.

### **Why Didn't the Upgrade Work?**

That's how it's supposed to work. If you're attempting to upgrade disks that should work (see “Not All Disks Are Upgradable”) and the upgrade doesn't take, then something may be wrong with the disks or with a volume on the disk.

When Disk Management attempts to convert a basic disk to dynamic, it first performs a system check to make sure that the conversion will take. The disks must be working (you can't write a 1MB database of disk information to a disk that's having I/O errors), and the volumes on the disks have to be working and visible to the Server 2003 Volume Manager. For instance, if you create a partition with something other than the Disk Management tool, then until you restart the system the Volume Manager may not be able to “see” it. If the Volume Manager is unaware of that volume, it will stop the disk conversion process.

## **Using Dynamic Disks**

You'll need to use dynamic disks if you want to use Server 2003's software RAID protection. Read on for more information about how to create and delete RAID volumes and use them to improve fault tolerance and/or disk performance.

### **CREATING A DYNAMIC DISK VOLUME**

Creating a dynamic disk volume is much like creating a volume on a basic disk, but you'll have some more options depending on the number of dynamic disks you have available and the kind of volume you're creating. The basic process goes like this:

1. In the Disk Management tool, right-click unallocated space on any dynamic disk to open the shortcut menu. Choose New Volume.
2. You'll open the New Volume Wizard. Click past the opening screen to the one shown in Figure 10.16. Pick a type of volume to create.

**FIGURE 10.16**

Choose a type of dynamic volume to create.

**NOTE** Not all volume types will always be available. If you have available only a single dynamic disk with unallocated space, you'll only be able to create a simple volume. Two dynamic disks with unallocated space available will permit you to create a stripe set, spanned volume, or mirror set. To create a stripe set with parity, at least three dynamic disks with unallocated space must be present.

3. In the next screen, choose the disk or disks that you want the volume to reside on. The currently selected disk will be in the list on the right side (see Figure 10.17) and the available disks will be on the left side. Select a disk and click the Add or Remove buttons to pick the disks you want the volume set to be on.

**FIGURE 10.17**

Choose the disks that should support the volume.

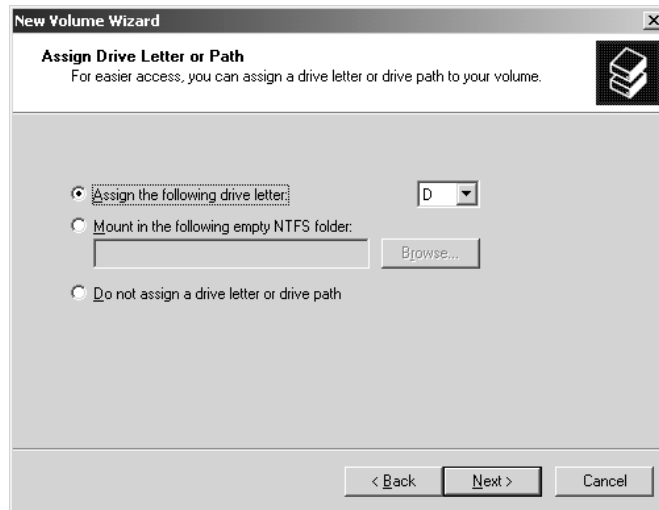

4. In the same screen of the wizard, pick the size you want the volume to be. By default, the new volume will be as large as possible, based on the amount of unallocated space available on the disks you've chosen. You can make it smaller than this size, down to 1MB, but you obviously can't make the volume bigger.
5. In the next screen of the wizard (see Figure 10.18), choose a drive letter or map the new volume to a path on an NTFS volume. Although you don't have to do either at this time, you will need to call the new volume *something* before you can use it.
6. Click to open the next screen of the wizard and choose a disk format for the new volume: NTFS, FAT32, or FAT. Again, as you can see in Figure 10.19, you don't have to format the volume while creating it, but you will need to format it before you can use it.

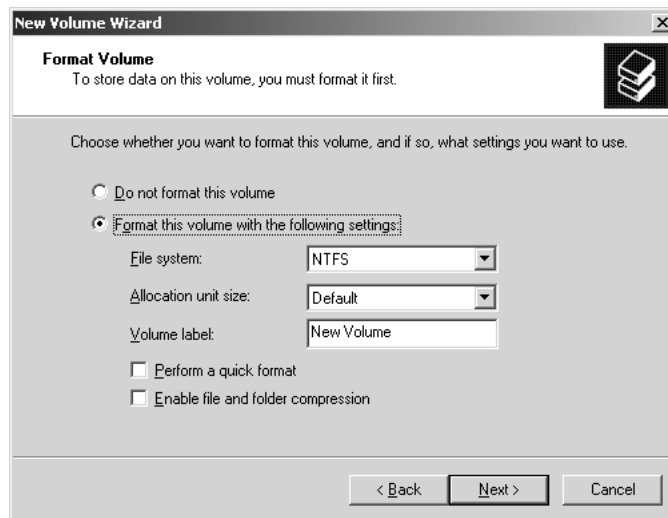

**NOTE** You can always perform a quick format on any volume (just wiping the volume and not checking for bad clusters), but file and folder compression—and other features such as disk quotas and file encryption—are only available for NTFS volumes.

**FIGURE 10.18**

Choose a drive letter or mount the volume to a drive path.

**FIGURE 10.19**

Format the new volume.

The final screen of the wizard displays the choices you've made so that you can go back and change them if need be. Otherwise, click Finish, and the new volume will be accessible as soon as it's formatted—no rebooting required.

### DELETING A DYNAMIC DISK VOLUME

Deleting a dynamic disk volume is straightforward: right-click the volume to delete and pick Delete Volume from the shortcut menu. You'll see a message like the one in Figure 10.20, warning you that you're about to delete any data on that volume. Click Yes to continue deleting the volume and it's instantly gone—no rebooting or further warnings required.

**FIGURE 10.20**

Deleting a volume permanently deletes the data stored on that volume.

### CONVERTING A DYNAMIC DISK TO A BASIC DISK

If you mistakenly upgrade a basic disk to dynamic, all is not lost. You can reverse the process. The only catch is that you can't convert volumes on a dynamic disk to basic disk volumes, because they don't exist in the disk's partition table—just in the dynamic disk database. If you have volumes on the disk, then the Convert to Basic Disk option in the disk's shortcut menu will be grayed out. You'll need to delete all volumes before this option becomes available.

Assuming that the disk is empty, however, the process is simple for a data disk. Right-click the gray area of the physical disk (all the way to the left in the Disk Management tool's display) and choose Convert to Basic Disk. That's it. No reboot required.

### Creating a Volume Set

I explained how to build a dynamic disk volume in the earlier section, "Creating a Dynamic Disk Volume." The only volume set-specific parts to remember are these:

- ◆ Simple volume sets will only use space on one dynamic physical disk.
- ◆ Spanned volume sets may use space on from 2 to 32 dynamic physical disks.

Other than that, the process of creating a simple or spanned volume is now blessedly simple: pick the disks to place the volume on, pick a size for the volume, assign the volume a drive letter or mount it to a path, format it, and you're done.

### ENLARGING A VOLUME SET

If it turns out that your NTFS-formatted volume set is smaller than you need it to be, it's not necessary to delete it and re-create it from scratch. Instead, you can *extend* it by adding areas of free space to its volume.

**NOTE** *You cannot make a volume set smaller. To do that, you must delete the volume set and create it again.*

To extend an existing simple or spanned volume set, follow these steps:

1. Right-click the simple or spanned volume set you want to expand and choose Extend Volume from the shortcut menu. You'll start up the Extend Volume Wizard.
2. Click through the initial page of the wizard to display the screen shown in Figure 10.21. From here, choose the disk or disks onto which you want to extend the volume set. Only dynamic disks with unallocated space will be available.

**FIGURE 10.21**

Pick the disks to add to the volume set and specify how much space you want to add.

3. In this same screen, choose the amount of unallocated disk space you want to add from the new disk. The Disk Management tool will display both the amount of space that you're adding and the total size of the newly extended volume.
4. The final screen of the wizard will show the choices you've made. Review them and click either Back to make changes or Finish to extend the volume set.

The volume set is now the larger size that you specified, and all of the area in it will have the same drive letter. The unallocated space that you added is automatically formatted to the same filesystem as the rest of the volume set—NTFS.

There are a few catches to extending volume sets:

- ◆ You can only extend NTFS volumes, so you'll need to reformat or convert FAT or FAT32 volumes to NTFS before you can extend them.
- ◆ When you convert a basic disk to dynamic, it makes any partitions that exist on the basic disk become simple volumes. With Win2K, you could not extend *those* simple volumes. Only volumes originally created on a dynamic disk were extensible. That is still partially true in Server 2003, at least for volumes originally created on a basic disk in Win2K. Consider the following example. If you have upgraded a basic disk to dynamic in Win2K, which includes the volumes originally created on that basic disk, and then you upgrade to Server 2003, you will be unable to extend those volumes. If, however, you upgrade a basic disk to dynamic in Server 2003, which includes volumes originally created on those Server 2003 basic disks, you will be able to extend them. It's an improvement in Server 2003, but not one that can reach back and fix the existing problem in Win2K.
- ◆ Again, you cannot use this procedure to make a volume set smaller. To do that, you need to delete the volume set and create a new one.
- ◆ You cannot combine two volume sets, nor can you add a logical drive to a volume set.

## Creating a Stripe Set

Creating a stripe set without parity is just like creating any other dynamic disk volume: make sure that you've got at least two dynamic disks with unallocated space available, right-click an area of unallocated space, and choose New Volume to start the wizard. In the first screen that includes any data, make sure that you've selected the Striped Volume type as shown in Figure 10.22.

**FIGURE 10.22**

Choose striped volumes to reduce disk access times.

From here, the volume creation process is the same for all dynamic volumes, as described in the earlier section, “Creating a Dynamic Disk Volume.” Just keep in mind the following:

- ◆ Stripe sets must include at least 2 and no more than 32 physical disks.
- ◆ Each stripe will be the same size. That is, if the largest area of unallocated space on Disk 0 is 50MB, then the largest stripe set you can create on three disks is 150MB, even if Disk 1 and Disk 2 each have, say, 200MB of unallocated space.
- ◆ Stripe sets do not include any parity information, so the volume size the wizard lists is an actual reflection of the amount of data you can store on the striped volume.

If anything happens to any member disk of your non-parity stripe set, all the data in the set is lost. It doesn't hurt the other disks in the stripe set, but it means that the data in the stripe set itself is unavailable.

## DELETING A STRIPE SET

If you make a stripe set too small or too big, there's no way to resize it. You'll need to delete the stripe set and start over. Just right-click it and choose Delete Volume from the shortcut menu. As always, you'll be prompted to confirm that you want to delete the volume, and when you do, the stripe set—and all the data stored on it—will disappear.

## Establishing a Mirror Set

To create a mirror set, you can either start from unallocated space on a dynamic disk or mirror an existing simple volume.

**NOTE** You cannot mirror a volume on a basic disk. Although Win2K supports mirrors on basic disks left over from upgrading NT to Win2K, Server 2003 has no support for this.

To create a mirror set from unallocated space, right-click an area and choose New Volume from the shortcut menu. Go through the wizard as described in the earlier section, “Creating a Dynamic Disk Volume,” noting the following:

- ◆ You’ll need two dynamic disks with unallocated space on them.
- ◆ Both halves of the mirror set will be the same size. You cannot mirror a large volume with a smaller one.
- ◆ A mirror set can use any disk format: NTFS, FAT32, or FAT.

To mirror an existing simple volume, right-click the volume and choose Add Mirror from the shortcut menu. You’ll open a dialog box like the one in Figure 10.23, asking you to select the disk that you want to create the mirror on. Click the disk so that it’s highlighted—this won’t work otherwise.

**FIGURE 10.23**

Choose a dynamic disk to hold the mirrored data.

**NOTE** Only dynamic disks with areas of unallocated space big enough to mirror the selected volume will be listed. If no area of unallocated space is big enough, then you won’t have the option of mirroring the volume.

Click the Add Mirror button, and the Disk Management tool will create in the unallocated space a partition that’s the same size as the simple volume being mirrored. The partition will be formatted to match the filesystem on the original volume, and the redundant data will be regenerated. (Depending on the size of the volume you’re mirroring, this may take a while. It’s not a fast process on large volumes.)

The new partition will have the same drive letter or mounted path as the one you mirrored and will be available immediately—no reboot required.

**GETTING RID OF AND RECOVERING DATA FROM A MIRROR SET**

If you don't want to maintain redundant information anymore, then you can delete the mirror set. How you get rid of it depends heavily on what you're trying to do:

- ◆ If you don't want any of the information in the mirror set anymore, then *delete* the mirror set.
- ◆ If you only want to keep half the data in the mirror set (either the original volume or the redundant half), then *remove* the mirror set.
- ◆ If you want to keep all the data—original and redundant—but don't want to mirror it anymore, then *break* the mirror set.

You don't have to delete, remove, or break a mirror set to keep using its data if half of it fails—it just won't be fault tolerant until you replace the failed disk and establish a mirror again.

**Deleting a Mirror Set**

To destroy all data in a mirror set, right-click the mirrored volume and choose Delete Volume from the shortcut menu. The Disk Management tool will ask you if you're sure; click Yes to continue deleting the mirror.

This will delete both halves of the mirror set—and destroy the partition—so only do this if you don't need the data or you've backed it up. (Strictly speaking, you shouldn't mess around with your data unless you've backed it up anyway, but this time you'll *definitely* delete it.)

**Removing a Mirror Set**

If one of the disks dies, the data on the still-functioning disk will still be accessible, but it won't be protected anymore (see Figure 10.24).

**FIGURE 10.24**

If one of the disks supporting a mirrored volume dies, then the mirror set is displayed as failed.

To protect it again, you'll need to remirror the volume. However, you can't *rmirror* a mirrored volume, and even if half of it's dead, the mirror itself is still valid. To start protecting the data again, you'll need to get rid of the original mirror.

To delete one half of the redundant data and stop mirroring, remove the mirror set. Right-click the mirror set and choose Remove Mirror from the context menu. You'll see a dialog box like the one in Figure 10.25.

**FIGURE 10.25**

Pick a half of the mirror set to remove.

Be sure to pick the half that you *don't* want to keep. When you click Remove Mirror, the Disk Management tool will ask if you're sure. Click Yes to continue. The partition you selected will be deleted. The mirrored partition that you *didn't* select will become a simple volume. Its data will not be affected.

### **Breaking a Mirror Set**

If both halves of the disk are still working, but you don't want to mirror the data anymore, then you can break the mirror set and thus make the two volumes act again like simple volumes. Both volumes will begin their new lives with all the data they had as their half of the mirror set; breaking the set does not affect the data.

To break the mirror set, right-click a mirror set that's still functioning (if the mirrored volume has failed, then you'll have to remove the mirror, not break it) and choose Break Mirror from the shortcut menu. You'll see a message asking if you're sure and warning you that your data will no longer be fault tolerant. Click Yes to continue.

**NOTE** If an application is referencing data stored in the mirror set—even if its contents are just displayed in Explorer—you'll see an error message telling you that the volume is in use. Stop using the mirror set before breaking it if you want to copy the data currently being viewed to both halves of the mirrored volume.

The two halves of the mirrored volume will now become simple volumes. One half will retain the drive letter that had belonged to the mirrored volume, and the other will have the next available drive letter.

### MIRRORING CONSIDERATIONS

As you're deciding whether or not to protect your data by mirroring it, keep these things in mind:

- ◆ Mirroring to drives run from the same drive controller does not protect your data from drive controller failure. If any kind of controller failure occurs, you won't be able to get to the backup copy of your data unless you are mirroring to a disk run from a separate controller.
- ◆ For higher disk-read performance and greater fault tolerance, use a separate disk controller for each half of a mirror set.
- ◆ Disk mirroring effectively cuts your available disk space in half. Don't forget that as you figure out how much drive space you've got on the server.
- ◆ Disk mirroring has a low initial cost, since you must purchase only one extra drive to achieve fault tolerance, but a higher long-term cost due to the amount of room your redundant information takes up.
- ◆ Disk mirroring will slow down writes, as the data must be written in two places every time, but will speed up reads, as the I/O controller has two places to read information from. It gets the best performance of the two fault-tolerant RAID levels.
- ◆ You cannot extend a mirrored volume. The size it is when mirrored is the size it will stay. (Of course, you can always break the mirror, extend the simple volume that you are left with and then create a new mirror with that bigger volume.)

### Establishing RAID 5 Volumes

To create a RAID 5 volume on a computer, follow these steps:

1. Right-click any area of unallocated space on any dynamic physical disk. From the shortcut menu that appears, choose New Volume.
2. Click through the opening screen of the wizard. On the first real screen, select RAID 5 Volume, as shown in Figure 10.26.
3. In the next screen (see Figure 10.27), choose at least three disks that you want to be involved in the stripe set. The disk you started with (the one with the area of unallocated space) will be in the right column of disks to use; the other dynamic disks with unallocated space will be on the left side. In the figure, I've selected three disks to use. To add a disk to the stripe set, select it in the list of all available dynamic disks and click the Add button. To remove a disk from the stripe set, select it in the list of selected dynamic disks and click the Remove button.
4. In this same dialog box, pick the size of the stripe set. In the Size box, the Disk Management tool will display the maximum size of the stripes based on the unallocated space on the chosen drives. You can go smaller than this amount, but not bigger. The value in Total Volume Size will reflect the total amount of room available for *data*, not the total space in the stripe set. Since  $1/n$  of the space in a RAID 5 volume (where  $n$  is the number of disks in the set) is used for parity information, the more disks you have, the larger percentage of room for data you'll get.

**FIGURE 10.26**  
Choose RAID 5  
to establish a  
stripe set with  
parity.

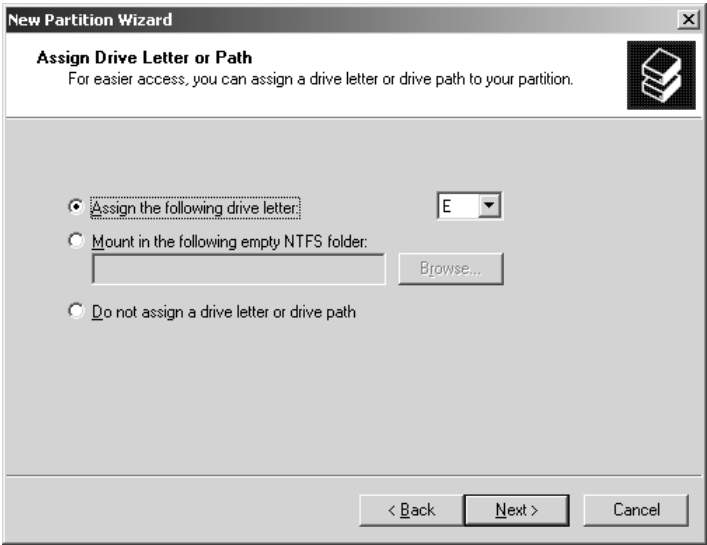

**FIGURE 10.27**  
Select the disks  
to be in the stripe  
set and the size  
of the set.

**NOTE** The amount of unallocated space on each physical disk will determine the size of the stripe set. Each section of the stripe set must be the same size, so if one disk has only 50MB unallocated space on it, then the entire stripe set spread across three disks can be no more than 150MB, even if the other two disks have 500MB of unallocated space each. That said, not all the unallocated space must be contiguous. If a single disk has one chunk of unallocated space that's 50MB and another that's 100MB, then the disk can contribute 150MB to the RAID 5 volume.

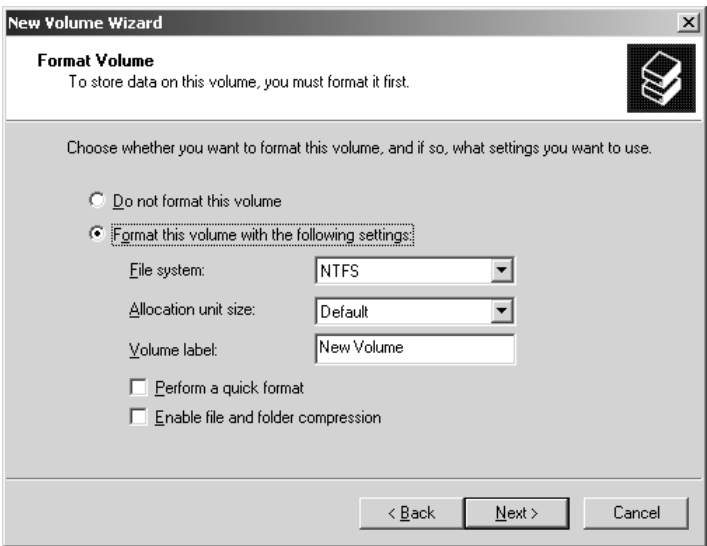

5. Choose to assign a drive letter or mount the volume to an NTFS path (see Figure 10.28).

**FIGURE 10.28**  
Assign the volume a drive letter or path.

6. Choose whether or not to format the new volume right away and choose the disk format you want to use (see Figure 10.29).

**FIGURE 10.29**  
Pick a format for the volume.

7. Review your choices, backing up to change any of them or clicking Finish to create the RAID 5 volume.

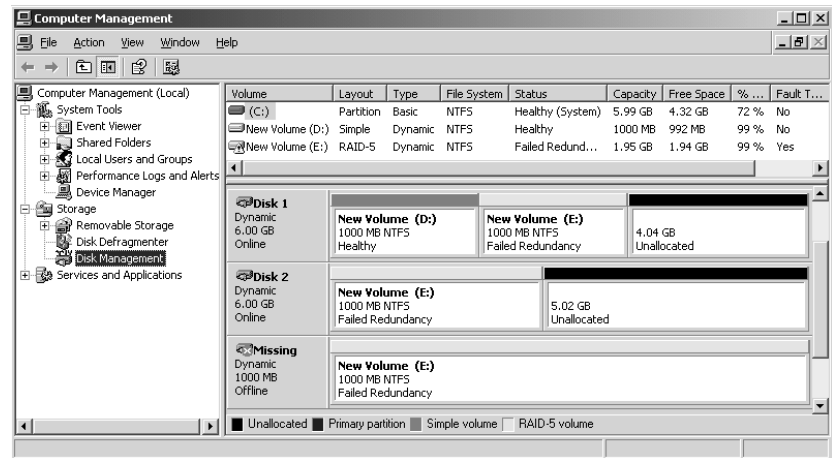

Server 2003 will grind away for a few minutes, setting up the new stripe set. When it's done, the RAID 5 volume will be immediately ready to use.

### RETRIEVING DATA FROM A FAILED STRIPE SET

If an unrecoverable error to part of a stripe set with parity occurs, you'll still be able to read and write to the volume, but the volume will be marked Failed in the Disk Management tool (see Figure 10.30). This is a warning: lose one more disk, and the data will be inaccessible and unrecoverable.

**FIGURE 10.30**

You can still read and write to failed RAID 5 volumes, but they're no longer fault tolerant.

To make the volume fault tolerant again, replace the failed disk, rescan the disks, and reactivate the disk. If this doesn't make the volume healthy again, then right-click the stripe set and choose Reactivate Volume. The computer will chug away for a couple of minutes, rebuilding the missing data with the parity information on the remaining disks, and the stripe set will be back in one piece. You don't have to reboot. If you don't have the choice to Reactivate the volume, then choose Repair Volume from the options. You will be asked to choose the disk you would like to use to regenerate the stripe set.

### DELETING A STRIPE SET

Deleting a stripe set is quite simple. Right-click the volume and choose Delete Volume from the shortcut menu. You'll see the usual warning message telling you that you're about to delete the volume and lose data; click through it, and the stripe set will again be unallocated space. Don't forget that deleting a stripe set destroys the data in it—even the parity information.

### THINGS TO REMEMBER ABOUT DISK STRIPING WITH PARITY

Keep these things in mind when it comes to disk striping with parity:

- ◆ Striping with parity has a greater initial hardware cost than disk mirroring does (it requires a minimum of three disks rather than two and can contain no more than 32 disks). Nevertheless, it allows you to get more use out of your disk space.

- ◆ You cannot make a stripe set bigger (even if more unallocated space becomes available) or extend it to another physical disk.
- ◆ Although you can access the information in a stripe set even after one of the members has failed, you should regenerate the set as quickly as possible. Server 2003 striping cannot cope with more than one error in the set, so you're sunk if anything happens to the unregenerated stripe set.
- ◆ Striping with parity places greater demands on your system than disk mirroring, so add more memory and processor power to the server if you plan to use disk striping.
- ◆ If you have fewer than three dynamic disks on your server with unallocated space, you cannot make stripe sets with parity.

## Performing Disk Maintenance

The job doesn't end with setting up disk volumes on the physical disks. To keep those volumes working well, you'll need to perform some routine maintenance on them. There are several tools which can help you do that which we'll talk about here.

### Background: Disk Geometry and File Formats

Before getting into some of these routine maintenance chores like disk formats, disk defragmenting, and evaluating the health of your disks, let's take a quick look at the relationship between Server 2003 and hard disks and how this relationship makes all these tasks necessary.

A hard drive is not one but several disks called *platters*. Each platter is divided two ways: pie-shaped wedges and concentric circles. The pieces defined by the intersection of these divisions are called *sectors* and are the physical units of storage on a hard disk. Each sector on a disk is normally 512 bytes in size.

Server 2003 doesn't know a sector from a hole in the ground. To let its file storage component store and retrieve data on the disk, Server 2003 must impose some kind of logical structure over the physical structure of the disk. That logical structure is called a *disk format*, and it groups sectors together in logical units called *clusters*. The number of sectors in a cluster varies, depending on the size of the disk partition (all other things being equal, larger disks typically have more sectors per cluster) and the disk format you're talking about. All clusters have at least one sector in any filesystem that Server 2003 supports.

A cluster is the smallest organizational unit that the filesystem can recognize, which means that you can only store one file per cluster. If a file is too big to fit into a single cluster, then it will be spread over multiple clusters, as close together as possible. If a file is smaller than the cluster size, it will still fit into a single cluster, and any unused space in that cluster goes to waste. Larger clusters reduce the likelihood that files will get fragmented, but smaller clusters generally use file space more efficiently.

Sound irrelevant? Trust me; you'll need this background on clusters and sectors when it comes to performing basic disk maintenance.

### Formatting Disks

Server 2003 is the first generation of NT sensible enough to let you format volumes while creating them with the Disk Management tool. However, you can still format volumes from Explorer or from the command prompt, as you needed to do in earlier versions of Windows.

### DISK FORMATS SUPPORTED IN SERVER 2003

Server 2003 supports three disk formats: the old FAT format that includes long-filename support, the FAT32 file format introduced with Windows 95 OSR 2, and an updated version of the NTFS format that's been around since NT 3.1.

#### FAT and FAT32

FAT is the granddaddy of Microsoft filesystems, the one that all Microsoft operating systems support. It uses a simple catalog called the *file allocation table* to note which cluster or clusters a file is stored in. If a file's stored in more than one cluster, then the cluster includes a pointer to the next cluster used for that file until the final cluster includes an End of File marker.

FAT and FAT32 have a great deal in common: a simple set of attributes that note creation and access dates and the settings of the hidden, archive, system, and read-only bits. The main difference between FAT and FAT32 lies in their relative cluster sizes. FAT is actually FAT16, which means that it uses a 16-bit addressing scheme that allows it to address up to  $2^{16}$  (that is, 65,536) clusters. To address very large volumes that include a lot of sectors, therefore, FAT must organize those sectors into very large clusters and can't format a volume larger than 4GB.

FAT32, in contrast, has 32-bit addresses, which means that it can name up to  $2^{32}$  (that is, 4,294,967,296) clusters. Because of this, FAT32 can use much smaller clusters even on large volumes; on volumes up to 8GB, it uses 4KB clusters. Other than this difference, however, it's the same as FAT.

The main reasons FAT and FAT32 are included with Server 2003 is for downward compatibility with other operating systems. Most often, the advanced features of NTFS will make it your first choice for a server filesystem.

#### NTFS

NTFS is the filing system especially designed for use with Server 2003, Win2K, and NT Server:

- ◆ NTFS is designed for system security (that is, setting file permissions); FAT and FAT32 are not. (You can, however, restrict access to *shared* directories even when using FAT.) To learn how file permissions work, see Chapter 11, "Creating and Managing Shared Folders."
- ◆ Only NTFS volumes support Server 2003 file encryption, disk quotas, volume mounting, and data compression. Only volumes formatted with NTFS may be extended.
- ◆ NTFS keeps a log of activities in order to be able to restore the disk after a power failure or other interruption. It won't replace *data* on the NTFS drives, but if it's interrupted in the middle of a write procedure, it will restore the volume structure. This prevents the disk's volume from becoming corrupted.

Server 2003 uses a later version of NTFS than either Win2K or NT 4 does. Not only that, if you install Server 2003 onto a machine with Win2K or NT 4 already installed, Server 2003 will automatically upgrade the NTFS volumes to NTFS 5.1, rendering those volumes unreadable by NT 4. The good news is that NT 4 can read and write to the latter version of NTFS if you install Service Pack 4 or later. To set up a dual-boot system, install NT 4, install SP4 or later, then install Server 2003. That way, when NTFS volumes exist, you'll never have a time when you can't read the NTFS volumes from NT 4.

One of the other things that NTFS can do is find its own shortcuts when you move the file that the shortcut points to—even if the shortcut is on a different computer from the one where the file is located. For example, say that there's a file called `myfile.txt` on `\\serpent\workingfiles`, a shared directory. You refer to `myfile.txt` often, so you create a shortcut to that file (using its UNC `\\serpent\workingfiles\myfile.txt`) on the Desktop of your workstation so you don't have to drill down to find the file. Even if the file gets moved on SERPENT, the shortcut on your computer will still work because the properties of the shortcut will note the new location. This feature is called Distributed Link Tracking and was introduced in Win2K.

### NAMING CONVENTIONS FOR LONG FILENAMES

All disk formats in Server 2003 support long filenames. Even FAT uses the extensions that make this possible. Filenames in Server 2003 can be up to 256 characters long with the extension, including spaces and separating periods. You can use any upper- or lowercase character in a long or short filename except the following, which have special significance to Server 2003:

? " / \ < > \* | :

Even though NTFS supports long filenames, it maintains its compatibility with DOS by automatically generating a conventional FAT filename for every file. The process doesn't work in reverse, however, so don't save a file with a long filename when working with an application that doesn't support long filenames, or else you'll only have the abbreviated name to work with. If you do, the application that doesn't like long names will save the file to the short name and erase all memory of the long filename. The data won't be erased, however; only the descriptive filename is affected.

When converting a long filename to the short format, Server 2003 does the following:

- ◆ Removes spaces.
- ◆ Removes periods, except the last one that is followed by a character—this period is assumed to herald the beginning of the file extension.
- ◆ Removes any characters not allowed in DOS names and converts them to underscores.
- ◆ Converts the name to six characters, with a tilde (~) and a number attached to the end.
- ◆ Truncates the extension to three characters.

You may want to keep these points in mind when using long filenames so your filenames will make sense in both versions. For example, you could name a file `PRSNLLET-Personal letters file.DOC`, so that the shortened name would be `PRSNLL~1.DOC`.

You can't format a floppy to NTFS format. There's a good reason for this: the NTFS file structure is complex, so finding data on large disks is fast and easy, but it takes up more room than a floppy disk can supply. Floppy disks don't need NTFS.

However, you can create files with long names on a floppy, since the Server 2003 version of FAT supports 256-character filenames. Server 2003 keeps two names for floppy files, the long name that you originally assigned and a truncated 8.3 name. DOS sees the shorter 8.3 name, making it possible for you to work with files that have long names under Server 2003 but short names under DOS.

### Which Filesystem?

Which filesystem should you use? Table 10.1 gives you an at-a-glance comparison of NTFS and the FAT filesystems.

**TABLE 10.1:** COMPARING NTFS AND FAT IN SERVER 2003

FEATURE	NTFS	FAT32	FAT
Filename length	256 characters	256 characters	256 characters under Windows 9x, NT, Win2K; 8.3 under DOS
File attributes	Extended	Limited	Limited
Associated operating system	Server 2003, Win2K, and Windows NT	Server 2003, Win2K, Windows 9x, OSR2	DOS
Organization	Tree structure	Centrally located menu	Centrally located menu
Software RAID support?	Yes	Yes	Yes
Accessible when you boot the computer from a DOS floppy?	No	No	Yes
Maximum volume size supported	2TB minus 4KB (basic), 256TB minus 64KB (dynamic)	32GB (and will not format volumes smaller than 512MB)	4GB
Cluster size on a 1GB volume	2KB	4KB	32KB
Supports extensible volumes?	Yes	No	No

NTFS supports file compression, file encryption, transaction logging that can keep your disks from becoming corrupted due to aborted writes, and granular local security. It's more efficient than FAT in the way it uses disk space, particularly on the large disks that are so common these days. You need to use it to support drive mounting and extended volumes, discussed earlier in this chapter. It builds strong bodies 12 ways. (Okay, maybe that was Wonder Bread.) So, when *shouldn't* you use NTFS?

The only times NTFS won't work for you is when you need to support other operating systems which reside *on the same computer* as Server 2003. (When it comes to network access, the filesystem does not matter—a Windows 98 computer can read an NTFS volume across the network.) FAT is widely supported by other operating systems, so you should use it on any volume that you'll need to have accessible to other OSes on the same computer. (You'll also need to put those volumes on a basic disk, recall.) The exception to this is Windows 95 OSR 2 or Windows 98. FAT32 is more space efficient than FAT, so you should use FAT32 on any volumes that need to be locally accessible to both Server 2003

and Windows 9x. FAT32 volumes are *not* readable by NT 4 without the FAT32 support available for purchase from [www.wininternals.com](http://www.wininternals.com), so if you need to keep data for NT 4, Windows 9x, Win2K, and Server 2003 and don't have this tool, you should use FAT.

### SHOULD I USE FAT ON THE SYSTEM PARTITION?

*Mastering Windows NT Server 4* recommended that you format the system partition with FAT. If you did this, then you could copy the installation files from the CD to the system partition. That way, if you needed to reinstall, you could reinstall from the hard disk after booting from a floppy instead of using the slower CD.

The only trouble with keeping all system files and said installation files on a FAT-formatted partition is that doing so is enormously wasteful of disk space. Like many of us, Server 2003/Win2K/NT has gotten fatter as it's gotten older. To be pretty sure I wouldn't run out of room, I'd need a system partition at least 2GB in size. You can format a 2GB partition with FAT—barely. That's the largest amount of disk space that FAT can “see” under Server 2003. But doing so is horribly wasteful. As discussed earlier in this chapter, the FAT filesystem is wasteful of space on large partitions because it organizes the disk into very large clusters. 2GB might not be enough to store all the system files.

Thankfully, a new tool first introduced in Win2K called the Recovery Console makes formatting the system drive with FAT no longer necessary. I'll go into the Recovery Console in detail in Chapter 19, but the short version is that it's an NTFS-compatible command-line recovery tool that you can use to get at your system directory and make repairs. You can install support for the Recovery Console while you still have a working OS; you can also get to this tool from the Server 2003 Setup program. As long as you have the original CD or the Setup boot floppies, you can get to the Recovery Console and fix things, which means that it's fine to use NTFS on the system partition.

FAT system partition or no, it's still a good idea to copy the installation files to the hard disk. That way, you've always got an easily accessible copy of them when you need them to install a new driver or service.

### USING THE FORMATTING TOOLS

If you chose not to format a volume that you created in the Disk Management tool, you can format it whenever you are ready to use it. Or you may also want to reformat an already formatted volume to quickly delete all data. You can accomplish this task either in Explorer or from the Disk Management tool, and, yes, my fellow command-line junkies, you can still do this with the command-line tool.

Of course, if you skipped Win2K altogether and are upgrading from NT4, you'll find that formatting in Server 2003 is a little different from formatting in NT and perhaps a little more confusing in terms of the GUI. First, fault-tolerant volumes can use any format that Server 2003 supports, not just NTFS. Second, you can use the Quick Format option to format any new volume, even fault-tolerant volumes, which you could not do with NT 4.

#### *Using the Gooney (GUI)*

Something that drives me a little insane when using the GUI tools to format in Server 2003 is that every dialog box seems to be different depending on how I access the volume (or do I mean disk?). Stick with me in this section and you may find yourself wanting to switch to the command-line version to format your volumes.

If you try to access an unformatted volume from Explorer, one that you have initialized but have not yet formatted, you'll see a message telling you that the disk (volume, really, but it says "disk") isn't formatted and asking if you want to format the volume now. Click Yes to format the disk, and you'll open the Format Local Disk dialog box in Figure 10.31.

**FIGURE 10.31**

Choose a filesystem for the new volume.

In the Format Local Disk dialog box, choose the filesystem that you want to use on the partition: NTFS (the default), FAT32, or FAT. If you format with NTFS, you can even change the cluster size—but that's a trick reserved only for the true filesystem junkies out there. (And for you junkies, note that file compression is only supported on NTFS volumes that have cluster sizes of 4KB or less.)

When you format a volume that has been previously formatted (either to change the existing filesystem to a different filesystem or simply to delete all the data on that volume) using either the Disk Management tool or Explorer, right-click the volume and choose Format from the shortcut menu. When you do this from Explorer, you'll see almost the same dialog box you just saw in Figure 10.31, but instead the dialog is titled Format New Volume (or whatever you titled the new volume when you initially formatted it), as shown in Figure 10.32.

If, however, you choose to perform this task from the Disk Management tool, you'll see a completely different dialog box altogether, as you can see in Figure 10.33. The only real difference (besides the obvious shape of the box) is that it doesn't show you the Capacity of the volume, as it does from Explorer. Type in any name you like and then choose the disk format you want to use: NTFS, FAT32, or FAT. Click OK, and Server 2003 will format the selected volume. Of course, any data already on the disk will be irrevocably deleted in the course of the format, so if you're reformatting, be sure that you've already saved any data on the volume that you want to keep.

**FIGURE 10.32**

Format and label the previously formatted partition or drive from Explorer.

**FIGURE 10.33**

Format and label the new partition or drive from the Disk Management tool.

If you are trying to format a dynamic volume using the Disk Management tool, you will find that only the NTFS file system will be available, although you can format dynamic volumes with any filesystem you like by using either the command-line tool or Explorer. Whew! I hope this wasn't too confusing. As you can see, there are lots of ways to format a disk in Server 2003 using the GUI.

### **The Command Line**

If you're addicted to the command prompt, you can still use it to format disks. To do so, open the command prompt from the Start menu and type the following:

**format driveletter: /fs:filesystem**

*driveletter* is, of course, the drive letter of the logical drive, and *filesystem* is FAT, FAT32, or NTFS. For example, to format a newly created E: drive as NTFS, you would type **format e: /fs:ntfs**. You must specify a file format—there's no default.

When you are ready to start formatting, keep in mind that you cannot format either the system or the boot volume. Also, if you choose to do a quick format, the files are deleted, but the disk itself is not checked for bad sectors. You should only perform a quick format if the disk was previously formatted completely and you are sure the disk is healthy.

And remember, for the best security, make all of your partitions NTFS, which is locally accessible to Server 2003, Win2K, and NT (with Service Pack 4 or later installed) and, of course, to any operating system across the network. With the addition of the Recovery Console (discussed in Chapter 19), it is no longer necessary to format the system partition with FAT for recovery purposes.

### CONVERTING FAT OR FAT32 TO NTFS

If you have FAT or FAT32 volumes on your disk that you'd like to be NTFS, you don't have to back up their data, reformat the disks, and start over. Instead, you can use the CONVERT command-prompt utility. Its format is simple:

**convert driveletter: /fs:ntfs**

So, for example, to convert the P: drive to NTFS, you'd type **convert p: /fs:ntfs**. You'd see output like the following:

```
The type of the file system is FAT32.
Volume Serial Number is B447-D3E5
Windows is verifying files and folders...
File and folder verification is complete.
Windows has checked the file system and found no problems.

523,247,616 bytes total disk space.
    4,096 bytes in 1 files.
523,239,424 bytes available on disk.

    4,096 bytes in each allocation unit.
127,746 total allocation units on disk.
127,744 allocation units available on disk.

Determining disk space required for file system conversion...
Total disk space:          512000 KB
Free space on volume:      510976 KB
Space required for conversion:  5329 KB
Converting file system
Conversion complete
```

Notice that you must have a certain amount of free space (in this case, *free space* means unused space in the partition) on the volume to convert it. That's a place to store data while the clusters are being reorganized. If you don't have enough free space, then you can't convert the volume. Thus, it's a good idea to convert volumes before they get too full.

You cannot convert to any filesystem other than NTFS, and you cannot reverse the process. You also can't convert the current drive, which means that you cannot convert the system drive to NTFS without rebooting. The conversion will happen during the reboot process.

## Defragmenting Disks

One of the simpler ways you can improve disk performance is to regularly defragment disks that need it, thus putting all the parts of each file into the same place on the disk for easier retrieval.

Defragmenting? What's that? Well, recall that each cluster can hold only one file at most, even if the data file is 1KB and the cluster is 8KB. If a file is too big to fit into a single cluster, then the remaining file data will go in the next available cluster, and the next, and the next, until the file is completely stored. Each cluster that the file's stored in contains a pointer to the next cluster where that file's data is contained, until you get to the last cluster containing data for that file and the pointer says, "That's all, folks." When you open a file stored on disk, the filesystem driver looks in the file catalog—remember the master file table?—at the top of the disk and finds the clusters that the file is stored in. It then pulls the data from those clusters and reads it into memory.

### HOW DISKS GET FRAGMENTED AND WHY YOU CARE

When a disk is new, the available clusters are all next to each other, so it doesn't matter much if a file is distributed among several clusters. As you use a disk, however, this is likely to change. Create and delete files, and clusters get freed up unevenly. And the filesystem driver doesn't look for a run of clusters big enough to store all a file's data in one place; it just stores data in the first clusters available. If clusters 1–3, 10, and 15–100 are available, file A (which needs six clusters) will go into clusters 1–3, 10, 15, and 16 and not into contiguous clusters 15–20. When a file is spread among several noncontiguous clusters, it's said to be *fragmented*.

**NOTE** *Because large FAT volumes use much bigger clusters than large NTFS volumes, files on NTFS volumes are more likely to be fragmented. This isn't an argument in favor of using FAT—those larger clusters also imply more wasted disk space, and you don't get the other benefits of NTFS—but it is an observation about how clusters work. You can increase the cluster size on NTFS volumes if you'd like to reduce file fragmentation.*

Data is stored in the cluster it's originally put in—if a more convenient cluster becomes available, then the data isn't moved. Even if clusters 4–9 become free when a file is deleted, file A will keep using the same clusters it started with.

This isn't terrible. You'll still get all the data from the file, even if the file is fragmented. However, it will take a little longer to open fragmented files, and in case of serious disk errors, it's harder to recover badly fragmented files than ones stored in contiguous clusters. A *very* fragmented system disk can actually cause Server 2003 to crash if it takes too long to find a file that it needs. Therefore, it's a good idea to keep your disks defragmented.

### WHAT'S NEW IN SERVER 2003'S DEFRAG TOOL?

Server 2003 comes with a defragmenter tool which has seen some much needed improvements over the version that was previously released with Win2K. Until now, you were not able to defragment volumes that were formatted with greater than a 4K cluster. In addition, Disk Defragmenter (the new defragmentation tool) can now defrag the master file table (MFT)—Win2K couldn't do this, which was certainly

one reason why so many chose a third-party defragmentation utility over the free one. Essentially, the MFT keeps track of all of the files on a volume—it's similar to the file allocation table in FAT partitions—and if that gets fragmented, it can cause serious performance issues, since it increases the number of reads required to find a file. Microsoft says that Server 2003's defragmenter tool has also been seriously improved in terms of speed. These are good improvements, but they may not be enough to convince administrators not to look elsewhere for a defrag tool, since most of the better third-party tools include the ability to defrag across the network along with other useful tools.

### USING THE DISK DEFRAGMENTER

To use Disk Defragmenter to defragment a volume or see whether it needs to be defragmented, right-click the volume in Explorer or in the Disk Management tool and open the volume's property sheet. Click the Tools tab that's shown in Figure 10.34.

**FIGURE 10.34**

The Tools tab contains all disk maintenance tools.

Click the Defragment Now button to open the screen shown in Figure 10.35. Notice that only local volumes are listed. You can't defragment volumes across the network.

First, see whether the disk needs to be defragmented at all. Highlight the volume in the list and click the Analyze button. The Disk Defragmenter will chug away for a minute (it's pretty fast—a 2GB volume took only a few seconds to analyze) and then display its recommendation (see Figure 10.36). If the analysis says the volume is "dirty" which indicates possible corruption, you should run CHKDSK to assess the health of the volume. You'll learn all about CHKDSK in the next section if you are not already familiar with the tool. You can find out if a volume is dirty by typing **fsutil dirty query** at the command prompt.

**FIGURE 10.35**

The Disk Defragmenter shows all logical volumes on the computer.

**FIGURE 10.36**

Analyze disks before defragmenting them.

If you want to see more information about how fragmented your disk is, click the View Report button to open the dialog box shown in Figure 10.37.

**WHAT DOES ALL THIS MEAN?**

What are you looking at here? The top part of this dialog box displays six types of information:

- ◆ Basic volume statistics
- ◆ Volume fragmentation
- ◆ File fragmentation
- ◆ Pagefile fragmentation
- ◆ Folder fragmentation
- ◆ Master file table fragmentation

**FIGURE 10.37**

View the report to see how badly the disk is fragmented.

Most of the information about the volume should be pretty simple to figure out: the volume size is the size of the partition, the cluster size is the size of each logical storage unit on the drive (in this case, 4KB, or 8 sectors), and the rest of the section describes how much space on the disk is currently used, how much is free, and what the percentage of free space is. Although you can't see all of the details of the report in Figure 10.37, if you will run a report of your own, you can follow along while I discuss the rest of the information which is visible by using the scroll bar in the upper window of the Analysis Report dialog box.

The Volume Fragmentation section below the Volume Information section is a little more relevant to the question of how much file reads are delayed, describing the status of the files themselves. The total fragmentation describes how fragmented the entire disk is; the file fragmentation tells how fragmented the used parts of the disk are (that is, the proportion of files that are fragmented), and the free space fragmentation describes how fragmented the unused space on the disk is. Free space fragmentation matters when it comes to creating new files—the more fragmented the unused space, the more likely it is that new files will be fragmented too.

File fragmentation gives you file-level fragmentation information. This area lists the total number of files on disk, the average size of a file, the total fragments, and the average number of fragments per file. Ideally, the value for fragments per file should be as close to 1.00 as possible, as that number indicates that all files are contiguous. In this particular analysis, the ratio is 1.25, which indicates that about 25 percent of files are fragmented into two or more clusters. As you can see in Figure 10.37, the recommendation was that running defrag was necessary in this case. The Most Fragmented Files window at the bottom of this dialog box gives you more specifics about which files are most

fragmented, but you don't need to worry about this unless you're interested in comparing the "before" and "after" results.

**TIP** If you are interested in comparing the before and after readings, click the *Save As* button to save the entire fragmentation report as a text file or click the *Print* button to print out a report.

The rest of the information shows fragmentation for specific parts of the disk volume structure so you can see just how fragmented the pagefile and master file table are in your system.

That's the current status of your volume. To fix it, close any files (including application files) currently using the fragmented volume, then click the *Defragment* button. The tool will start reorganizing the files on the disk to put them into contiguous clusters. Defragmenting the disk will *not* free up space on the disk, but it will group all free space together to allow it to be used more efficiently, which can greatly improve the performance of your system.

**NOTE** You can defragment a volume with open files, but this makes it difficult to defragment the system volume. It will take much less time if you close all files first.

### GIVE DEFRAG SOME SPACE!

When's the last time you cleaned out your desk? It usually works best to take everything out and lay it on top of the desk or on the floor beside you before you start putting everything back into the desk, carefully setting things back in a more orderly fashion than they were before. After all, why would you bother cleaning it out if you weren't going to make it more organized? That is what the defrag tool is all about, and it needs some room to do the job. So make sure that you defragment your disks before they get too full. The Disk Defragmenter requires 15 percent of free volume space to store data that it's rearranging. If the volume is too full, you'll need to remove files or (if possible) extend the volume before you can defragment it.

### FOR REAL ADMINISTRATORS: THE COMMAND LINE

For those of you who thrive on never using the mouse unless Microsoft forces you to, Server 2003 also ships with a command-line tool that will both analyze and defragment your disks. It isn't nearly as pretty as the GUI version, so if you analyze your disks just to see the bright colors that represent your files as a quick pick-me-up on an otherwise dreary day, this isn't the tool for you. Here's what the output looks like for a quick volume analysis and report.

```
C:\>defrag c: /a /v
Windows Disk Defragmenter
Copyright (c) 2001 Microsoft Corp. and Executive Software International, Inc.
```

#### Analysis Report

Volume size	= 5.99 GB
Cluster size	= 4 KB
Used space	= 1.93 GB
Free space	= 4.06 GB
Percent free space	= 67 %

```

Volume fragmentation
    Total fragmentation          = 10 %
    File fragmentation          = 21 %
    Free space fragmentation    = 0 %

File fragmentation
    Total files                  = 12,033
    Average file size           = 190 KB
    Total fragmented files      = 1,503
    Total excess fragments      = 3,063
    Average fragments per file  = 1.25

Pagefile fragmentation
    Pagefile size               = 768 MB
    Total fragments             = 1

Folder fragmentation
    Total folders               = 807
    Fragmented folders          = 37
    Excess folder fragments     = 545

Master File Table (MFT) fragmentation
    Total MFT size              = 13 MB
    MFT record count            = 12,856
    Percent MFT in use          = 99
    Total MFT fragments         = 2

```

You do not need to defragment this volume.

I just showed you the command to do just the analysis and report. Here are some of the other available commands you can use with the defrag tool.

To perform an analysis on a single drive, you should type:

```
defrag <drive>: /a
```

To both perform an analysis and see results of the analysis, type:

```
defrag <drive>: /a /v
```

To defragment a drive, type:

```
defrag <drive>:
```

If you want to both defragment a drive and see the defrag report, type:

```
defrag <drive>: /v
```

While the volume is being defragmented, you will see a blinking cursor. When the defrag tool is finished, it will display the analysis and/or the defrag statistics—depending on what you asked for—and then exit to the command prompt. Note that you can only run one version of the defrag tool

(you have to choose either the GUI or the command-line version) at one time, even on two different volumes. If you try to run both the Disk Defragmenter and the defrag command-line tool at the same time, you will get an error that looks like this.

```
C:\>defrag c: /a /v
```

Another command line or GUI defragmenter is already running.

Only one instance of Windows Disk Defragmenter can run at a time.

As with the GUI version of this tool, you can send output to a file. It might also be handy to know that you can now defragment at the same time you are performing a backup on the volume; this is new in Server 2003.

## Using CHKDSK

File data is stored in clusters. If a file is stored in more than one cluster, then each cluster the file's stored in contains a pointer to the next cluster holding file data. If those pointers are lost, you can't pull up the entire file from disk.

NTFS's transaction logging prevents this from happening. Each NTFS volume maintains a *transaction log* of all proposed changes to the volume structure, checking off—*committing*—each change as it's completed and only then. When you restart the system, NTFS inspects the transaction log and rolls the state of the disk back to the last committed change. Basically, it's similar to the Last Known Good option that you can choose on startup to restore your server to its status at the last successful boot, except that transaction logging and rollback is automatic. Notice that transaction logging works only for *system* data, not for user data. If the disk failed in the middle of a write action, then the data that was supposed to be written to disk is lost. However, the volume structure of the disk will be all right. Any data already written to disk will be recoverable.

FAT and FAT32, however, do not have transaction logging. If the disk fails—perhaps due to a kicked power cord or a good hard knock by the infamous janitorial staff's vacuum cleaner—before a write action is completed and you restart the disk, there's no record of the last valid disk structure. You may need to run CHKDSK to check the pointers used in the file allocation table.

**NOTE** *This isn't to say that there's never any need to run CHKDSK on an NTFS volume—NTFS protects the integrity of filesystem data, or metadata, not user data.*

You can use the command-line version of the tool to edit the size of the transaction log or to check the disk for bad sectors (sectors to which the filesystem shouldn't write because they're damaged and might not read properly). Read on to learn more about what CHKDSK is doing and how to use both the graphical and command-line versions.

## WHAT IS CHKDSK DOING?

Let's take a look at how CHKDSK works on an NTFS volume. When you run CHKDSK, you're telling the tool to make three passes over the specified drive to examine the structure of the metadata on the disk—again, that's the data describing how user data is organized on the disk. Metadata tells the filesystem what files are stored in which clusters, how many clusters are free and where they are, and what clusters contain bad sectors. In addition, it provides pointers to files.

During CHKDSK's first pass over the selected drive, it scans each file's record in the master file table (MFT). It examines each file's record for consistency and lists all the file records in use and which clusters those file records are stored in. It then compares this record with the drive bitmap stored in the MFT. Any discrepancies between the two are noted in CHKDSK's output.

During the second pass, CHKDSK checks the drive's directory structure. It makes sure that each index record in the MFT corresponds to an actual directory on the drive and that each file's record in the MFT corresponds to a file stored somewhere in the volume. CHKDSK also makes sure that all time and date stamps for all files and directories are up to date. Finally, it makes sure there aren't any files that have an MFT entry but don't actually exist in any directory. If the MFT entry is complete, the file can usually be restored to the directory where it should be kept.

The third pass of CHKDSK is for checking the integrity of the security descriptors for each file and directory object on the NTFS volume. During this pass, CHKDSK makes sure that all security settings are consistent. It does not check the security settings to make sure that they're appropriate to a particular folder or even to make sure that the group or user account named exists. Rather, the security pass of CHKDSK simply makes sure that, assuming all security information is correct, the security settings for the files and directory objects in the volume will work.

The final and optional pass of CHKDSK (performed only if you use the /R switch) tests the sectors in the volume reserved for user data (the metadata sectors are always checked) to see whether all of them can be read from and written to correctly. If CHKDSK finds a bad sector, then it marks the placement of this sector in the volume report. If the sector was part of a cluster that was being used, CHKDSK will regenerate and move the data to a new cluster that contains only good sectors if the volume is fault tolerant, or fill the bad sector with a string that means "no data should be stored here." The data in the bad sector won't be recovered unless there's some redundant data to copy it from, but at least the filesystem won't store more data in the cluster containing the bad sector.

How long does this process take? Depends on the size of the volume, the depth of the check, and what else the computer is doing during the check. CHKDSK is extremely CPU and disk intensive, and if it must contend with other processes for CPU time, the check will necessarily take longer. The best rule of thumb is that, if you can avoid it, you shouldn't run CHKDSK on a computer that is actively trying to do something else. In any case, you can't run CHKDSK on a volume that currently has files open. If you attempt to do so, CHKDSK will tell you that it can't get exclusive control of the volume and ask if you want to schedule the check for the next time the computer restarts.

There are two forms of CHKDSK in Server 2003: the graphical tool and the command-line utility. The graphical tool is simpler to use, but the command-line utility has many more options and is more flexible.

**NOTE** *The version of CHKDSK changes as the file systems change. In other words, the version that came with NT 4 is not compatible with the newer versions of NTFS because the NTFS file structure is different. So make sure you use the version of CHKDSK that comes with the OS that you are working on.*

## **RUNNING CHKDSK FROM EXPLORER**

The simplest way to run CHKDSK is from Explorer, as this tool doesn't demand that you know the command syntax and just uses the default options. To use the tool, select a drive in Explorer and open its property sheet. Turn to the Tools tab, then click the Check Now button to open the dialog box in Figure 10.38.

**FIGURE 10.38**

The graphical  
disk checker

There are two options available from the graphical version of CHKDSK. If you tell CHKDSK to attempt to fix file system errors, then it will try to resolve any orphaned files—files that have entries in the file system catalog but don't appear in a directory on the volume. If you check the box that tells CHKDSK to scan for and attempt recovery of bad sectors, you're telling it to make the optional fourth pass of checking each sector on the disk instead of just those containing meta-data. As you'll recall from the description of what CHKDSK does, data in bad sectors will not always be recoverable—only if the volume is fault tolerant and CHKDSK can get the data's redundancy information elsewhere is the data recoverable.

To begin checking the selected volume, click the Start button. The computer will begin grinding away using the options you supplied. (If you don't check either box, CHKDSK runs in read-only mode. Since the graphical tool doesn't display a report, read-only mode doesn't help you much.) The dialog box will display each phase of the disk check and display a status bar showing how far along each pass is until it's completed.

When the disk check is done, a message will appear telling you that the disk has been checked. No report of bad sectors or other information will appear. You can check another disk by exiting the current drive's property sheet and selecting another drive from Explorer.

### **RUNNING CHKDSK FROM THE COMMAND PROMPT**

You have little control over how CHKDSK works when you run it from Explorer. If you'd like more control, you'll need to use the command prompt. The command-line options can be a little tricky to use, but they're faster and more flexible than the GUI once you get accustomed to them.

Without any arguments, CHKDSK runs in read-only mode on the current drive. You'll see command-line output showing the progress of each pass over the volume, and then you'll get a report like the following, showing you how the total disk space is used:

```
2096450 KB total disk space.
1011256 KB in 9214 files.
  2248 KB in 539 indexes.
    0 KB in bad sectors.
 31116 KB in use by the system.
  4096 KB occupied by the log file.
1051830 KB available on disk.

2048 bytes in each allocation unit.
```

```
1048225 total allocation units on disk.
525915 allocation units available on disk.
```

You should recognize the terminology used from the previous discussions of how NTFS organizes files on disk. The indexes are in fact directories on the disk. The log file is the transaction log used to record changes to the volume metadata so that any incomplete changes can be rolled back. The allocation units are clusters.

So—you’ve got a disk report, but that report doesn’t allow you to do anything. To control the process, you’ll need to plug in one or more of the switches explained in Table 10.2.

**TABLE 10.2: COMMAND-LINE SWITCHES FOR CHKDSK**

<b>SWITCH</b>	<b>WHAT IT DOES</b>
<code>/f</code>	Tells CHKDSK to attempt to fix file system errors, such as orphaned files. The help file for this switch says that it fixes errors on the disk, but that’s not really accurate. It fixes inconsistencies in the file system catalog.
<code>/v</code>	Has different results depending on whether you use the switch on FAT volumes or on NTFS. On FAT volumes, this switch lists the full path of every file on the volume. On NTFS volumes, it runs CHKDSK in verbose mode, reporting any cleanup messages relevant to fixing filesystem errors or missing security descriptors.
<code>/r</code>	Checks every sector on the disk to make sure it can be written to and read from. Any bad sectors are marked as bad.
<code>/x</code>	Forces the volume to dismount first if dismounting is necessary to run CHKDSK (that is, if there are open handles to the chosen volume). Choosing this option will dismount the volume being checked.
<code>/i</code>	Tells CHKDSK not to check the indices on NTFS volumes. In other words, CHKDSK will skip the second pass of the disk checking operation. Although selecting this option can save you quite a bit of time on volumes with a lot of directories, it’s not a good idea to use this switch unless you must; using it causes any inconsistencies in the directory structure to go unnoticed.
<code>/c</code>	Tells CHKDSK not to check for cycles on the NTFS volume. Cycles are a rare kind of disk error wherein a subdirectory becomes a subdirectory of itself, creating an infinite loop. You can probably turn this switch on safely since cycles are rare, but it won’t save you much time.
<code>/l[:size]</code>	On NTFS volumes, specifies a new size for the transaction log. The default size is 4096KB, and for most purposes that’s just fine.
<code>volume</code>	Specifies the mount point, volume name, or (if followed by a colon) the drive letter of the logical volume to be checked.
<code>filename</code>	On FAT volumes, tells CHKDSK to evaluate the specified filename to report on how fragmented it is. This option does not work on NTFS volumes.

The order of the switches is as follows:

```
chkdsk [volume[[path]filename]] [/f] [/v] [/r] [/x] [/i] [/c] [/l[:size]]
```

## Advanced Disk Management Topics

The earlier sections in this chapter covered the basics, introducing the grammar of disk management in Server 2003 and showing you how to set up the various kinds of logical divisions available on the physical disks. I also discussed how to maintain your disks and the data that resides on them. So, as long as all you're ever planning on doing is setting up volumes once, you're fine.

Things rarely remain that simple, however. What if you want to install a second copy of Server 2003 on the same computer—what kind of volume can it reside on? Dynamic disks on the same computer, as you've learned, share information. If you move a physical disk from one computer to another, then what happens to that shared information? For that matter, how do you recover from a boot disk failure if you mirrored it? That's what we're going to talk about here.

### Windows Server 2003 Setup and Dynamic Disks

Say that you've installed Server 2003 on a computer, fudged around with the Disk Management tool a bit, and now want to create a parallel installation of the OS. If you have dynamic and basic disks and a variety of the divisions of those disks available, where can you install Server 2003?

If you're attempting to install to a basic disk, it's easy. You can install Server 2003 on a primary partition or on a logical drive within an extended partition. (It's okay to install on an extended partition. Server 2003 will make it a boot partition.) Or, if the basic disk has enough unallocated space, you can use Setup to create a new partition. If you've ever installed Win2K or Server 2003, you know all about installing to basic disks, since that is the default.

Dynamic disks make life more complicated. Setup (and the Recovery Console described in Chapter 19) only recognizes dynamic disk partitions that are *hard-linked*, or created when you upgrade a basic disk (with preexisting primary partitions or logical drives configured) to dynamic. Each of the preexisting partitions retains a legacy-style partition table entry (type 42 for primary and type 05 for extended), even after upgrading the disk to dynamic. These special hard-linked entries allow Setup to recognize them as valid partitions for installation. In other words, you cannot install Server 2003 to a volume that you created *after* upgrading the disk to dynamic. The disk may appear in the list of available options in Setup when you're picking the partition to install to; Setup will display a drive letter for the dynamic volume, so if your dynamic disk had only one volume, you might be fooled into thinking everything is okay. However, if you select the native dynamic volume, Setup will tell you that it can't recognize it and ask you to pick another option. This means that you cannot install Server 2003 onto a simple volume, spanned volume, stripe set without parity, or stripe set with parity created on a dynamic disk, since by definition all those volume types are created from unallocated space on a dynamic disk. You can install Server 2003 onto a dynamic disk only if you pick a partition that existed before you upgraded the disk and is now a simple volume. Remember though, the partition had to exist while the disk was a basic disk, so that Setup can find the disk location in the disk boot record.

Good so far? Here's where things get strange. If you decide not to believe a word that I have said about not being able to install Server 2003 on a native dynamic partition and you insist on trying it yourself, you'll find some very strange behavior. Say you're creating a parallel installation of Server 2003 and attempt to install it onto a dynamic disk. You might see what looks like your dynamic disk—it will have the volume name and even the drive letter you assigned it—but the disk space estimates will probably be way out of synch with what you know the volume to be. And if you try to delete an existing dynamic partition and attempt to create a new partition, you'll just end up deleting ALL the volumes on that disk and in the end you will find yourself with a basic disk. In other words, creating new

volumes on a dynamic disk during Setup will destroy any data currently on the disk and convert it to basic without warning.

**WARNING** *Don't create partitions on dynamic disks during Setup.*

In short, keep the following in mind when choosing a location for a secondary Server 2003 installation:

- ◆ Any partitioned or unpartitioned space on a basic disk: good
- ◆ Any hard-linked volume on a dynamic disk: good
- ◆ Any soft-linked volume on a dynamic disk: impossible
- ◆ Creating new partitions on a dynamic disk: very bad

Frankly, if you want to make the system partition fault tolerant, then the easiest way is—as was the case for Win2K—still to install Server 2003 onto a basic disk and then upgrade that disk to dynamic. The primary partition that you installed Server 2003 into will become a simple volume, and you can mirror that volume onto another dynamic disk. Which leads us nicely to our next topic: making the system disk dynamic.

## Upgrading a System Disk to Dynamic

When you upgrade disks in Windows Server 2003 from basic to dynamic, all partition information is moved into a private database at the end of the disk. Only one partition table entry of type 0x42 is entered in the master boot record (MBR) at sector 0.

The process of becoming dynamic is different for disks containing the system or boot partition. The process with system/boot disks is called *rooting*. When Server 2003 roots a disk, the system partition remains intact, but the Filesystem ID fields are changed to 0x42 to show that they are dynamic volumes recorded in the database at the end of the volume. The system partition remains intact so that the BIOS knows how to communicate with the disk and can boot Server 2003. This is done so that the BIOS can load the kernel and other files necessary to start the Disk Management driver files to read the dynamic volumes. If there is any unallocated space on the volume, an entry is added similar to those of other dynamic volumes (not rooted) that encompasses the rest of the space.

If you want to revert the system disk, you're a bit stuck. As noted earlier, the option to revert volumes from dynamic to basic only exists if the disk is empty and unpartitioned. You can't delete the system partition when you're using it. Backing up the system configuration, reformatting the disk, and reinstalling is really your only option.

## Moving a Dynamic Disk

You might want to move a dynamic disk to a new computer, say, if you're moving half a mirror set to re-create duplicate data on a different computer. Recall that Server 2003 organizes dynamic disks into disk groups. When you move a dynamic disk from one computer to another, you're moving it to a new group, because even if those disk groups have the same name (as they will, since Windows Server 2003, Standard Edition only supports one disk group per computer and they're numbered starting with 0), they're not the same group. Therefore, to make this work, you'll need to introduce the disk you're moving to its new disk group—*without* deleting the volume information on the disk you're moving.

**NOTE** *In case it's not obvious, when you move the last dynamic disk from a computer, the disk group no longer exists, since dynamic disk information is stored only on dynamic disks.*

### PREP WORK

Before you start swapping disks around, take a look at what you've got. First, if any multidisk volumes don't show up as Healthy in the Disk Management tool, then fix them before moving the disk. Second, if you're planning to move more than one dynamic disk from the same disk group that contains parts of the same multidisk volume, it is a *very* good idea to move all those disks at once. Spanned volumes won't work unless all their disks are present—you will lose their data if you only move one of the disks supporting a stripe set or spanned volume—and fault-tolerant volumes may get out of sync. For instance, say that you have a mirror set on server ALPHA. If you *break* that mirror set and move half of it to server BETA, then you don't have a problem. But if you keep the mirror set intact, move half of it to server BETA, and keep using the disks on both systems (you can keep writing to a failed mirror set in Server 2003; it'll just show up as Failed Redundancy in the Disk Management tool), then try to move the other half from ALPHA to BETA, the data on the two mirror halves will be inconsistent. In such a case, Server 2003 will re-create the mirror set with the data from the physical disk moved first to BETA.

In this discussion, I'm going to call the computer you removed the disk from the *source* computer and the computer you moved it into the *destination* computer. When you remove a dynamic disk from a computer, information about it and its volumes is retained by the remaining online dynamic disks. The removed disk is displayed in the Disk Management tool on the source computer as a Dynamic/Offline disk with the name Missing. You can remove this Missing disk entry by removing all volumes or mirrors on that disk, and then use the Remove Disk menu item associated with that disk.

### INTRODUCING THE NEW DISK

After you physically connect the disks to the destination computer, open the Action menu and choose Rescan Disks. The new disk will show up as Dynamic/Foreign. By default, Dynamic/Foreign disks should be brought online automatically, but if it's not, then right-click the disk and choose Online.

To use Dynamic/Foreign disks, you'll need to *import* them. Right-click one of the moved disks and choose the Import Foreign Disks option. The importing procedure works slightly differently depending on whether there's already a disk group on the new computer. If there are no preexisting online dynamic disks, then the disk group is brought online directly as it is, except that you'll lose any nonredundant information partially contained on disks you didn't move (e.g., if you moved only one disk supporting a stripe set). The disk group remains the same as it was; the database doesn't change. If a disk group was already present on the destination computer, then Server 2003's Volume Manager will merge the old disk group information with the new disk group information, so that all the dynamic disks can work together. The imported disks will become members of the local disk group.

### CAN I USE THE DATA ON THE MOVED DISKS?

So what happens to the volumes on the dynamic disks you moved? Well, that depends on whether you moved enough data for the volume to work. Either the data or the redundancy data to re-create the data must be on the destination computer.

Simple volumes, which are contained on a single disk, should be fine if they were fine before you moved the disk.

If you moved only part of a multidisk but non-fault-tolerant volume, such as a volume set or stripe set, that volume is disabled on both the source and destination computers until and unless you move the disks containing the rest of it. So long as you don't delete the volume on either the source or

destination computer, you should be able to move the rest of the volume to the destination computer and re-enable it, but you will need to move all the disks supporting that multidisk volume. If you delete and overwrite part of the volume, you can't rebuild the volume.

If you move a disk containing part of a RAID 5 volume, then the data may be available even if you didn't move the entire volume to the destination computer; this depends on whether you moved enough parity data to regenerate what's missing. If the parity information is valid, one disk of the RAID 5 volume can be missing and the volume should still work, just as it would if one of the disks in the volume failed.

If you move a mirror set that's up to date, then you can use the data on the new computer or even (if you broke the mirror set on the source computer) re-create the mirror set using unallocated space on a dynamic disk on the destination computer. If you move the two halves of the mirror set at different times, then reaffixing the mirror set on the source computer will cause the first mirror half to overwrite any data on the second mirror half. So, if you made changes to the second mirror half and then moved that disk to join its ex-twin on the new machine, those changes will be lost, not merged when the two halves come together again.

**WARNING** *All these comments apply to data disks. If you move the system disk to a new computer, the computer will not boot unless the right Plug-and-Play ID information for the mass storage controller is already in the Registry. Otherwise, Server 2003 will not be able to load the right drivers. The simplest way to avoid this situation is to only move system disks to computers that are identical to the source computer.*

## Changing a System Drive Letter

Under a couple of circumstances, you might need to change the system drive letter. If you mirrored the boot disk and the main disk fails, then when you break the mirror, the second—working—partition will automatically be assigned the next available drive letter. Which means that if Server 2003 still thinks that, say, C: is the boot drive, you're going to have a hard time booting if the only working system drive is now called J:. Or, as one reader wrote:

*I made the mistake of leaving an alternate drive in my laptop when I installed [DOS followed by] W2K on the primary drive. Now the boot disk (which ought—in the natural order of things—to be “D”, as I have the DOS partition) is H:. And of course, the W2K tools won't let me reassign the drive letter at all. (In NT, you could reassign the drive letter—but you had to reboot when you left Disk Manager.) Know of any way that I can get that H: to D:?*

Although this question was written during the days of Win2K, this dilemma still exists in Server 2003 and, since it's still a common question, I'll include it. Trouble is, if you right-click the system volume in Disk Management and choose Change Drive Letter and Paths from the shortcut menu, then, although you'll be able to open the dialog box you'd normally use for this purpose, when you click the Change button to do the actual editing you'll see an error message telling you that you can't modify the drive letter of your system or boot volume. What to do?

To change or swap drive letters on volumes that cannot otherwise be changed using the Disk Management snap-in, you'll need to edit the Registry. For example, say that you want to swap H: and D:. Open REGEDIT or REGEDT32 and go to the HKLM\SYSTEM\MountedDevices key. Within that key are values for each of the lettered drives on your computer. In the list, find \DosDevices\D:. Right-click it and choose Rename to edit it to \DosDevices\Y: (or some drive letter not currently being used).

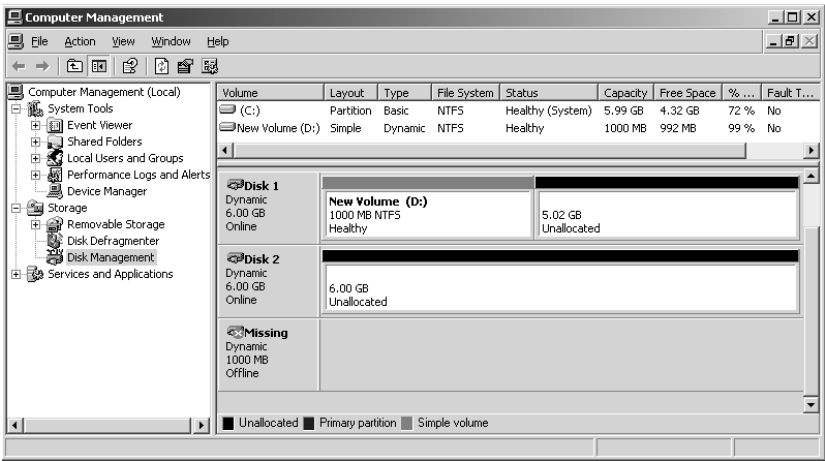

***TIP** To make this change, you'll need Full Control over the HKLM\SYSTEM\MountedDevices key. In Win2K, you would have had to edit the security settings for the key in REGEDT32 and then use REGEDIT to actually rename the key. Finally (!), Microsoft has merged those two tools, combining the best features from both. REGEDIT had some good features and REGEDT32 had some different good features. Now you can use either tool to both edit the security settings and rename the key. In fact, the interface for both tools is identical. Way to go Microsoft!*

Next, right-click \DosDevices\H: and change it to \DosDevices\D:. Finally, right-click \DosDevices\Y: and rename it to \DosDevices\H:. (If you're only changing one drive letter, then you don't need to do the swapping—just change the drive letter to the unused letter.) You'll then need to restart the computer.

**Recovering a Failed Data Disk**

Recovering from simple disk failure isn't too bad, if the disk that died is not the disk with the operating system files on it. If you accidentally switch off an externally mounted drive, or if the drive comes loose in the box, any volume sets or nonparity stripe sets that depended on that disk will be temporarily dead—reasonable, because for all practical purposes, one of its disks has failed. The missing disk either will not show up in the Disk Management tool at all (if you rebooted with the disk off) or will show up with a Missing label on it (see Figure 10.39).

**FIGURE 10.39**  
A dead drive in the Disk Management tool

If it's a simple matter of a loose cable or an accidentally flipped power switch, just reconnect the cable or switch the drive back on. After you've done so, right-click the Disk Management tool's icon in the left pane with the rest of the Computer Management tools and choose Rescan Disks. You'll see an informational dialog box telling you that the Disk Management tool is rescanning. When it's done, right-click the failed volume and choose Reactivate. Server 2003 will caution you to run CHKDSK on the volume. Click OK, and your disk will appear as it was before, and the volume set will again have a drive letter and be operational.

Or, if you're just recovering from a single failed data disk in a fault-tolerant disk volume (mirror set or RAID 5 volume), you can use the procedures I just described to regenerate the missing data and make the volume fault tolerant again. Even before you do so, the data will still be available.

**TIP** If you are using disk duplexing—where each disk has its own controller—prior to installing a new disk to replace a failed disk in a mirror set, make sure you break the mirror and look in the system logs to make sure the disk is really the problem. It could be the controller. If the controller is failing, installing a new disk will not solve the problem, you'll have to replace the controller.

## Creating and Using a Fault-Tolerant Dynamic Disk for System Recovery

A lot of people ask whether they can use a dynamic disk for their boot disk and thus make it fault tolerant. The answer is yes... to a point. Since you can't install Windows Server 2003 onto a native dynamic disk partition (Setup and the Recovery Console rely on the partition table, not the disk group's database, to find disk partitions) you can only use mirroring to protect a system disk. A RAID 5 volume is, by definition, a native dynamic disk volume, but a mirror may be built from a partition on a basic disk later upgraded to dynamic.

**NOTE** Just a reminder: you will need at least two physical hard disks in the server to mirror its system partition.

To mirror the system files, install them onto a basic disk as you would normally; we'll call this Disk 0. Having made sure that there is an area of unallocated space of equal size to the system partition, on another disk—Disk 1—upgrade Disk 0 to dynamic. Upgrade Disk 1 to dynamic as well. Now, right-click the system partition on Disk 0 and choose Add Mirror. As described earlier in this chapter, select the dynamic disk with the empty space that you want to copy the original system data to, and create the mirror. The data on the newly mirrored system partition will be copied—*resynched*, in Disk Management tool lingo—to the blank half of the mirror set, as shown in Figure 10.40.

**FIGURE 10.40**

Building a mirrored boot partition

The system disk is now fault tolerant. Good thing, because the next time you boot the computer, you see a message like this:

Windows 2000 could not start because of a computer disk hardware configuration problem. Could not read from the selected boot disk. Check boot path and disk hardware. Please check the Windows documentation about hardware disk configuration and your hardware reference manuals for additional information.

This message does not inspire happy thoughts. What we've got here is a failed primary partition.

Microsoft has made yet another huge improvement with the release of Server 2003. In the old days of Windows 2000, if the primary partition failed, Win2K wasn't smart enough to say, "Hey—the partition I normally boot from isn't working. I guess I'll boot from this mirrored partition that was so cleverly built for me and then tell the sysadmin that the primary boot partition failed so they can fix the mirror." When that happened, you had to create a Windows 2000 boot disk, edit the `boot.ini` file to let Win2K know where to boot from, then reboot the machine using the floppy to get into Win2K. It wasn't clever enough to realize that since the system partition was mirrored, it could simply boot from the remaining half of the mirror. In Server 2003, however, the system recognizes the mirror as soon as you create it and edits the `boot.ini` file for you, allowing you to boot from the mirrored partition any time you boot the machine.

## The Rest of the Story

There were lots of new features introduced in Win2K that related to storage, among them encrypted file system, dynamic disks, disk quotas and mounted volumes. Server 2003 has added even more features and functionality to the OS, both improving some services that debuted in Win2K and giving us a few new tools, such as the Volume Shadow Copy Service, which will enable users—yes, *users!*—to be able to restore lost versions of files without calling the overworked and (admit it) sometimes testy sysadmins. Some other examples of cool new features in Server 2003 are open file backups, support for SANs, and the ability to extend basic disks using the new and powerful command-line disk management utility DiskPart. (I introduced DiskPart, which is installed by default, in my discussion of basic disks.)

Now that you are (I hope) more comfortable with the types of storage that Server 2003 offers and know how to manage the disks in your system, I'll go over a few of the more useful features that can give you even more control over the way you manage the files on those disks.

## Using Encrypted NTFS

Native public key encryption, allows you to secure your documents and folders so that only you—or the people you give the key to—can view the documents. It's a handy way of keeping even shared documents private or of protecting files on a machine that can be easily stolen, such as a laptop.

Encryption doesn't conceal the fact that the documents exist. Rather, when you attempt to open an encrypted file, Server 2003 checks to see whether you have a key to that file. If you don't, then you're forbidden access to the file. This denial is not application dependent—for example, a Word document won't be accessible in Word or WordPad. The user without the public key can't open the file object at all.

**TIP** *The process of checking for an encryption key is processor intensive, so it's probably best not to encrypt files stored on a terminal server or other CPU-bound server.*

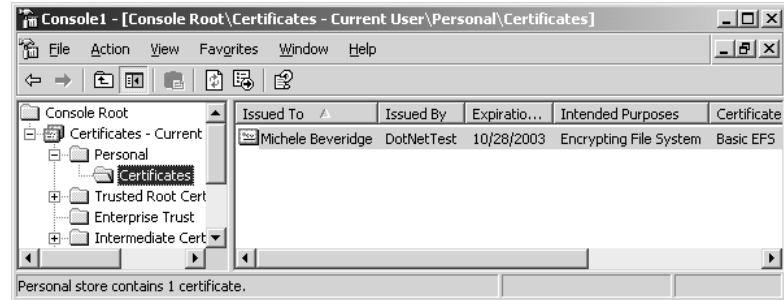

Since encryption is an attribute, like compression or the archive bit, it's only supported on NTFS volumes in Win2K and Server 2003, as far as servers go.

## HOW SERVER 2003 ENCRYPTION WORKS

When you encrypt data, you're generating a request for a new security certificate identifying you to Server 2003 as who you say you are. A *cryptographic service provider (CSP)* generates two 56-bit keys: a public key, used for encrypting data for you, and a private key, used for decrypting that data. The two keys are unrelated—knowing a public key does not give you the ability to guess the private key.

The CSP passes the public key to the certificate authority, which uses it to create a public key for you. The certificate and public key are stored in the `Personal\Certificates` folder located in the Certificates add-in to the MMC (see Figure 10.41).

**FIGURE 10.41**  
Personal encryption  
certificate

Users can encrypt data across the network, but the data is only encrypted when written to a disk, not while traveling across the network—you'll need network encryption for that. Only Server 2003, XP and Win2K users will be able to encrypt and decrypt data. Even though NT and Windows 9x users can read and open files on the newer NTFS volumes and, even though encryption standards apply to them too, the NT and Windows 9x users don't have the tools they'd need to encrypt the data unless they're running a Server 2003, XP or Win2K session.

This information isn't required when it comes to encrypting or decrypting your own data, but it could come in handy when it comes to recovering someone else's encrypted data or in protecting laptop encryptions. We'll do the simple part first, and then return to the question of why you need to protect certificates and how you can do it.

### Encrypting Files

To encrypt a file or folder from Explorer, right-click the file or folder (you cannot encrypt entire volumes) and open its property sheet. On the General tab, click the Advanced button to open the Advanced Attributes dialog box shown in Figure 10.42.

**TIP** If there isn't an Advanced button visible, make sure that you're looking at an NTFS volume, not a FAT or FAT32 one.

**FIGURE 10.42**  
Encryption is an  
advanced NTFS  
attribute

You can either compress or encrypt file data, not both. Check the option you want and click OK. If the folder containing the file is not encrypted, you'll be warned of this and prompted to encrypt both the folder and the file. Normally, it's a good idea to let Server 2003 encrypt the folder as well. If you leave the folder unencrypted and then save an encrypted file within that folder using the Save As feature, the file will be left unencrypted since it is effectively now a new file. All new files created within a folder inherit the folder's encryption attributes.

**TIP** *If using encryption, encrypt the My Documents folder for all users (%userprofile%\My Documents) to ensure that the personal folder, where most Office documents are stored, will be encrypted by default.*

The encryption attribute is now set. If anyone but you, even someone with administrator privileges, attempts to open the file or run the encrypted executable, they'll be denied access. Encrypted files will appear in an alternate color in Explorer if your folder options are set to the default.

### COPYING, MOVING, AND BACKING UP ENCRYPTED FILES

New files in a directory inherit the encryption attributes of that directory: if the directory is encrypted, the file will be encrypted as well. If the directory is not encrypted, the file won't be encrypted. What about files copied to a directory? This is where it can get a little tricky:

- ◆ If you copy or move an unencrypted file to an encrypted NTFS directory, that file will become encrypted.
- ◆ If you copy or move an encrypted file to an unencrypted NTFS directory, the file will remain encrypted.
- ◆ If you copy or move an encrypted file to a FAT or FAT32 directory, that file will no longer be encrypted (since encryption is an NTFS attribute).
- ◆ Backups of encrypted documents are stored and restored in their encrypted state even if the backup media is a FAT-formatted drive.

You can also encrypt files from the command prompt with the CIPHER command. To encrypt a single folder in the current directory, type **cipher /e *foldername***, where *foldername* is the name of the folder you want to encrypt. To decrypt the same folder, replace the /e switch with /d, like this: **cipher /d *foldername***. The command will report back to you whether the operation succeeded or not.

**NOTE** *Again, you can't encrypt compressed data or vice versa. If you attempt to encrypt a compressed file with CIPHER, it won't work. If you try to encrypt a compressed folder with CIPHER, it won't encrypt the contents of the folder, but it will add the encryption attribute to the folder so that any new files added to that folder will be encrypted (but not compressed—remember, you can only have one of these attributes for any file or folder at a time). Uncompress the folder and try again to encrypt it, and the operation should be successful.*

Normally, CIPHER will only encrypt the files in the immediate folder you specify, not the subfolders. It will also only encrypt parent folders if told to, leaving the files' parent directories unencrypted. To keep from accidentally decrypting a file (by "Saving As" a new file in a decrypted folder), encrypt the folder as well by typing **cipher /e /s:*foldername* /a**. This will encrypt all files within the specified folder and all subfolders within the folder.

### Enforcing Encryption

The contents of an encrypted folder are displayed like any other shared or locally available data, except that they are displayed in a lovely spring green color to identify them as encrypted. (Compressed files and folders are blue.) Sadly, the error messages you get when attempting to access files that someone else has encrypted represent a help-desk call waiting to happen. Whether accessing the encrypted file locally or from the network, from Server 2003 or from an earlier operating system, you'll see an error message like the one in Figure 10.43.

**FIGURE 10.43**

Windows 9x and NT 4 users may not be sure why they can't open an encrypted file.

What about administrators? If someone with administrator privileges opens the file's property sheet and edits the encryption attribute, they'll be unable to apply the change—they'll be denied access. What happens if an administrator takes ownership of the file? File ownership doesn't actually matter to encryption. Even if you (as the administrator) take ownership of an encrypted file, you won't be able to read it unless you are a designated recovery agent, which is a user who has been designated as someone who can decrypt a particular file or set of files.

Sometimes, you may just want to know who encrypted a file. If you create an unencrypted file and are that file's owner, and you allow me read and write permissions on the file, then I can encrypt it, and you won't be able to see its contents anymore because you're not the one who encrypted it. Still with me? Anyone with read and write permissions on an unencrypted file has the ability to encrypt it, rendering it unavailable to everyone else with rights to that file. To find out who encrypted the file, you can click the Details button in the Advanced Attributes sheet. This will reveal the list of users who have the ability to encrypt the file and any recovery agents who are defined. As a recovery agent, you can fix things by decrypting the files, as you'll see in the next section, "Recovering Encrypted Files."

Another way of finding out who can encrypt a file is by using a command-line Resource Kit utility named EFSINFO. You can run EFSINFO with the /u option (to show user information), the /r option (to show Recovery Agent information), and the /s option (to show directory and subdirectory information) like this:

```
efsinfo /u /r /s:c:\userdata
```

It'll tell you whether the folder and its files are encrypted, who encrypted the folder and files, and who can decrypt them. Here's the output from that command:

```
c:\userdata
.: Encrypted
  Users who can decrypt:
    DOTNETTEST\Michele (Michele Beveridge(michele@dotnettest.local))
  Recovery Agents:
    DOTNETTEST\Administrator (Administrator)
```

```
Encrypted letter.doc: Encrypted
```

Users who can decrypt:

DOTNETTEST\Michele (Michele Beveridge(michele@dotnettest.local))

Recovery Agents:

DOTNETTEST\Administrator (Administrator)

Recipes.doc: Not Encrypted

C:\>

### **Protecting Encryption Keys**

Microsoft positioned these encryption services especially for laptop users who wanted to keep their data secure even if their laptop was stolen. However, there's one major hole in this security plan. If someone *does* steal a laptop and can log in with administrator rights, they can edit the certificate settings in a way that allows them to decrypt the data.

**NOTE** *Of course, if you don't password-protect your laptop, then decrypting your files is as easy as logging in as you.*

To avoid this problem, Microsoft recommends exporting each user's certificate and saving it to disk, then deleting the certificate on the computer. To do so, follow these steps:

1. In the MMC, add the Certificates snap-in.
2. In the **Personal** folder, open the **Certificates** folder. The per-user certificates on the computer will be displayed in the right pane.
3. Right-click the certificate that you want to export as a file and choose **Export** from the **All Tasks** menu. This will start the Certificate Export Wizard, which asks whether you'd like to export the private key along with the certificate. You'll need the private key to decrypt data.
4. In the next screen, choose the export options, including the file type, the strength of encryption you want to use, and what you want to do with the local key if the export works.
5. If you chose to export the private key, you'll need to supply a password to import the key again. Choose this password carefully, as it's protecting your encryption.
6. Choose a filename for the key by either typing a path or browsing for it. You can save the file on any volume, not just NTFS.
7. The final screen of the wizard will display your choices. Review them carefully and click **Finish** to export the keys. If the export operation worked, Server 2003 will pop up a quick message box to tell you it was successful.

Save the certificate on a floppy disk or, better yet, a safe network location where it can get backed up, then delete it from the computer. You'll be able to open encrypted files, but the certificate will no longer be on the machine.

To import the certificate to another computer or replace it on the same one, open the same **Personal** folder, right-click the **Certificates** folder, and choose **Import** from the **All Tasks** menu. This will start the Import Certificate Wizard:

1. Browse for the file you saved.

2. If the certificate you're importing includes the private key, you'll need to supply the password assigned when the key was exported. Type it in and choose the degree of control you want over the private key.
3. Specify where the new key should go. For user keys, the **Personal** folder should be fine.
4. Review the importing options and click Finish to import the key. Server 2003 will tell you if the importing action succeeded.

**NOTE** For more about certificates, see Chapter 8.

### **Recovering Encrypted Files**

If I encrypt a file, how do I recover the file? This is where the recovery agent comes in. By default, workstations and member servers' recovery agents are just the default Administrator account—not members of the Administrators group, but the Administrator *account*. The default recovery agent for a domain is the default administrator for the computer that was the first domain controller installed for that domain.

To recover a file for someone, you must log in as the recovery agent and decrypt the file, either through the GUI by removing its encryption attribute in the Advanced section of the file or folder properties, or with the CIPHER command that we discussed earlier:

**cipher /u/a filename**

In other words, EFS doesn't see any difference between you (the person who originally encrypted a file) and the recovery agent; if you had an encrypted Word file and the recovery agent tried to open it, she'd see your file. If you've denied the recovery agent access to your Word file, then she won't be able to open it. Of course, if the recovery agent doesn't have access to your file, then she also can't decrypt it for you—but that's easily remedied by an administrator who can take ownership of the file and then grant read and write access for the file to the recovery agent. Again, if you haven't changed the defaults, then the recovery agent is the default Administrator. That account can do just about anything anyway, so getting control of a file is no trouble.

Let's look a bit further into the recovery agent account. First, do you really want to have to use the default Administrator account for anything? Probably not—that's a lot of power to give to the person in charge of making sure users can read their files—so how do you change which account can handle emergency decryptions? It's harder than you might expect. EFS encrypts and decrypts your files using a simple symmetrical algorithm; the same "password" (not a user password that you can change, but a "password" that you give to EFS to permit it to encrypt and decrypt) encrypts and decrypts your files. But it *stores* that password using an asymmetric, public key—type of encryption method. When you encrypt a file, EFS encrypts the password using your public key and stores the now-encrypted password in NTFS. When EFS needs to decrypt a file, it asks NTFS for that encrypted password. NTFS passes the request to an independent module of the EFS driver that handles all reads, writes, and opens on encrypted files and directories, as well as operations to encrypt, decrypt, and recover file data when it is written to or read from disk, and which passes the information back to NTFS. NTFS then gives the password to the EFS driver, which uses your private key to decrypt the password. Now that it has the password, it can decrypt the file. (You've probably guessed by now that encrypting files slows things down a trifle.) How does EFS, then, allow more than one person to decrypt a file? By again exploiting NTFS: Not only can it store the file's password encrypted with your public key, EFS will also include that same password encrypted with the public key or keys of as many recovery agents as you like.

Where things get sticky is in the process of introducing EFS to a prospective recovery agent's public key/private key pair: you need a hierarchy of certificate authorities recognized by your computer. Without a certificate hierarchy, there are no certificates, and without certificates, you can't introduce new recovery agents to EFS. (With an exception—stay tuned.) So you'll need at least a certificate server or two running before you can monkey with the list of recovery agents. In an Active Directory environment, that's not too hard to accomplish, although it does require some work: AD doesn't install a certificate hierarchy by default. And in a stand-alone server environment, you could, if you wanted, install a certificate server to act as a one-server hierarchy and issue certificates with that.

But wait—at least one account has a certificate without having to go through all of the certificate-authority stuff. Where did the first recovery agent, the default Administrator, get its certificate? Here's the exception. Apparently EFS generates a self-signing certificate for the default Administrator. I've not been able to find a way to get it to build certificates like that for other accounts; it'd be a nice, low-overhead way to add some flexibility to EFS administration.

In Win2K, the absence of a recovery agent meant that you could not encrypt files, and EFS was basically disabled (a backward way of allowing you to turn encryption on or off). That was the only way that you could disable encryption on a system. With Server 2003, the EFS policy actually gives you the ability to turn EFS on or off, allowing you to decide on which systems you enable the service. Because it is a machine policy, you can apply it wherever you want in the domain. This is a significant improvement, since if you removed the recovery agent, it was basically a one-way street. Without installing a certificate authority, you couldn't reverse the decision not to run EFS. Now you can turn it on, off, and back on again with just a flip of the venerable Group Policy switch.

### **Decrypting Files**

Decrypting encrypted files is a simple matter if you're the person who encrypted the file in the first place. When you open it, the file is automatically decrypted—the action is completely transparent to the user.

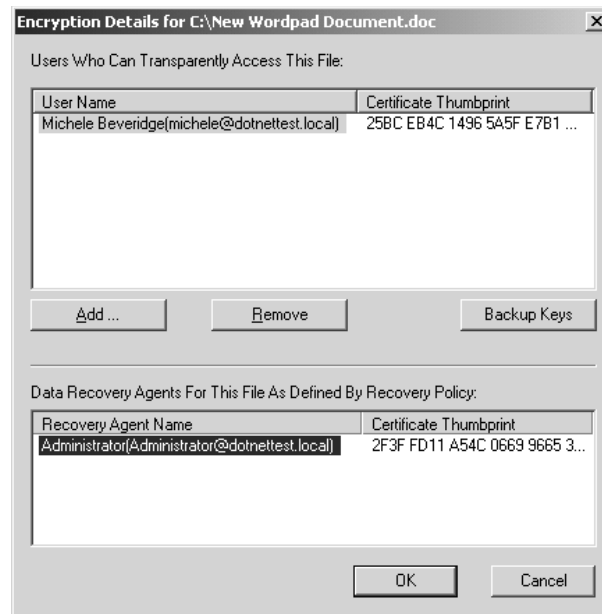

That decryption is temporary, however—as soon as you close the file, it's encrypted again. If you want other people to be able to use the file, then you'll love the newest encryption (or rather decryption) feature included in Server 2003. You now have the ability to assign other users the right to access (or decrypt, basically) your encrypted files. Here's how it works. First, you need to make sure the users that you want to access your encrypted documents have the right to access them in the first place. By that, I mean that the users must have the proper NTFS permissions to access those files. Next, right-click the document that you want to “share” and choose Properties. Clicking the Advanced button will expose the Advanced Attributes dialog box, as shown back in Figure 10.42, except in this case the Details button will no longer be unavailable.

Click the Details button and you will see the Encryption Details sheet, as seen in Figure 10.44, which will display users who have the right to decrypt the file and any recovery agents defined. Click Add to configure new users to be able to decrypt the file. You can add users from either the local account or the domain.

To permanently decrypt a file or folder from Explorer, open its property sheet and click the Advanced button on the General tab. Uncheck the box next to Encrypt Contents to Secure Data. The file is now open to anyone who has the right to access it.

property sheet

## Dealing out Disk Space...Managing Disk Quotas

Many administrators found NT 4 incomplete in one way or another, and one of the perennial complaints was its lack of quota management tools. Without quota management, it's hard to control the amount of disk space people on the network use; even in these days of cheap and plentiful storage, there comes a limit to the amount of time and money you want to put into storing every single JPEG John Doe receives.

Several NT-compatible quota management applications exist, but adding quota management to NT has historically not been cheap. To help those who need a basic form of quota management, Win2K was released with a set of simple quota management tools, and those have been continued but not improved in Server 2003. Server 2003's quota management tools don't include all the functionality some third-party products do—one big shortcoming is that you must assign disk quotas on a per-user basis—but they're a start and have the usual advantage: you've already paid for them.

### BACKGROUND: HOW QUOTA MANAGEMENT WORKS

The process of quota management is straightforward: The quota manager keeps an eye on writes to the disk of protected lettered volumes based on criteria set by the network administrator. If the protected volume reaches or exceeds a certain level, then a message is sent to the person writing to the volume warning them that the volume is near quota, or the quota manager prevents the user from writing to the volume altogether, or both. The mechanics of how all this works varies from product to product, but the basic effect is the same: users can't write to volumes that are at or exceed their preset quota.

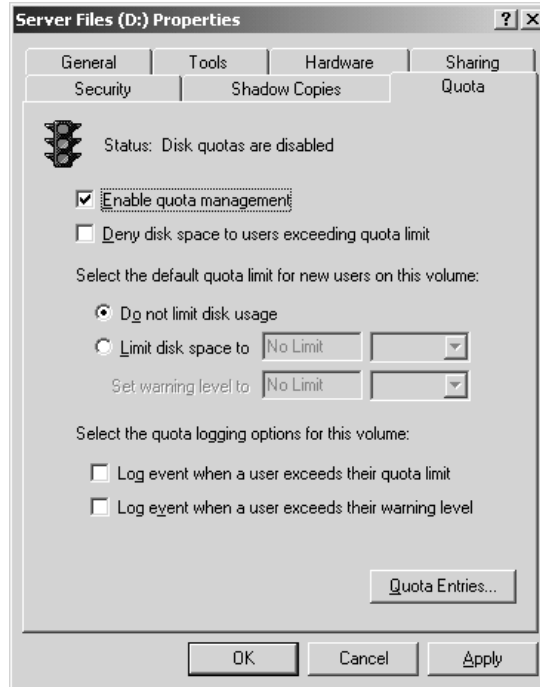

Server 2003's quota management is based on both the user's identity and the attributes regarding quotas that are set for the volume on which that particular user is storing information, so you can control how much space a person uses on any particular volume.

### SETTING UP USER QUOTAS

By default, Server 2003 quotas are turned off. To start working with quota management, open Explorer, right-click the volume you want to protect, and choose Properties. This can be any NTFS volume with a drive letter, be it a local drive or a drive letter mapped to another server that was created with Win2K, Server 2003, or upgraded from NT 4. Click the Quota tab shown in Figure 10.45.

**FIGURE 10.45**

Disk quotas are disabled by default.

**NOTE** You cannot enable quotas on a folder within a volume; you can only set them on the entire volume.

The first order of business is to enable quotas. To turn on disk quotas and make the management options available, check that box. You can set up all the options before clicking OK or Apply to enable quotas. Choose Apply to keep the property sheet open.

Next, choose whether to enforce quotas by denying disk space to anyone violating a quota. If you don't check this box (it's not checked by default), then people violating their disk space quotas will still be able to write to the volume.

**WARNING** Never enforce a quota on a system partition and deny disk space to those exceeding it. When booting, Server 2003 writes data to the disk. If you enforce quotas, then the system may not be able to boot. Actually, there's really no reason to put quotas on the system partition if it's separate from the data partition.

Third, set a default quota limit. Notice that the default value is 1KB, which means that unless you're in a particularly draconian mood, you're going to want to change the default to something a

bit more reasonable. You might, for example, limit each user's quota on the volume containing home directories to 10MB.

Finally, set the logging options, sending events to the System log in the Event Viewer tool when users exceed their quotas or reach the warning level. Users will be identified by name in the System event log, so you know who is running out of assigned disk space.

You've now done the basic job of setting up quota management on the volume. Next, you'll need to create quotas for each person who'll be using that volume. To do so, click the Quota Entries button to open the screen in Figure 10.46.

**FIGURE 10.46**

Add quota entries to the list.

When you start, the only entries will be the default entry for the local server's administrator and any users that already have data that resides on the disk. To add a new entry, choose New Quota Entry from the Quota menu. You'll see the dialog box in Figure 10.47.

**FIGURE 10.47**

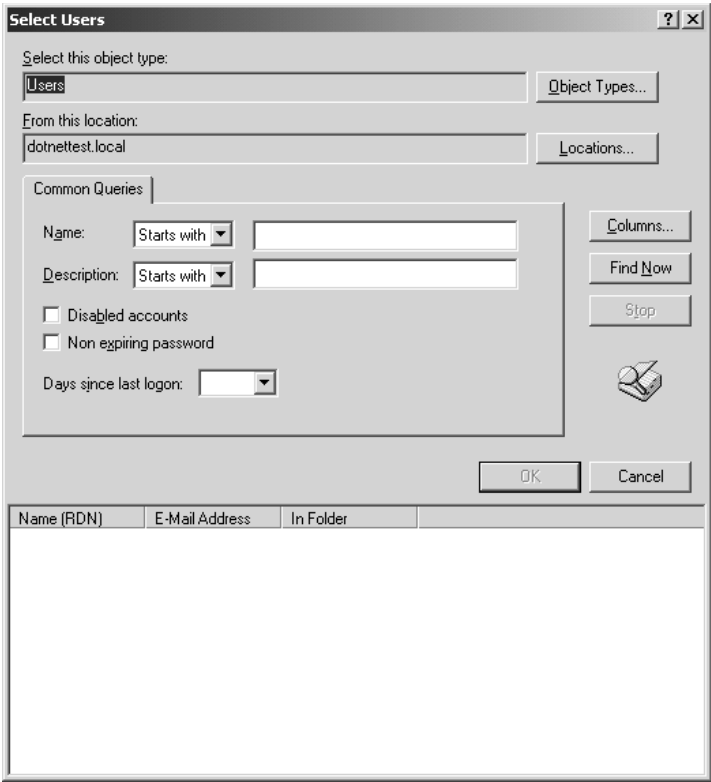

The Select Users dialog box

You can enter accounts from either the local user account database or the domain. Specify the location from which you want to add the names, either the local machine or the directory, by clicking the Locations button. When you are ready to add users, you can either type in each account name you want to add, or you can choose the Advanced button, which will expose the advanced Select Users dialog box as shown in Figure 10.48. You can search for accounts using queries or by clicking the Find Now button to enumerate a list of users from the location you specified in the first Select Users dialog box. You can also select a new location from which to search for user accounts here by clicking the Locations button.

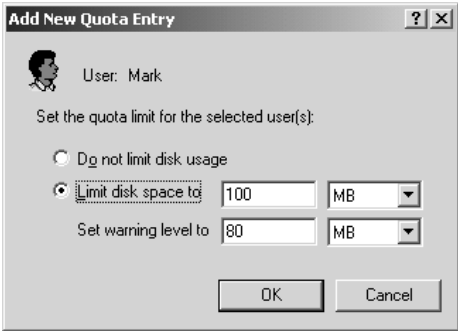

**FIGURE 10.48**  
The advanced Select Users dialog box.

Because quotas are enforced on a per-user basis, you can't create quota entries on a per-group basis. This is unfortunate, and more than a bit ungainly. However, you can create quota entries for multiple users by holding down the Ctrl key while selecting the users you want to add. All users will start with the same settings. When you have the users you want, click OK to return to the first Select Users dialog box and then click OK again. This will bring you to the Add New Quota Entry dialog box, as shown in Figure 10.49.

**FIGURE 10.49**  
Specify the amount of disk space allocated to the new quota entry.

Here you can choose whether to enforce quotas for the new entries, and (if so) how much disk space in the volume they get. The amounts shown in this window will be the default you set on the Quota tab.

In this same box, specify the level at which the users will be warned that they're about to run out of disk space. The warning level, obviously, should be less than the quota limit. Server 2003 will fuss at you if the warning level is more than the quota and make you edit the value so that the warning level is less than or equal to the quota.

Click OK, and you'll return to the list of quota entries. The new entries will be listed and take effect immediately. If you elected to deny your users disk space when they exceed their quota and a user attempts to write to the volume once she has exceeded that limit, she will get a write error. The exact nature of the error message will depend on what application users are working with when they attempt to write to the volume, but the basic idea will be the same: they're denied access to the volume because it's now write-protected. To write to the volume, they'll need to delete some of their files to get below quota or have someone else take ownership of their files. The files in the Recycle Bin are also considered part of a user's quota on the local volume. In addition, compressed files, although smaller than their original value, are calculated using the uncompressed value for the purpose of calculating quota limits.

**NOTE** Some quota management software allows users a "grace write" when they're over quota, permitting them to save the file they're working on before locking them out. Server 2003's quota management does not.

If you want to use the same quota limits on more than one NTFS volume, you can export the quotas and import them on the new volume. To export a quota, select it in the list in the Quota Entries management tool and choose Export from the Quota menu. The extension for the export files is not displayed. Choose a name for the file and save it. To import the quota settings, open the Quota Entries management tool for a volume and choose Import. Browse for the file, and you can import the quotas.

Quotas may not work as expected on volumes that you originally formatted with FAT or FAT32 and then converted to NTFS. Any files that users created on the FAT volumes will appear to the quota manager to belong to the Administrator, not to the person who created them, since the FAT filesystems don't distinguish file ownership like NTFS volumes do. Therefore, the files that people created on the FAT volume before it was converted to NTFS won't be charged to their quotas, but to the Administrator.

### MANAGING QUOTA ENTRIES

Some time after you implement quotas in your network, people will start running up against them. If you open the Quota Entries folder, you'll see three possible statuses for quotas. Quotas may be within acceptable limits, at warning levels, or over quota (if you haven't prevented users from writing to volumes for which they're over quota).

Server 2003 doesn't include any messaging application that is tied to quota limits, so you'll need to keep an eye on this yourself. You can sort the entries in the list by clicking the columns, so if you need to find all the people (for example) who have crossed the warning threshold for quotas, you'd click the Status column. Sadly, there's no mechanism from here to send people messages; you'll need to rely on e-mail or some other messaging technique.

***TIP** Of course, you can always use the command-line tool called `EVENTTRIGGERS` to alert you to certain events that you specify, including those for quotas.*

## Volume Shadow Copy Service

You are sitting at your desk, desperately trying to figure out how you will ever get enough done so you can spend just a little time at home tonight playing Death Match instead of working into the wee hours of the morning. . . again. Suddenly the phone rings. It's a (groan) user. "Um, I can't seem to find the spreadsheet that Mr. Dickle needs to present at the World conference in Hawaii tomorrow. I think, somehow, it may have been deleted. Can you help me get it back?" This is an all-too-common scene in many a sysadmin's daily life and, usually, a huge waste of time. "Okay, what was the name of the file, and when did you last have a working copy of it? Where is it stored?"

Wouldn't it be great if you could, with just a little bit of user training, let your users help restore their own files simply by accessing the properties sheet of the file? "A pipe dream?" you ask. "Are you trying to tease us, Mark?" No, my friends, it's true, and it's brand new in Server 2003.

The Volume Shadow Copy Service (VSS for short) debuts in Server 2003 and it offers two services that I think you'll like. First, it will allow users to access and/or restore previous versions of saved files using a client feature called Previous Versions. The server feature is known as Shadow Copy to us administrators. Secondly, VSS enables applications that take advantage of the volume shadow copy API to access locked files or files that are in use by other services or applications. We'll look at this first.

### APPLICATIONS CAN USE THE API

"What does that mean," you ask? Well, let me give you an example. Since Server 2003's backup software has been built to take advantage of this API, it is now able to offer the new and improved functionality of backing up open or locked files. Here's what happens. If, during a backup, a file is locked by another application, the backup application can't access the file to copy it. In the old days, that might have meant that the backup couldn't complete and, of course, you wouldn't know about it until you came in the next morning. More often, nowadays, it means that those files will be skipped during the process and won't be backed up, unless you have a really expensive backup software. What the VSS does is to take a snapshot of these open or locked files when applications, like Server 2003's Backup Utility, come face to face with the lock. This allows the application that needs access to those files to use the shadow copy as its source for those files. Of course, if the file was open and being edited at the time of the backup (and subsequent shadow copy), the backup will reflect the file as it existed when the snapshot was taken. This API is available to vendors, and I am sure that other applications will take advantage of it. Microsoft has announced that the newest versions of Exchange and SQL will feature great improvements based on the use of this API. The VSS is available by default to applications that use the API, regardless of whether you enable shadow copies (for the user, this means Previous Versions) on your volumes, which is a manual process.

### VOLUME SHADOW COPY AND PREVIOUS VERSIONS

When an administrator enables volume shadow copies for a volume, it gives the users the ability to restore previous versions of the files that they access through a share on that volume. In fact, it *only* works through shares. The previous versions of the files won't be accessible to the user if they access

the file locally. You *can* map a drive through Explorer if you want to access a file on that volume from the console though. Shadow copies can only be enabled on a per-volume or per-partition basis. For a network share, you will need to configure shadow copies on the volume where the share resides. Once enabled, VSS immediately takes a snapshot of the volume. You can also create a manual snapshot of the volume any time, or you can create a schedule for the VSS snapshots. The scheduler offers a very granular way to schedule this routinely.

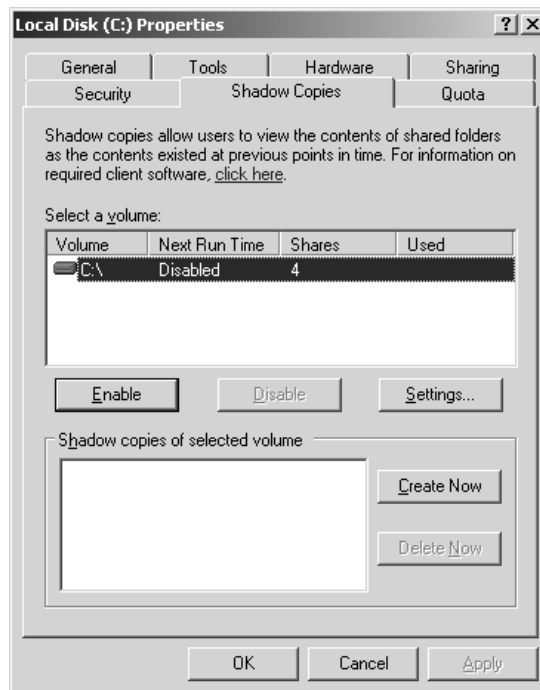

When you initially enable VSS on a volume, you will find that a new hidden folder called System Volume Information appears in the root of the volume. This is where the snapshots are stored by default, along with the log files. This folder is created for each volume on which you enable VSS. The minimum amount of disk space you'll need for a snapshot is 100MB. You can configure a maximum allowable space for this folder, but you need to have a good idea of how much space you'll need for these snapshots, because going over the maximum means the deletion of the older Previous Versions files. I don't know exactly how to estimate the space needed for this other than to experiment, at this point. The default storage space allocated is 10 percent of the size of the volume that is being copied. It is recommended that you store the shadow copy on a different volume from the one you are copying from. I'll show you where you can configure this, but first, let's look at how to enable VSS on a volume.

### HOW TO ENABLE VSS

Right-click the volume on which you would like to enable volume shadow copies and choose Properties. Select the Shadow Copies tab to open the Shadow Copies property sheet, as shown in Figure 10.50.

**FIGURE 10.50**

Highlight the volume and click Settings to configure the Volume Shadow Copy Service.

Highlight the volume you wish to enable and click the Settings button to determine where you want to store the shadow copy data, configure the space allocated to the shadow copies, and set up a schedule for the service. Click OK to apply your settings and return to the Shadow Copies properties sheet. Shadow copies are now enabled on the volume. As you can see in Figure 10.50, you can elect to manually take a snapshot of your volume by clicking Create Now. You can also delete snapshots here. Once a volume has been enabled, when a user accesses the properties sheet of a file, they will notice a new tab has appeared, called Previous Versions. This tab can only be seen when volume shadow copying has been enabled on the volume that a file resides on, and only if the user accesses the file through a share.

### HOW IT WORKS

Here's how it works. When the administrator enables volume shadow copies on a volume, a snapshot is taken of the entire volume and all of its files. When I say snapshot, I don't mean a backup or a copy, just that the VSS records the "state" of the volume and all of the files that reside on it. Are you with me? Keep this in mind. The VSS now has a "memory" of the volume and all the files on it at the moment that snapshot was taken. Let's say I, the user, have a Word document that resides on a volume where VSS is enabled (which I access through a share) and that a snapshot was taken this morning at 7:30 A.M. before I arrived at work. When I arrive at 8:00 A.M., I edit the document and make some changes. As soon as I commit those changes to memory (i.e., save the file), the VSS goes to work.

VSS says, "Hey, I've got a file that has changed here. Do I have anything about this file in my snapshot?" The file existed on the volume when the snapshot was taken this morning, and it was in a different state than it is now that I am trying to commit changes to it. So, the VSS says, "Yup, that Word doc that is being saved is different from what I see in the snapshot." The VSS then creates and saves an exact copy of the Word doc as it existed at 7:30 A.M. this morning when the snapshot was taken, and it stuffs it in the System Volume Information folder. VSS then makes that file available to me, the user, by placing a link to that 7:30 A.M. version of the Word file in the Previous Versions tab of the property sheet of the Word document that I just saved. Now, if I access the file by double-clicking it or opening it from Word, I am editing the version that I saved at 8 A.M. However, if I access the properties of that doc and view the Previous Versions tab, I will have available to me the version of the file as it existed at 7:30 this morning (VSS saved that for me when I saved the file at 8:00 A.M.).

Okay, stick with me here. Keep in mind that the VSS is scheduled to take a snapshot of the volume every morning at 7:30 A.M. Here's what that means to me, the user. Since the time that I edited that Word document at 8:00 A.M. this morning, I have made several more changes. It is now 10:00 A.M. and I decide to save the file again. When I last checked, I had one previous version available to me (the one from the 7:30 A.M. snapshot that was given to me because I changed the file at 8:00 A.M.). Since I am saving the file again, I should have two now, right? Actually, no.

Remember how I said that when I commit a change to a file, the VSS goes out and looks at the last snapshot it has of the volume to see if the file is different from the snapshot? And how, if the VSS finds that the snapshot is indeed different, it creates and then saves an exact copy of that file, as it existed at 7:30 A.M. during the last snapshot? Well, I did this once already this morning at 8 A.M., and that file was indeed copied and made available to me in the properties sheet of the file. Since the only information the VSS has to work from is the 7:30 A.M. snapshot, its job is done. The file, as it existed

the last time the VSS recorded a snapshot was made available to me at 8 A.M. and it can't be done again, not until two things happen. First, another snapshot has to be taken (tomorrow morning at 7:30, according to the schedule) and second, once that snapshot is taken, I have to make changes (and save those changes) to the file. Once those two things happen (and not before then), I'll have yet another previous version available to me when I access the properties sheet of that file. I could make 10 more changes to that Word document today, and if I completely destroy the formatting and want to roll it back to a previous version, my only option is the copy of the file as it existed at 7:30 A.M.

The same rules apply to the deletion of the file, with one exception. Let's say that Word file was called **BigMeeting.doc**, and let's say that at 11:00 A.M. I accidentally deleted it. I took a snapshot of the volume that morning at 7:30 A.M. "No problem!" you say. "Just go to the property sheet of the file...and, um..." Okay, I'll bet you're with me here, aren't you? How can I access a previous version of a file, if I can't access the Previous Version tab on the properties sheet on the file because the file has been deleted? Well, it's easy and it's not. What I have found is that you can simply recreate a file with the exact same name. When you access the properties of that file, the previous version will be available to you. It will be an exact copy of the file as it existed the last time a shadow copy was taken. So what's not easy about that? Well, what if I can't remember what the file was called? "I've had a lot on my mind and my kids are sick and I was late and..." Sound like your average user? Sure. The best way to think about it is this: if you don't know the name of the file, there is no way you can recreate it to see the previous versions of the file. If you were restoring this file from tape, you'd be in the same boat. You just can't get around needing to know the name of the deleted file to restore it.

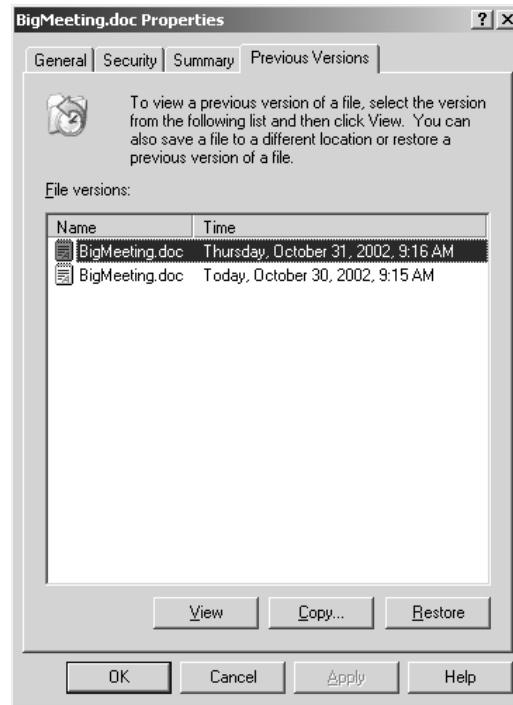

When a user accesses the Previous Versions tab of a file's properties sheet, as seen in Figure 10.51, they can view the list of the previous versions of that file and will have three choices, in terms of what they can do with that file. They can view the file, they can copy the file to another location, or they can restore the file, which will overwrite the current version of the file. A couple of interesting things to note here:

- ◆ When you view a previous version of a file, the resulting action will depend on what kind of file it is. If the file is viewable, it will be opened for you to see. If it is an executable, it will attempt to run it. One of the first files that I tested the VSS on happened to be an **autoexec.bat** file that I had recently edited. VSS wasn't able to run it, but it tried. Perhaps "view" is not the best choice of words for this feature.
- ◆ If you copy a file to a different folder, it will inherit the permissions of the new folder, much like the file copies that you know now.
- ◆ If you rename the file, you will lose the previous versions that you have collected to date. You won't have any previous versions available to you until, a) the next snapshot is taken for the volume and, b) you commit changes to the newly named file.

Of course, since this feature is new to Server 2003, that is the only version of Windows that has the full features of the VSS built-in. Once you have installed Server 2003, the Previous Version client for XP can be found in the **Windows\system32\clients\twclient\x86** folder. It is an MSI file (**twcli32.msi**) and thus can be distributed through a network share or applied using Group Policy or SMS.

**FIGURE 10.51**

The client's view of the Previous Versions property sheet

## Remote Storage

One nice feature that was initiated in Win2K and continues in Server 2003 is Remote Storage. What the Remote Storage feature does is allow you to mix tape-drive space and hard-drive space as if they were one unit.

The idea of Remote Storage is this. Suppose you have a 24GB hard disk on your server; perhaps it's a nice amount of storage, but not quite enough for your users' needs. Suppose also that you've got a tape backup device, a carousel device that can automatically mount any one of 16 tapes into the tape drive without the need for human intervention. Perhaps it's a DLT loader and each tape can store 20GB of data; that works out to about 320GB of tape storage and, again, 24GB of hard-disk storage. Here's what Remote Storage lets you do:

It lets you lie about the amount of hard disk space you have.

You essentially advertise that you've got a volume containing 320 plus 24, or 344GB of online storage space. As people save data to that volume, Remote Storage first saves the data to the hard disk. But eventually, of course, all of that user data fills up the hard disk; at that point, Remote Storage shows off its value. Remote Storage searches the hard disk and finds which files have lain untouched for the longest time. A file could have, for example, been saved eight months ago by some user but not modified since. Remote Storage takes those infrequently accessed files and moves them from the hard disk onto the tape drives, freeing up hard-disk space.

Ah, but Remote Storage has been claiming the file that was untouched for eight months is ready and available at any time. What happens if someone decides to go looking for that file and it's on the

tape? Remote Storage just finds the file on tape and puts it back on the hard disk, where the user can get to it. Yes, it's slow, but the fact is that many files are created and never reexamined, which means there is a good chance that putting the file on tape and off the hard disk will never inconvenience anyone.

I worked with mainframe systems that did things like this years ago, and it was quite convenient—files untouched for six months or so would be said to be “migrated” to tape. I could “unmigrate” the tapes, and that would take a while, but it wasn't that much of a nuisance and it helped keep the mainframe's disks free.

## DiskPart for Disk Management

Earlier I discussed how to use DiskPart to expand basic disks, a feat that the Disk Management tool in Server 2003 is simply not capable of doing. I have also used DiskPart to accomplish other tasks that the GUI couldn't seem to handle, like deleting a boot partition that should never have been there in the first place. Here's what happened. During an upgrade from Win2K to Server 2003, a system with two physical disks gave me a little trouble. The first disk contained the OS and it fared well during the upgrade process (this is what I was actually trying to test). The second disk had a bit of a history and had been through several different conversions from one filesystem to another, converted from basic to dynamic and back again—basically a misfit disk without any real duties at the time of the upgrade. I believe, in the end, that it was a dynamic disk with a single volume on it just before the upgrade, but the important part about this disk was what happened during the upgrade. When I looked at the Disk Management tool, intending to use this lost disk for some data I wanted to house, the disk was marked as Dynamic Missing, and the lone volume that Server 2003 was calling a boot volume was still there. Nothing I did in the Disk Management tool fixed the fact that Server 2003 couldn't seem to recognize this misfit disk, nor would it allow me to delete the volume. However, DiskPart had no trouble recognizing or deleting that volume, and I was able to restore the disk in no time at all. DiskPart's commands are pretty intuitive and it has proved to be a great tool for me. It is installed by default in Server 2003, and I suggest that you add it to your bag of sysadmin disk tricks.

## SCRIPTING WITH DISKPART

If you are deploying your systems using Unattended Installs or Sysprep and want to create more than just the sole partition those tools are capable of creating, you might look at DiskPart's scripting features. There are 42 commands that you can use with DiskPart's command-line interface that will allow you to create, delete, expand, and manipulate the disks in a system in any way that you can (and more!) by using the GUI. For example, you can use a single script to delete all those crazy partitions that come installed on so many OEM machines (I once received a box with *six* 2GB partitions on it!). Then you can create the logical disk division so that it is standardized across all of those similar machines that are sitting in boxes just waiting to be deployed on your users' desktops.

Here's how it works. Create a simple text file with the commands that you need to create your logical disk environment and include that file when you call the script. To run a DiskPart script, you'll type the following at the command prompt:

```
diskpart /s Myscript.txt
```

*Myscript.txt*, of course, is the name of the text file you'll create that contains your DiskPart commands.

You can type the following if you want to redirect DiskPart's output from the script to a file:

```
diskpart /s Myscript.txt > MyLogFile.txt
```

*LogFile.txt* is the name of the text file to which you want DiskPart to write the output.

**TIP** By default, DiskPart will not continue the script if it encounters an error. You can avoid this and force DiskPart to continue processing the script by using the **noerr** parameter. You have to make sure your syntax is correct though, because the **noerr** option will not help you there. DiskPart can't process a command with syntax errors; it will return an error.

## The Evolution of Storage

When Win2K was released early in 2000, its storage management toolkit included quite a few new features to support the storage environment, some for which NT administrators had been clamoring for years. With the release of Server 2003, Microsoft has managed to add even more functionality to their storage management and has improved upon several of the features that debuted in Win2K. All told, Server 2003 is starting to look a lot more like an enterprise solution than NT 4 ever hoped to be. It's becoming a far more "grownup" solution than many ever expected and that some Microsoft adversaries prayed it would never become.

In this chapter, you saw how the Disk Management tool works to protect data and system disks and learned about the available options for choosing a disk format and the ways to logically divide those disks. You also learned about some of the advanced features of NTFS, like disk quotas, encryption, Remote Storage, and the Volume Shadow Copy Service. I hope by now you feel pretty comfortable with the concepts of storage and how to better manage your systems. Using these tools, you should now be better able than ever to protect and manage your data files.

## Chapter 11

# Creating and Managing Shared Folders

MICROSOFT THREW ALL SORTS of new services, features, and functions into Windows 2000 Server, but at the heart of it all was still the requirement to be a good file server. Windows 2000 took the solid file sharing capabilities of Windows NT, extended them with the Distributed File System (Dfs), and made permissions and shares easier to manage—not to mention that this was all on top of a more stable and powerful operating system. The release of Server 2003 brought a few enhancements, the most important being that the new default permission sets are far more secure than they were in Windows 2000. In this chapter, I will talk about what file sharing really is, how those permissions work, and how to set it all up. Next, we'll dig into the Dfs. You'll find out what it is, how it works, and how to make it work for you. Finally, you'll take the basic file sharing capabilities and push them right out to your users' Web browsers. I'll also show you how to make your users files available for offline use.

## Basics of File Sharing

The core component of any server is its ability to share files. In fact, the Server service in all of the Windows NT family, including Server 2003, handles the server's ability to share file and print resources. But what exactly does that mean, and why is it so important? By default, just because you have a server running doesn't mean it has anything available for your users. Before they can actually get to resources on the server, you must share out your resources. Let's say you have a folder on your local I: drive named APPS with three applications in subfolders, as shown in Figure 11.1.

When you share this folder out to the network under the name of APPS, you allow your clients to *map* a new drive letter on their machines to your I:\APPS folder. By mapping a drive, you are placing a virtual pointer directly to where you connected. If you map your client's M: drive to the APPS share of the server, their M: drive will look identical to the server's I:\APPS, as shown in Figure 11.2.

**FIGURE 11.1**

Subfolders in  
I:\APPS

**FIGURE 11.2**

M:\ mapped to  
I:\APPS

**NOTE** Don't worry, I'll slow down and explain how to create this share later—and I'll explain how to connect to it in Chapter 14.

That's really all there is to it. Sharing resources means that you allow your users to access those resources from the network. No real processing goes into it as far as the server is concerned; it just hands out files and folders as they are.

## Creating Shared Folders

Before you can create a shared folder, you must have appropriate rights to do so. This requires that you are either an Administrator or a Power User. You can create shares in a few ways: You can use the Explorer interface when sitting at the server or use the Computer Management Console to create shares either at the server or remotely.

### Creating Shares from Explorer

If you're sitting at the server, the Explorer interface provides a simple and direct means for creating and managing all properties of a share. Let's go back to the I:\APPS folder that you want to make available to the network under the name of APPS.

**NOTE** Don't forget that not all clients can handle names longer than eight characters. This applies to shares as well. If you have old DOS LAN Manager clients, they won't be able to interpret share names longer than eight characters, for example, if you named the share **Applications** instead of **APPS**. For this chapter, I am assuming at least a Windows 98 user base, so long filenames and share names won't be a problem.

In Explorer, right-click the APPS folder and select the Sharing and Security menu option. This will bring up the properties page for the folder APPS, already set to the Sharing tab. To share the folder, click the Share This Folder radio button, as shown in Figure 11.3.

**FIGURE 11.3**

Properties for the APPS share

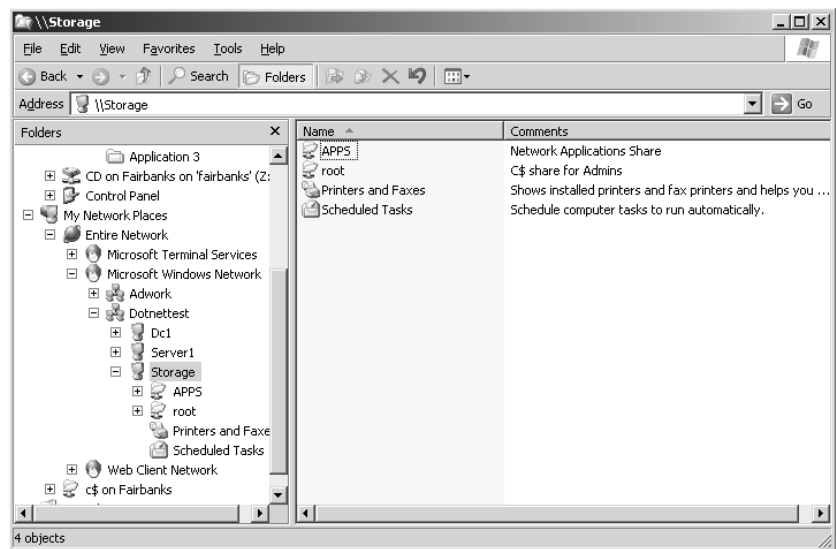

**NOTE** If you want to stop sharing this folder later through the Explorer interface, go back into the properties as you just did and select the *Do Not Share This Folder* button.

The Share Name option on this page is the most critical entry. This is how your users will reference this share. For our purposes, share this folder as APPS. The Description field is used to provide more descriptive information about this share. Technically, the description has no real bearing on the server or client; it just makes browsing a little less cryptic—I'll comment this share as Network Applications Share. This information will be visible to the users in the Comments field when they browse My Network Places for available shares, as shown in the Explorer window in Figure 11.4. Click OK, and your share is enabled and ready for immediate use by your users.

**FIGURE 11.4**

Browsing network shares

Once you share the folder, you can revisit the properties sheet by right-clicking the shared folder and choosing the Sharing and Security option. This looks like the same properties page as before, but there is now an additional option available, the New Share button, as you can see in Figure 11.5.

If you click the New Share button, you'll see the dialog box shown in Figure 11.6. Here you can share the folder using a different name and different permissions.

Of course, once you set up a share, you need to worry about securing it. You can define your share permissions by choosing the Permissions button. I'll discuss this in more detail later in the section titled "Managing Permissions."

You can enable another feature from the Sharing properties page with the Offline Settings (formerly known as Caching) button. You've probably heard of *caching* or *offline files* and that is exactly what we are talking about here. Offline Settings is a handy tool that gives your users offline file and folder access so they can get to their resources when they are away from the office. This will be covered in more detail in the "Using Offline Files/Client-Side Caching" section.

**FIGURE 11.5**

The New Share button is only available once you have shared a folder.

**FIGURE 11.6**

Share the folder using a different name with different permissions.

**SETTING USER LIMITS**

You can also configure how many users can connect to a share simultaneously in the User Limit area of the Sharing properties page. If the applications under your share are each licensed for 100 concurrent users you can configure your server share to maintain a that limit, even though you may have 200 users on your network. Just check the Allow This Number of Users radio button and fill in the appropriate number (it defaults to 10). As users connect to the share, they build up to the user limit. As users log off, or disconnect from the share, the number drops. This type of licensing enforcement can be handy in reducing your licensing costs.

*Continued on next page*

**SETTING USER LIMITS (continued)**

Be careful with your licensing, however. Not all applications have a concurrent license mode, although they might have a client license mode. (Unfortunately, as Microsoft has abandoned concurrent licensing, more and more other firms have stopped offering this useful licensing option.) With client license mode, the manufacturer doesn't care how many users are accessing the application at any given time, they just care about how many people have installed the application altogether. This user-limit option will not protect you in these cases.

Another thing to keep in mind is that this user-connection concurrency limit is based on the entire share. It cannot be defined further to each folder within a share. If Application 1 has a concurrency limit of 100, and Application 2 and Application 3 are unlimited, you don't want to inadvertently limit those other applications.

Finally, you need to consider how your users connect to the share to use these applications before you limit them based on concurrency. If your users all connect to the share upon logging in, but don't disconnect until logging off, your concurrency limit may be used up based on who shows up for work first, and you'll have 100 people using up your concurrency limit even if only a small percentage of them are actually using the application. If connections are made only when actually using the application, the user limit will work quite nicely.

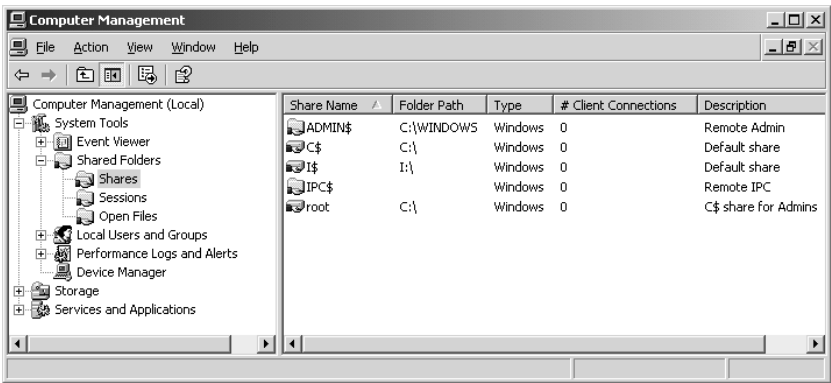

**Remotely Creating Shares with the Computer Management Console**

Within your Administrative Tools program group is the Computer Management Console. With this tool you can, among other things, create and manage shares locally or remotely. In contrast, within the Explorer interface, if you right-click a folder that is not local to your machine, you won't see the Sharing menu option. If you are going to create a share using the Computer Management Console from your local machine, you're set. If you want to manage a share on a remote server, you have to first connect to that server. Right-click the Computer Management (Local) icon, and select Connect to Another Computer. From there, you can type in the name of the server you want to manage or browse the network for the computer you want.

To begin with the share management, you need to select Computer Management\System Tools\Shared Folders\Shares, as shown in Figure 11.7.

**FIGURE 11.7**

Computer  
Management,  
Shares

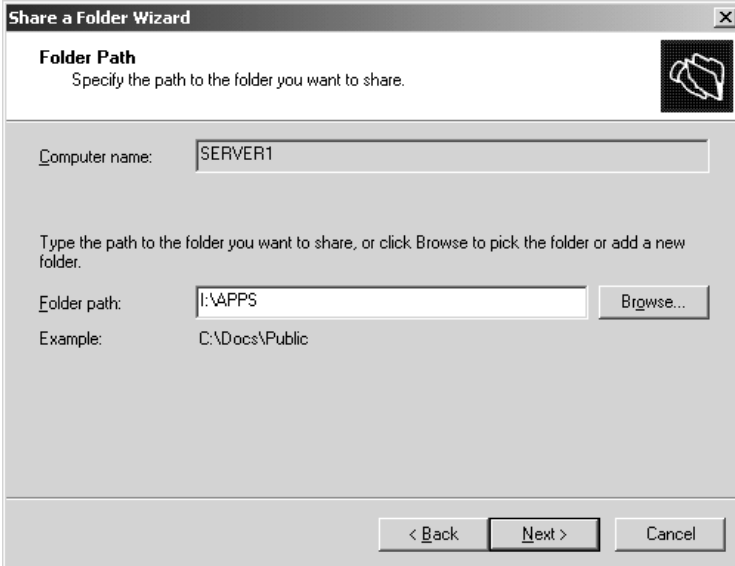

You can now either select the Action menu or right-click in the Shares window and select New Share. Click Next in the initial screen of the Share a Folder Wizard, and you will see the screen shown in

Figure 11.8. Make sure that the Computer Name field is correct so that you are creating the share on the right computer. To create the share, you can browse through the given drives and folders, or you can create a new folder on-the-fly by simply typing out the full drive and folder name in the box labeled Folder path. For this example, share the I:\APPS folder. Once you have completed the path, click Next.

**FIGURE 11.8**

Specifying a folder location in the Share a Folder Wizard

**Share a Folder Wizard**

**Folder Path**  
Specify the path to the folder you want to share.

Computer name: SERVER1

Type the path to the folder you want to share, or click Browse to pick the folder or add a new folder.

Folder path: I:\APPS Browse...

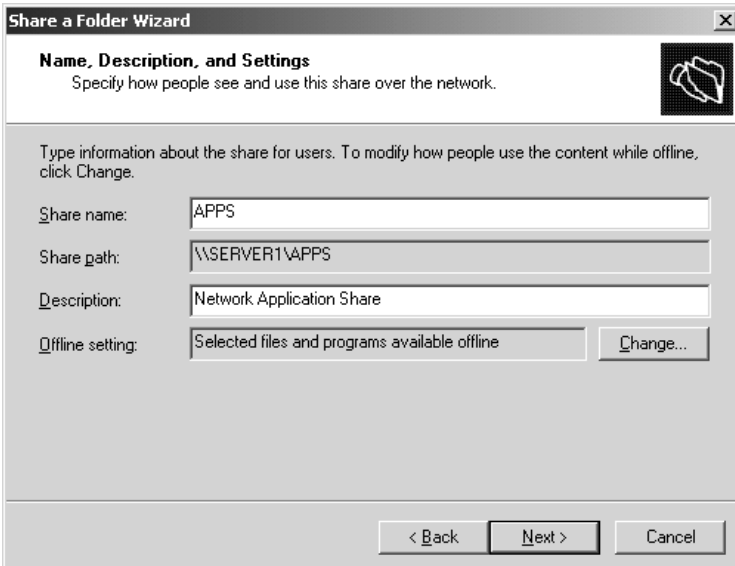

Example: C:\Docs\Public

< Back Next > Cancel

You'll then see the screen shown in Figure 11.9. Here you enter the name you want this share to be given, along with a brief description; select Next to continue through the wizard.

**FIGURE 11.9**

Assign a share name and description.

**Share a Folder Wizard**

**Name, Description, and Settings**  
Specify how people see and use this share over the network.

Type information about the share for users. To modify how people use the content while offline, click Change.

Share name: APPS

Share path: \\SERVER1\APPS

Description: Network Application Share

Offline setting: Selected files and programs available offline Change...

< Back Next > Cancel

**NOTE** Remember that share permissions apply only to users who connect via the network. They don't apply to users who log in locally, either by sitting directly at the server or in the case of terminal server users, whose access is also considered local. Keep in mind though, that share permissions are the only way to secure network resources on FAT or FAT32 volumes.

From here, you jump straight to defining your share permissions. In the next screen (Figure 11.10), you are given four options for defining permissions:

**All Users Have Read-Only Access** This option allows the Everyone group (which, in Server 2003, no longer contains Anonymous User) to have read-only access to the contents of the folder. This is the default setting in Server 2003 and is a great new feature that brings home the extra focus that Microsoft has given to security in the last year. Until now, the default, Everyone—Full Control, included anonymous users coming in across the network! Now, when creating a share, you don't have to start with a wide-open door. You start off with a closed door and open it up per your specifications at your leisure.

**Administrators Have Full Access; Other Users Have Read-Only Access** This option ensures that your users can view data and run programs, but they can't modify or delete anything within the share. This still gives administrators the appropriate rights to manage the data.

**Administrators Have Full Access; Other Users Have Read and Write Access** This option allows the users to do anything they want except delete files or folders, change permissions, or take ownership of the files.

**Use Custom Share and Folder Permissions** This option lets you define permissions based on specific users or groups.

**FIGURE 11.10**

Controlling computer access in the Share a Folder Wizard

**NOTE** In Windows 2000, there existed an option where administrators had full control and other users had no access. This was a handy option to choose when you knew that you wanted to customize the permissions but weren't sure how you wanted to set them up. You could choose this option and feel secure about the share until you opened it up at your leisure. That option doesn't exist anymore, but there are still two ways to get almost the same thing. Either use the second option, which still allows users read access, or customize the share by choosing the fourth option. Then add the Administrator account with full control and remove the read attribute from the Everyone group.

Once you set up the permissions on your share, click Next to see the final screen of the Share a Folder Wizard, which lists the results and gives you the option to run the wizard again, as shown in Figure 11.11.

**FIGURE 11.11**

The final dialog box shows a summary of the share you created.

## Publishing Shares in the Active Directory

One of the great things about the Active Directory is that it can unify all resources in an enterprise into a single directory, whether it's printers, groups, users, organizational units, or just about anything you can dream up—or more appropriately, serve up. This counts for shares too. To publish a share, you need to be in your Active Directory Users and Computers Management Console. Right-click the organizational unit of choice and select New/Shared Folder. From there, you'll be asked to provide a name for this publication of the share and, of course, the share name. That's all there is to it—your share is now published in the Active Directory. However, it is published under the name you provided, and not as its original share name. If you publish the share \\BS1\APPS as **Network Applications**, that is all the users will see.

Also keep in mind that you will need to perform this function with the appropriate rights. You'll need to be a domain administrator or an enterprise administrator, or to have been delegated the

proper authority to publish shares. Remember to consider using the RunAs feature, which allows you to masquerade as a powerful admin just long enough to do the job.

## Managing Permissions

Now that you've shared out your resources to the world, it's time to protect them *from* the world. Of course, there are numerous ways to secure your server and its resources from the outside—using routers and firewalls, for instance—but by setting permissions on your files and shares, you are more likely to stop an intruder who *does* manage to make it all the way past your other barriers. And, of course, this also ensures that even the folks on the inside are only allowed access to what they need. The two kinds of permissions that I'll talk about here are *share permissions* and *file and directory (NTFS) permissions*. These permissions let you control who accesses your data and what they can do with it.

**NOTE** *NTFS (NT File System) is the most common and the most secure file system used for Windows Server. For more information about NTFS, see Chapter 10.*

Share permissions are applied any time a user accesses a file or folder across the network, but they are not taken into consideration when a user accesses those resources locally, as they would by sitting directly at the computer or by using resources on a terminal server. NTFS permissions, in contrast, are applied no matter how a user accesses those same resources, whether they are connecting remotely or logging in at the console. So, when accessing files locally, only NTFS permissions are applied. When accessing those same files remotely, the sum of both share and NTFS permissions are applied by calculating the most restrictive permissions of the two types.

## Share Permissions

Share permissions are possibly the easiest forms of access control you will deal with in Windows Server. Remember that share permissions only take effect whenever you try to access a computer over the network. Consider share permissions to be a kind of access pass to a secure building. When you walk up to the front door and show your identification, the guard looks up your name and gives you a pass that shows your access level for everything else on the inside. If your pass says “Level One access,” then your pass will get you into every door on Level One—and nowhere else. Once inside, try to get into a room with Level Two access requirements, and it won't work. By defining share permissions, you can safely control the access level for each person at the front door.

Keep in mind, though, that this front door—or share-level permission—isn't the entire picture. The share-level permission only represents the *maximum* level of access you will get on the inside. If you get read permissions at the share, the best you can do once you've connected remotely to the share is read. Likewise, change permissions will grant change at best. If you want full control to *anything* inside the share, you need full control *at* the share. But understand that when I say the share permission is the *maximum* level of access you will get inside the share, it is entirely possible to restrict access more once you're inside, using file-level (or NTFS) permissions. You can have full control at the share, but an object inside can still have NTFS permissions that say you can only read it.

**NOTE** There are cases every once in a while where you will choose one of the FAT file systems for your logical drives. FAT has no file and directory permission capabilities, which leaves your data very insecure. However, you can alleviate some of these pains through share permissions. Even on FAT partitions, you can share out folders and assign whatever level of share permissions you like. In this scenario, the share permissions are it—they won't be overridden by file or directory permissions because there aren't any. If you get to change the share, you get to change everything within the share. Unfortunately, this still doesn't prevent an intruder from accessing data directly at the console. Physical security of the server is your only surefire protection.

### DEFINING SHARE PERMISSIONS

To define share permissions, we will work through the Computer Management Console. Select the share you want to secure by right-clicking the share name and selecting Properties, then selecting the Share Permissions tab. You can get to the same place from Explorer by right-clicking the locally shared folder, selecting Sharing and Security, and then clicking the Permissions button; both methods will bring you to essentially the same dialog box which is shown in Figure 11.12.

**FIGURE 11.12**

The Share  
Permissions tab

**NOTE** Note that the Everyone group, by default, has Read access permissions, which is a great step forward in the Windows world in terms of security. Until, Server 2003, the Everyone group was given Full Control access by default. Another new feature in Server 2003 is that the Everyone group no longer contains the Anonymous User account, which will help keep your resources more secure.

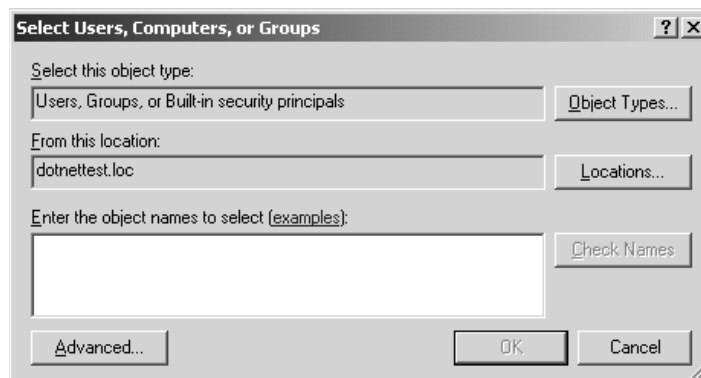

In this dialog, you are shown a Group or User Names box that lists users and groups assigned to the share; when a user or group is selected, the permissions for that user or group to access the share are revealed. You can assign different levels of permission for different users and groups. At the share level, you have the following types of permission:

Permission	Level of Access
Full Control	The assigned group can perform any and all functions on all files and folders through the share.
Change	The assigned group can read and execute, as well as change and delete, files and folders through the share.
Read	The assigned group can read and execute files and folders, but has no ability to modify or delete anything through the share.

The example in Figure 11.12 shows read access for Everyone. Although you won't see the administrator's account listed with any specific rights, note that local administrators always have full control of the shares on the computer. If you want to change share permissions to give all your network administrators full control, you will need to add the group and assign them rights. Select the Add button to see the dialog box shown in Figure 11.13.

**FIGURE 11.13**

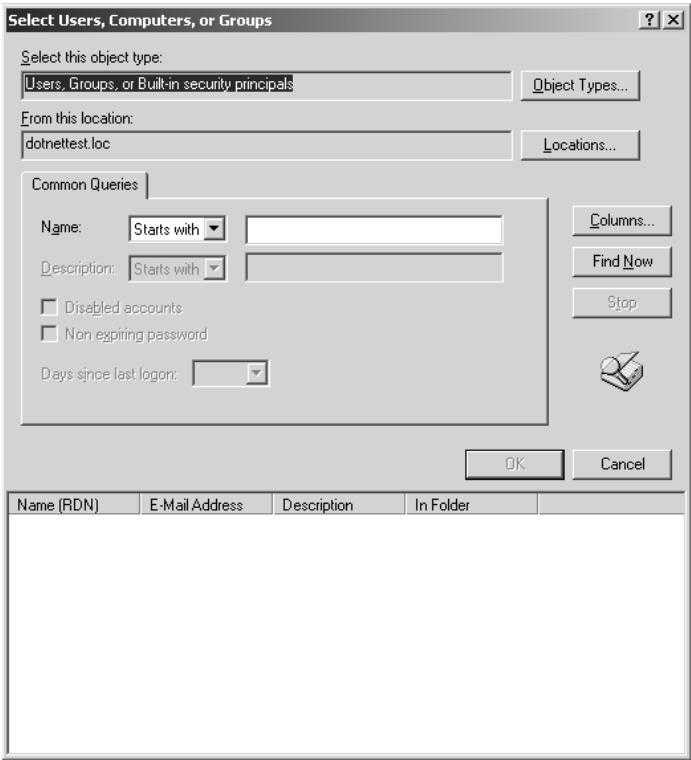

Select Users,  
Computers, or  
Groups dialog box

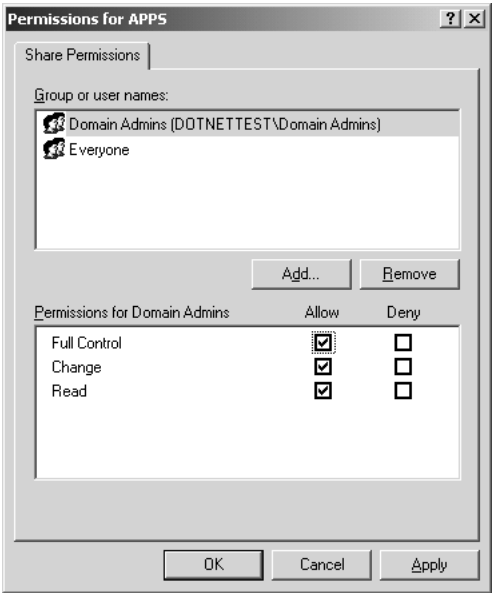

You can either type in the name of the account or group that you want to add, or click the Advanced button, which will bring you to the second Select Users, Computers, or Groups dialog box, shown in Figure 11.14. This dialog box enables you to search the directory.

You can either use the Active Directory search functions on the Common Queries tab to narrow down your choices or select the Find Now button, which will enumerate all of the users in the directory. From here you locate the group that you want to add—the Domain Administrators group in the example—and click OK and then OK again. This brings you back to the Share Permissions tab with the Domain Administrators group added to the display and highlighted. Select the Full Control check box, and as you can see in Figure 11.15, everything else is checked automatically.

**FIGURE 11.14**  
Enumerate users  
and groups by click-  
ing the Find Now  
button in the Users,  
Computers, and  
Groups dialog box.

**FIGURE 11.15**  
Share permissions,  
Full Control  
for Domain  
Administrators

Again, keep in mind that share-level permissions are just your first filter for users accessing files over the network. Whatever level of permissions you get at the share level will be the highest level of permissions you can get for files and directories (the most restrictive apply, remember?). If you get read-only rights to the share, but full-control rights to the file, the share will not let you do anything other than read.

### UNDERSTANDING ALLOW AND DENY

You probably noticed when you checked the Allow check box on the Full Control permission for the Domain Administrators group in the previous example that there also exists a Deny check box for each permission listed. Share permissions are just about the simplest set of permissions that we'll deal with, so they're a great place to explain this "allow" and "deny" notion. Here's how they work:

- ◆ An administrator of a share, file, user account, or whatever can change permissions on that object. (That's almost a complete definition of an administrator, actually.) There are several kinds of permissions—Full Control, Change, or Read in the case of shares. Anyone can be allowed or denied by the administrator, or the administrator can choose to clear *both* Allow and Deny, leaving a user with neither allow nor deny on that permission.
- ◆ If the user has no permissions, no allow or deny, then the user does not have access to the object.
- ◆ If the permission is checked Allow, the user can exercise the permission; if Deny is checked, the user can't. I know that's obvious, but let's see how it affects more complex situations.

Objects may have more than one permission on them. Figure 11.12 showed just one permission—Everyone/Read—but you'll see some Security dialog boxes with many entries giving different permissions to different individuals or groups. (Recall that these individual entries are called access control entries or ACEs, and the entire list is called an access control list or ACL, pronounced "ackel.") There may be conflicts in that case. For example, suppose I want to access some share, and there's an ACE for the group Domain Users that has neither the Allow nor Deny box checked. (I'm a member of that group.) Suppose there's also an ACE naming a group called Managers (which I'm a member of) where the Allow box is checked. Finally, suppose there's an ACE that names me specifically and checks the Deny box. Which permission wins?

The operating system looks at all of the ACEs relevant to me and computes this way: First, it ignores any "no checked" entries. No allow or deny from Domain Users. Next, it looks for any Allow checks. If I have none, then I don't get in. But I *do* have an Allow check, as I'm in Managers. So far, I've got one Allow check and no Deny checks. Finally, it looks for any Deny checks. If it finds even one of them, then I'm denied. And there is one, in the third ACE. Rephrased, then: I get permission if I have at least one Allow checked and no Deny checks. I am denied permission if I have no Allow checks at all, or if I have at least one Deny check.

For example, to deny just one person access to something, just add an ACE with their name on it and check Deny. To allow only one person access to something, remove all ACEs from the object and add that one person with an Allow check. Do *not* add that one person with an Allow check and then add Everyone with a Deny check—that one person is a member of Everyone, and so would have a Deny check...and would be denied access.

Here is where it gets dangerous. What if you have a share to which you allow read permissions for the Domain Users group, then you explicitly deny read permissions for another group called

Employees? I log in as a user who just so happens to be both a Domain User and Employees member. Now what? When I connect to that share, every group that I belong to, as well as my username, is checked against the permissions list for that share. If any one of those groups or my username comes up in the Deny column, I'm denied—end of story. Likewise, if through one group I'm allowed full control, but another group I belong to has the Deny box checked for the change permission, I can read but not change. So be careful when using Deny permissions on a share. In practical uses, you might find it extremely helpful to Deny specific individuals. You might want to create a group for Offenders that you want to specifically block. Denying general groups, though, could get you into more of an administrative nightmare than you bargained for.

## File and Directory Permissions

The old days of Microsoft networking (before the arrival of the NTFS file system) utilized share-level permissions only. Once connected to a share with a given set of permissions, you had those permissions for everything under the share. If you had 1000 users who all wanted private access to their data, you would have to create 1000 shares with specific permissions on each share. Then, with the introduction of Windows NT to the Microsoft networking platform, you could create one share for all users, and customize access via file and directory permissions—permissions that could be assigned directly to the files and folders. With this new feature came an unending ability to customize the security of your data.

You may hear a lot about how NTFS, in conjunction with file and directory permissions, can help you protect the server itself from an intruder. Theoretically, this is true. Assuming that you do not know an administrator username and password, if you sit down at the server, you cannot gain access to the server's data. The idea is that NTFS will not let you boot to anything less than the NT operating system and view files. This feature lets you relax a bit about the physical security of the server. You know that no one can log in to the server, and that your partitions are using the NTFS file system. Pop a DOS boot disk in, reboot the server, and you can't see a thing on the hard drive.

Well, it was only a matter of time. Someone *did* come up with a utility that allows you to gain access to NTFS partitions via a simple boot disk. Microsoft's Recovery Console, released with Windows 2000, lets you boot from the Windows 2000 Server or Professional CD. But actually, there was a similar package that existed long before Microsoft gave it to us. Mark Russinovich and Bryce Cogswell wrote a utility called NTFSDOS way back in 1996 that let you mount an NTFS volume from a boot disk. Mark is the same smart guy who discovered that the only difference between NT Workstation and NT Server code was just *one* Registry entry. You can still find this tool—and many others—through Mark and Bryce's freeware company, Sysinternals, or its sister company Winternals. (You can find out more at [www.sysinternals.com](http://www.sysinternals.com).) What all this means is that, to be secure, go back to square one: Lock your server up so no one can sit at its keyboard.

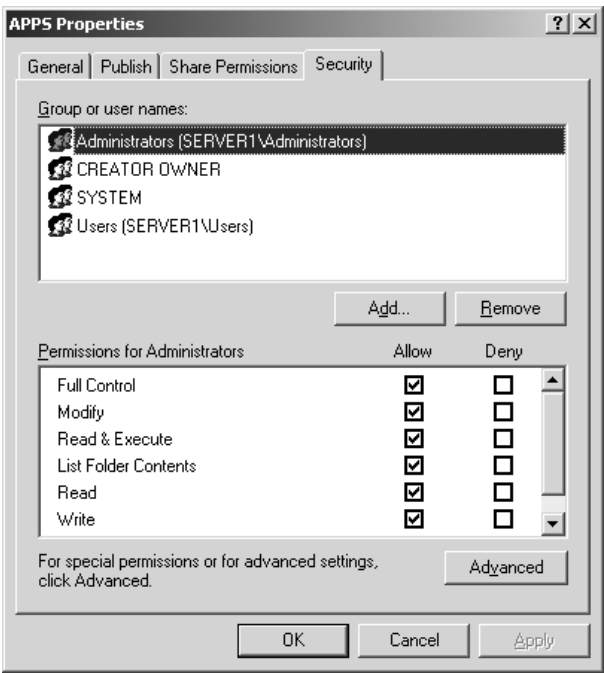

## PERMISSION TYPES

Before you assign permissions to your files and folders, you need to have a good understanding of what those permissions mean and how they work. There are two different levels of permissions.

To see the higher level, go to any NTFS folder, right-click it and choose Properties, and then the Security tab. You'll see a permissions dialog box like the one in Figure 11.16.

**FIGURE 11.16**  
Top-level NTFS permissions dialog box

Compare Figure 11.16 to Figure 11.15, a standard share-level permissions dialog box. Notice that share-level permissions only offered three permission types—Full Control, Change, and Read. Very simple, and note that there was no Advanced button in the dialog box, unlike Figure 11.16. You’ve already seen in Chapters 8 and 9 that most permissions dialog boxes have an Advanced button that lets you drill down to a lower, more-specific level of permissions. The permissions you see in Figure 11.16 are actually built up out of the lower-level permissions. For example, the high-level permission List Folder Contents comprises five lower-level permissions—Traverse Folder/Execute File, List Folder/Read Data, Read Attributes, Read Extended Attributes, and Read Permissions. I think of them as “molecular” and “atomic” permissions. There are 13 atomic permissions for NTFS. You’ll see that other object types have more or less atomic permissions; for example, any Active Directory object (a user account, a machine account, an organizational unit, a group policy object, and so on) has more than 35 atomic permissions. (Which leads to some odd things: What would a child object be for a group policy? The answer is of course that there *is* no such thing. But other sorts of Active Directory objects, such as organizational units, *can* have child objects because you can create users and other OUs inside OUs.) All AD object types share the same set of atomic permissions, even the ones that are irrelevant—go ahead and grant someone the ability to create child objects for a group policy object; it’ll be about as useful as granting someone at a brick factory the ability to set the sex of the bricks.

Look at Table 11.1 to see how groups of atomic permissions in the left column make up molecular permissions.

**TABLE 11.1:** ATOMIC AND MOLECULAR PERMISSIONS

ATOMIC	WRITE	READ	LIST FOLDER CONTENTS	READ AND EXECUTE	MODIFY	FULL CONTROL
Traverse Folder/ Execute File			X	X	X	X
List Folder/Read Data		X	X	X	X	X
Read Attributes		X	X	X	X	X
Read Extended Attributes		X	X	X	X	X
Create Files/Write Data	X				X	X
Create Folders/ Append Data	X				X	X
Write Attributes	X				X	X
Write Extended Attributes	X				X	X
Delete Subfolders and Files						X
Delete					X	X
Read Permissions	X	X	X	X	X	X
Change Permissions						X
Take Ownership						X

**SOME PERMISSIONS DO DOUBLE DUTY: FILES VERSUS DIRECTORIES/FOLDERS**

Notice in the table that some permissions have two names, such as Traverse Folder/Execute File or Create Folders/Append Data. What in the blazes does that mean? It's just one more little hurdle to get past when understanding permissions.

You see, NTFS permissions apply both to directories (or *folders*—the terms are interchangeable) and files. And Microsoft only allocated so much space on a file or folder for describing permissions—13 bits, to be exact. They use that same 13 bits whether describing a person's access level to a file or a folder.

But the kinds of things that you can do with files and folders are not exactly the same. Sure, they're similar—you change permissions on a file or folder, you read attributes of a file or folder—but some things are a bit different and in a few cases you end up with a file operation that has no corresponding action on folders and vice versa. For example, there's the “execute file” permission. You use this when you've got a file that is actually an executable file, such as `winword.exe`. If I deny you the Execute File permission, then you can't run Word, plain and simple. It's a useful permission, so it's good that Microsoft included it.

But there is *nothing* even remotely similar to it for folders. You don't execute folders.

So Microsoft looked around for a permission that was useful and that applied to folders, but that lacked a file analog. That permission is Traverse Folder. The idea is this: Suppose there's a folder you'd like to get to that is several levels deep, say a folder named C:\toplevel\level2\level3\level4. You have been denied access to C:\toplevel, C:\toplevel\level2, and C:\toplevel\level2\level3... but you have Full Control of C:\toplevel\level2\level3\level4. So you have godlike powers inside level4... if you can just *get* there.

The Traverse Folder permission lets you bypass all of the locks on the upper levels and essentially “beam yourself” right into level4. Like Execute File, it's a useful permission, but it has nothing to do with files. What's happening is this: When NTFS is examining a permission, it pulls up the 13 bits. When looking at the first one, it asks itself the question, “Is this a file or a folder?” If it's a file, then it interprets that first bit as Execute File permission. If a folder, then it's Traverse Folder permission. You'll see this in a somewhat less extreme manner on some of the other permissions as well.

Let's look at the other atomic permissions in some detail.

### ATOMIC PERMISSIONS

We'll start at the atomic level. These permissions are the building blocks of the permissions that we normally speak of, like Read, Modify, and Full Control. You will probably never see these permissions, much less refer to them on their own.

**Traverse Folder/Execute File** We just covered these in the previous section.

**List Folder/Read Data** List Folder permissions allow you to view file and folder names within a folder. Read Data permissions allow you to view the contents of a file. This atomic right is the core component of Read.

Think of the separation between these two atomic permissions. Is there really much of a difference? Yes, but probably not for long. Remember the days when we called everything files and directories? Now the file and *folder* terminology has become mainstream. Just when we start really getting used to it, another term is coming into play: *objects*. Everything on your machine is an object—both files and folders. This atomic permission could almost be rephrased to *read object*. Regardless of whether this permission applies to a file or folder, this right lets you examine the contents of an object.

**Read Attributes** Basic attributes are file properties such as Read-Only, Hidden, System, and Archive. This atomic-level permission allows you to see these attributes.

**Read Extended Attributes** Certain programs include other attributes for their file types. For example, if you have Microsoft Word installed on your system, and you view the file attributes of a DOC file, all sorts of attributes will show up, such as Author, Subject, Title, and so on. These are called *extended attributes*, and they vary from program to program. This atomic permission lets you view these attributes.

**Create Files/Write Data** The Create Files atomic permission allows you to put new files within a folder. Write Data allows you to overwrite existing data within a file. This atomic permission will not allow you to add data to an existing file.

**Create Folders/Append Data** Create Folders allows you to create folders within folders. Append Data allows you to add data to the end of an existing file, but not change data within the file.

**Write Attributes** This permission allows you to change the basic attributes of a file.

**Write Extended Attributes** This permission allows you to change the extended attributes of a file.

**Delete Subfolders and Files** This atomic permission is strange. Listen to this: With this permission, you can delete subfolders and files, even if *you don't have Delete permissions on that subfolder or file*. Now how could this possibly be? If you were to read ahead to the next atomic permission—Delete—you would see that that permission lets you delete a file or folder. What's the difference? Think of it this way: If you are sitting at a file or folder, Delete lets you delete it. But let's say you're sitting at a folder and want to delete its *contents*. This atomic permission gives you that right. There is a very vague difference between the two. One lets you delete a specific object, the other lets you delete the *contents* of an object. If I am given the right to delete the contents of a folder, I don't want to lose that right just because one object within that folder does not want to give me permissions. Hey, it's my folder, I can do with it what I want.

**Delete** Plain and simple this time, Delete lets you delete an object. Or is it plain and simple? If you have only the atomic permission to delete a folder but not its big-brother atomic permission to delete subfolders and files, and one file within that folder has no access, can you delete the folder? No. You can't delete the folder until it is empty, which means that you need to delete that file. You can't delete that file without having either Delete rights to that file, or Delete Subfolders and Files rights to the file's parent folder.

**Read Permissions** The Read Permissions atomic permission lets you view all NTFS permissions associated with a file or folder, but you can't change anything.

**Change Permissions** This atomic permission lets you change the permissions assigned to a file or folder.

**Take Ownership** We'll talk about what ownership is and what it does in more detail later, but this atomic permission allows you take ownership of a file. Once you are the owner, you have an inherent right to change permissions. By default, administrators can always take ownership of a file or folder.

## MOLECULAR PERMISSIONS

A full understanding of what atomic permissions do and of Table 11.1, which shows the atomic makeup of molecular permissions, provides exceptional insight into what these molecular permissions are and how they work. This section will try and put the atomic makeup of permissions in better perspective, but you should flip back and forth to the table while you read about these permissions. This information will form a solid foundation to help you manage permissions later.

**Read** Read permissions are your most basic rights. They allow you to view the contents, permissions, and attributes associated with an object. If that object is a file, you can view the file, which happens to include the ability to launch the file, should it be an executable program file. If the object in question is a folder, Read permissions let you view the contents of the folder.

Now, here is a tricky part of folder read. Let's say that you have a folder to which you have been assigned Read permissions. That folder contains a subfolder, to which you have been denied all access, including read access. Logic would say that you could not even see that subfolder at all. Well, the subfolder, before you even get into its own attributes, is *part of* the original folder. Because you can read the contents of the first folder, you can see that the subfolder exists. If you try to change to that subfolder, then—and only then—will you get an Access Denied.

**Write** Write permissions, as simple as they sound, have a catch. For starters, Write permissions on a folder let you create a new file or subfolder within that folder. What about Write permissions on a file? Does this mean you can change a file? Think about what happens when you *change* a file. To change a file, you must usually be able to open the file, or read the file. To change a file, Read permissions must accompany your Write permissions. There is a loophole though: If you can simply append data to a file, without needing to open the file, Write permissions will work.

**Read and Execute** Read and Execute permissions are identical to Read, but give you the added atomic privilege of traversing a folder.

**Modify** Simply put, Modify permissions are the combination of Read and Execute and Write, but give you the added luxury of Delete. Even when you could change a file, you never really could delete the file. You'll notice that, when you select permissions for files and folders, if you select Modify only, then Read, Read and Execute, and Write are automatically checked for you.

**Full Control** Full Control is a combination of all previously mentioned permissions, with the abilities to change permissions and take ownership of objects thrown in. Full Control also allows you to delete subfolders and files, even when the subfolders and files don't specifically allow you to delete them.

**List Folder Contents** List Folder Contents permissions apply similar permissions as Read and Execute, but they only apply to folders. List Folder Contents allows you to view the contents of folders. More important, List Folder Contents is only *inherited* by folders, and is only shown when looking into the security properties of a folder. The permission allows you to see that files exist in a folder—similar to Read—but will not apply Read permissions to those files. In comparison, if you applied Read and Execute permissions to a folder, you would be given the same capabilities to view folders and their contents, but would also propagate Read and Execute rights to files within those folders.

**Special Permissions** Special Permissions is simply a customized grouping of atomic rights you can create when one of the standard molecular permissions just covered isn't suited to your specific situation. Although it might appear that the Special Permissions feature is new to Server 2003, it did, in fact, exist in Windows 2000. It just wasn't visible as a molecular permission. In fact, in Win2K, there wasn't any way to tell whether or not a folder had customized atomic permissions unless you looked in the Advanced tab of the Securities properties sheet. In Server 2003, you can tell just by looking at the Allow/Deny check boxes used for Special Permissions whether the ACEs have been modified. If the check boxes appear shaded, then, by clicking the Advanced tab, you can view and edit those modifications.

## INHERITED PERMISSIONS

A tool that was released with Windows 2000 is the *inherited permissions* feature. By now, you are probably already accustomed to using this great feature, but for those of you who might not know about it yet, or who are upgrading from NT4, I'll explain. In Windows NT, if you wanted to set permissions for all files and directories for an entire directory tree, you had to check a box to apply permissions down from the root. When that happened, the server literally went through every single file and set the permissions as defined—what a tedious process. Now, there is inheritance. If a file or folder is set to inherit permissions, it really has no permissions of its own; it just uses its parent folder's permissions. If the parent is also inheriting permissions, you simply keep moving up the chain of directories until you get one that actually has some cold, hard permissions assigned. That being said, the root directory cannot inherit permissions.

For example, I have a folder named APPS, with three subfolders and files. All of the subfolders and files allow inheritable permissions. If I set my permissions on APPS to allow read and execute permissions for Users, all subfolders and files automatically mirror those new permissions. What if I want to customize the permissions on Application 1 so that users can also write? I right-click Application 1, select Properties, and then click the Security tab to view the permissions on the folder. If the check boxes for anything other than Special Permissions are grayed out, I can tell that the folder is inheriting permissions from its parent. From here, I need to select the Advanced tab in order to see the Allow Inheritable Permissions from Parent to Propagate to This Object and All Child Objects option (now there's a mouthful for you). This option shows me whether the object is inheriting permissions and lets me choose whether to allow inheritance or not. To get rid of those inherited permissions, I clear the check box and am immediately presented with the dialog box shown in Figure 11.17.

**FIGURE 11.17**

You're warned when you remove inheritance.

What is happening now is that this object is no longer going to be using inherited permissions; it will be using its own permissions. The problem is that it really doesn't have permissions of its own yet. This dialog box asks you how to start. Do you want to use the original parent permissions as a guide or baseline, or do you want to start from scratch with no permissions for anyone? If you already had highly customized permissions, you'd probably want to choose to copy those permissions and tweak them down a little further. In this case, I'll choose to copy the original permissions, and then I can just add the required write permissions on top of those. Of course, if you already have a combination of inherited permissions and permissions that you have applied directly to the folder,

you could select the second option, which would remove the inherited permissions but keep the permissions that you have explicitly defined for the folder intact.

I've covered removing the inherited permissions, but what about down the road, when I want to reset everything back to the standard top-level permissions at APPS? Just as easy. Simply reselect the check box, Allow Inheritable Permissions from Parent to Propagate to This Object and All Child Objects option. This will keep any custom, explicitly defined permissions of those objects and add the inherited permissions from the parent folder.

In Windows 2000, the effect of this action would have removed all permissions and replaced them with only the inherited permissions. A new feature in Server 2003 will allow you to see where the specific permissions come from. In Figure 11.18, you can see that specific permissions, or ACEs, have an entry in the Inherited From column, which shows you this valuable information.

**FIGURE 11.18**  
The Inherited From column allows you to see whether the permissions are inherited or not and, if inherited, from which folder the permissions are inherited.

In addition, by viewing the information in the Apply To column, you can determine where the ACEs will be applied further down the folder tree. You can highlight an entry and choose Edit to specify where those permissions should be applied in the tree, as shown in Figure 11.19.

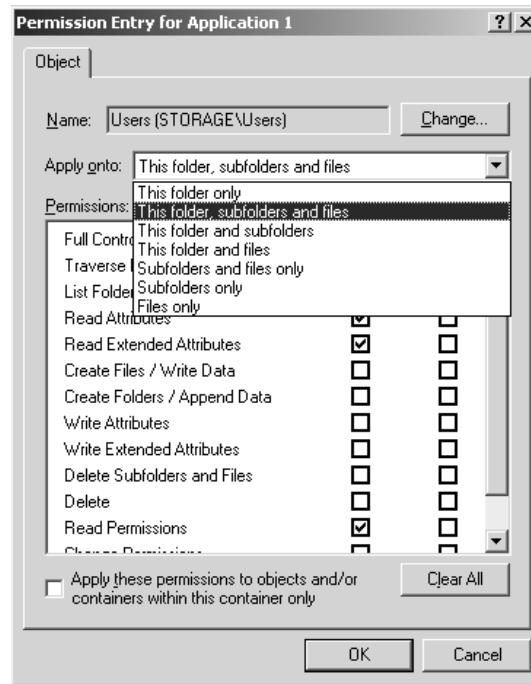

**Active Directory Objects and Inheritance**

Although I said that you can specify which child objects will inherit permissions by using the Apply Onto feature, something different happens when you use this in an Active Directory environment. Although the permissions you created will only be applied to the subset of files, folders, and subfolders that you chose when you used the Apply Onto functionality, a copy of the ACE will be given to

every child object, regardless of whether you specified that it should receive it, but only the ones you specified actually implement it.

**FIGURE 11.19**

You can apply permissions downward in a variety of ways.

### ***Deny or Allow with Inheritance***

When you add permission inheritance to the mix, things can get a little strange. Do you remember when I said that Deny always wins, that if you have a Deny entry you cannot access the object, whether you have an explicit Allow or not? That isn't exactly true for objects that have inherited permissions from a parent. If an object has an explicit Allow set on the object itself, then even if a Deny permission is inherited from a parent, the Allow will win out. Simple enough?

There is one other interesting note with respect to inheritance. Keep in mind that these ACEs can get pretty complex, with lots of different permissions having to battle it out. When an object is receiving inherited permission from more than one parent, the permission inherited from the closest parent will prevail. What, you say? This is starting to get complicated? Well, Microsoft has made it a little bit easier to determine what the end results of the various permission sets will be with a tool called Effective Permissions, which I'll tell you about next.

### **ASSIGNING FILE AND DIRECTORY PERMISSIONS**

Once you understand what the different permissions mean, assigning them to files and folders is a piece of cake. Start off in Explorer. Find the file or folder you want to assign rights to, right-click it, select Properties, and then select the Security tab. Take a look at Figure 11.20.

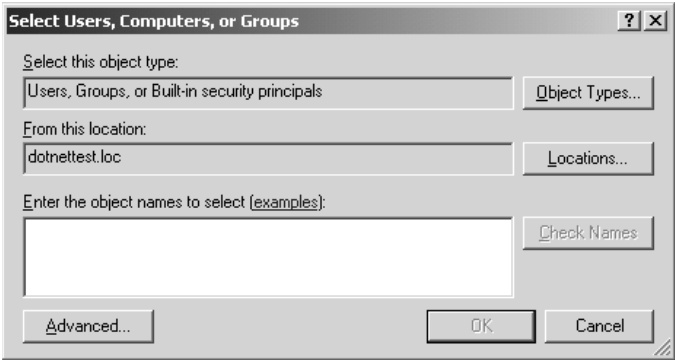

**FIGURE 11.20**  
The Security  
properties tab

The top window shows the different groups or users to whom permissions are assigned, and the bottom window shows the permissions assigned to the selected user or group. I'm starting off in my APPS folder. Ideally, because this is for applications, I want all users to have Read and Execute permissions and not have the ability to change, add, or delete anything. I also want to keep administrators in full control so they can still maintain the data, and there is also a group of database managers that I want to give Modify rights. Since the Users and Administrators groups already have an entry by default, I'll start off by adding the Database Managers group and giving that group Modify rights. Click the Add button, and the Select Users, Computers, or Groups dialog box appears, as shown in Figure 11.21.

**FIGURE 11.21**  
Select Users,  
Computers, or  
Groups

You can type in the name of the user or group, select the Advanced button, and click the Find Now button, or set up your query manually to enumerate a list of domain accounts. Since I know the name of the group I want to add (Database Managers), I'll just type it in here and then select the Check Names box. This will cross-check my manually typed entry with the list of names to find a match. Once the name is underscored, click OK to return to the Security tab of the properties page of APPS. Now that I have added the Database Managers group, the dialog box should look like the one shown in Figure 11.22.

**FIGURE 11.22**

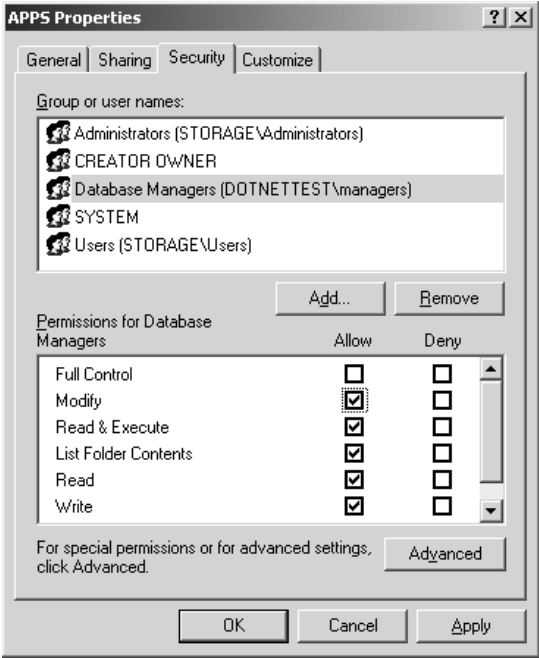

The Database Managers group is added.

**NOTE** You can add multiple users and groups at one time using either interface in the previous example. When you type the names in manually, just type the first name then click the Check Names box and start typing the next name. If you don't type a complete name before clicking Check Names, it will give you the closest match to your typed entry. If you choose to use the Active Directory Search interface, you can select multiple accounts by clicking on the first entry and then holding the Ctrl key down while you click additional entries.

Now that I have added the Database Managers group, all I have to do is assign the correct permissions, which are Modify rights. Highlight the Database Managers group and check the Modify box in the Allow column. The Security tab should now look like Figure 11.23. Since the Users and Administrators groups were added by default when I created the share, let's look at the default permissions that were applied and see if I need to make any adjustments. Click the Users ACE, and you will see the dialog box in Figure 11.24.

**FIGURE 11.23**  
New permissions

**FIGURE 11.24**  
Default permissions for the Users group

**NOTE** You need to be careful when selecting some permission levels. Selecting *Read and Execute* includes all of the rights of *Read*, so *Read* is automatically checked. If, on the other hand, you want to clear *Read and Execute*, unchecking the *Read* and *Execute* box won't automatically uncheck *Read*.

You can see, in Figure 11.24, that the Users group already has some default permissions, including *Read and Execute*, *List Folder Contents*, and *Read*. You can also tell that these are inherited because of the gray shading in the *Allow* boxes. However, as you may remember, the shading in the *Special Permissions* box doesn't mean that these permissions are inherited (although they might be). The shading here just represents the fact that there are more permission entries than you can see in this particular dialog box; click the *Advanced* tab to find out more. If you look at Figure 11.25, you will see a much more complex version of the permission entries you saw in Figure 11.24. I'm not quite sure why the good folks at Microsoft provide us with a sort of table of contents for the permissions story, when they could simply provide us with the whole story all at once. After all, we're not talking *War and Peace*, here. Just remember that you can get a basic idea of what is going on in the first screen, but you'll need to drill down to get to the details.

**FIGURE 11.25**  
Advanced Security  
Settings for APPS

The Permission Entries box shows your selected groups and users, with a description of their rights. The *Allow Inheritable Permissions from Parent to Propagate to This Object* check box is the same, and you can still add and remove entries from this box. So, what is different here? In this window, you get to see a few more details. First, you can see that what might have been one entry (ACE) in the previous screen can become two or more detailed entries, allowing you to see exactly which rights are inherited and from where, or whether the entries were specifically created for this

resource by hand. For example, notice that the Users group has two entries, both of which are inherited by the volume. You can also see exactly where the permissions flow downward by looking at the Apply To column. Of course, having all these details is great for troubleshooting because you finally have all the information in one place (well, almost).

You have the ability to tailor your extended permissions to the atomic level by choosing an entry and clicking the Edit button. Be careful, though. With so many permissions coming from so many different places (and we aren't even considering share permissions here!), this process can easily become messy to troubleshoot. Try to simplify your resources and users as much as possible, by volume, by group, or by machine, and your life will be a lot simpler when dealing with permissions.

To see what rights the Users group has so you can make sure they have the correct access to the APPS folder, select the Users entry with Read and Execute permissions, then click the Edit button. You'll get the options shown in Figure 11.26.

**FIGURE 11.26**

Viewing and editing the atomic permissions gives you the most information.

**TIP** Notice that when you click the Users entry with Read and Execute permissions, the Remove button becomes unavailable. Why? Well, you can see that this ACE is inherited from I:\, and you would have to disable inheritance if you wanted to remove this entry.

These permissions break down Read and Execute into smaller parts. If you want your users to have all the benefits of Read and Execute but don't want to allow them to view permissions, you can simply clear the Read Permissions box. Of course, there are still 13 atomic permissions available here. It seems odd, since there are, have always been—and who knows—may always be, 13 atomic permissions in NTFS, that they did not build the window size so that you can view them all at one time. However, for our purposes, the permissions you see checked in Figure 11.26 are all of the applicable atomic permissions for Read and Execute that apply to the Users group.

**TIP** You might have noticed that the *Apply Onto* drop-down list is also unavailable for the *Users* group entry. Remember, you couldn't remove it because of inheritance, and this is yet another result of inheritance. You can consider inheritance as an order from on high. These permissions will be applied to this folder, subfolder, and files unless and until you remove the inheritance check box and create your own custom permissions. Or you could go straight to the source, since, as the administrator, you are the ruler when it comes to inheritance. If you open up the properties for the volume itself and edit the entries for the *Users* group, you can remove or modify the permissions; you can then specify exactly where you want them applied throughout the volume by using the *Apply Onto* button from there.

These permissions are Read and Execute, by the book. No more and no less, these five atomic permissions make up Read and Execute. Consider it law.

But wait, there were two entries for the *Users* group, remember? Server 2003's default permissions are sure a lot more interesting (and safer) than those given to us in Win2K. (Remember, in Win2K, Everyone had Full Control on *everything*!) Let's examine the atomic permissions for the other *Users* group entry. If you are still looking at the dialog box in Figure 11.26, click *Cancel*—you don't need to modify the Read and Execute entry because that is exactly what you want for the APPS directory. Back at the Advanced Security Settings for APPS window, click the other entry for the *User* group and then click *Edit*. You'll see the dialog box in Figure 11.27.

**FIGURE 11.27**

Editing the Special Permissions for the *Users* group

The default permissions for the *Users* group include the ability to create files and folders on the volume as well as the ability to write data and append data to the files contained within that volume—unless, of course, you specifically deny that ability to any particular resources on the volume. So, what you have here is a set of permissions that is in between two of the molecular

groups we discussed previously. The first set of atomic permissions we looked at for the Users group made up the Read and Execute molecular permission. If you add these two atomic permissions, the molecular set falls somewhere between Read and Execute and Modify. In full, the Modify permission also includes the right to Write Attributes, Write Extended Attributes, and Delete files and folders.

If you know that you do not want to allow the Users group to have these extra two atomic permissions anywhere on the volume, you can simply edit the properties sheet for the volume and remove this particular entry for the Users group. If, however, this volume will also house directories where the users might need those permissions, you can edit these properties on the specific folders you want to restrict. Since this folder is used exclusively for applications and you know we don't want the Users to create anything, you can do one of two things. You can disable inheritance for this folder and modify the permissions, or you can simply deny the Users groups these two permissions on this folder.

For a couple of reasons, the easier of the two solutions is to use the Deny function. First, you don't have to worry about the rest of your inherited permissions from the volume, some of which you will need to keep—when you remove inheritance, you are given the right to copy the existing inherited permissions and can edit them as you like. Second, by removing inheritance, you take away your ability to push out permissions from the volume on a global scale, which is a pretty handy feature. As I said before, if you can simplify the permissions by doing things on a global scale, you can save yourself a lot of time and energy. To disable the ability for the Users group to create files or folders or to write or append data with the APPS folder, simply click the Deny check box (see Figure 11.28) for both of the atomic permission entries and click OK.

**FIGURE 11.28**

There isn't enough information to determine the *whole* permissions story from the initial property sheet.

### **Removing a Group or User**

To remove a group or user entry, just click the Remove button from either of the two property sheet interfaces that you just saw. If a user or group is there because of inheritance, the Remove option will be unavailable and you will have to disable inheritance by clicking the Allow Inheritable Permissions from Parent to Propagate to This Object and All Child Objects option.

### **Use the Detailed Interface to Get the Whole Story**

Look at Figure 11.28. Remember this dialog box? Let me remind you of something I said before about the interfaces used for managing NTFS permissions: This window just doesn't give enough information and it's kludgy. If you decided to disable inheritance to get rid of the Users group's Write permissions and clicked the Remove button in this interface to accomplish that, you'd remove *both* of the Users entries that you saw back in Figure 11.25. Also, if you used this window to add a user or group account, you'd only be able to check the molecular permissions boxes you see here—you wouldn't be able to specify exactly where you wanted those permissions applied using inheritance. You'd have to drill down to the interface in Figure 11.25 to do that. It's best to just bypass this unnecessary dialog box and go straight to the detailed view. That way, you have the full story to start with.

### **CONFLICTING PERMISSIONS**

You can assign permissions to files, and you can assign permissions to directories. Just as share permissions can conflict with file and directory permissions, file permissions can conflict with directory permissions. In share-level conflicts, the share wins; in file and directory permission conflicts, the file wins. If you assign read-only rights to a directory, but you assign change rights to a file within that directory, you will still be able to change the file.

Here is an interesting permissions riddle that I came across recently. Let's say you have read and execute permissions on a file and on the directory it resides in. You open the file and modify it. Sounds simple, right? Well, I've found that some applications actually *delete* the original file when they save a file with modifications, even if you don't change the filename. You are allowed to open the file, read it, and make your changes, but the minute you try to save it you will get an access denied message. Weird, isn't it? If you want to try this yourself, use Microsoft Word. I know that particular application behaves in this way, and perhaps others do as well.

### **MULTIPLE PERMISSIONS**

Now for another problem. You have given your Administrators group full control over the APPS folder, and everyone else has read and execute permissions only. Here is where permissions once again come into conflict. Everyone is a user, right? Even administrators are users. Hmmm. How does this work? Well, in the case of multiple permissions, the *least restrictive* permissions will prevail, as long as share permissions aren't involved. Let's say you have an administrator named Bob. Bob is part of the Users group, which has read-only rights on a file. Bob is also part of the Administrators group, which has full control. In this case, Bob will get full control because it is least restrictive.

### **DENY PERMISSIONS**

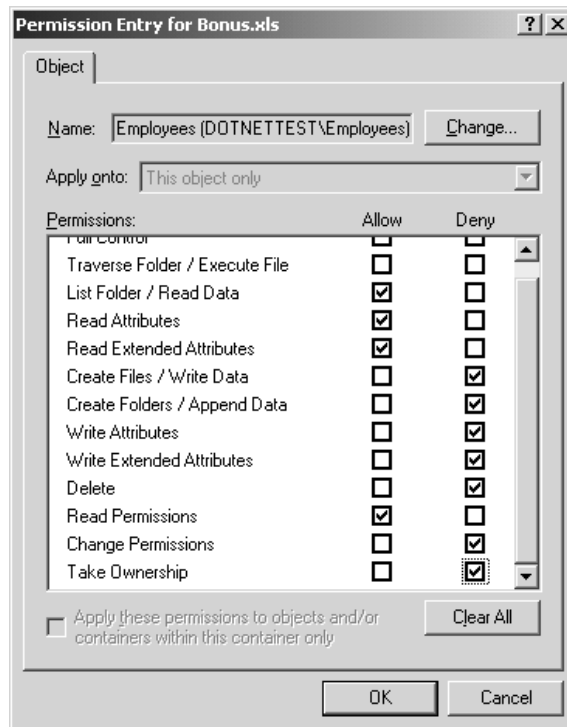

We talked about Deny permissions with respect to shares earlier and then briefly talked about the effects of inheriting permissions as it relates to Allow and Deny. The same thing applies in file and directory permissions, but in a way that's just a tad bit more complex because of the increased number

of security options. Think of a corporate bonus-award spreadsheet file that you are trying to protect. You want everyone to see the file, but you only want the managers to be able to actually change the file. It makes sense: Grant Employees the right to read and Managers full control. Imagine that, somewhere along the line, some low-level supervisor falls into both groups. They need to be part of Managers for some things, but are more like Employees in others. If you leave the permissions as I just described, this supervisor is going to get the best of both worlds with this spreadsheet—full control. For this reason, you decide that you explicitly don't want anyone in Employees to have full control. Now what?

Easy enough: simply deny those excess permissions. What you need to do is find out which permissions you specifically do *not* want Employees to have and check them in the Deny column; this way you can make sure that Employees are given Read rights only. To do this, from the Advanced interface (see Figure 11.29), right-click the file and choose Properties. Now click the Security tab and then click Advanced. Remember this interface from Figure 11.25? From here, highlight the entry for the Employees group and click Edit, which will allow you to modify the atomic permissions for the spreadsheet. Check the Deny column for the entries that you see in Figure 11.29.

**FIGURE 11.29**  
Deny permissions

You'll need to individually check the Deny boxes for each attribute. If you check the Deny box for Full Control, however, everything else below that will automatically be selected in the Deny column because Full Control *includes* all permissions.

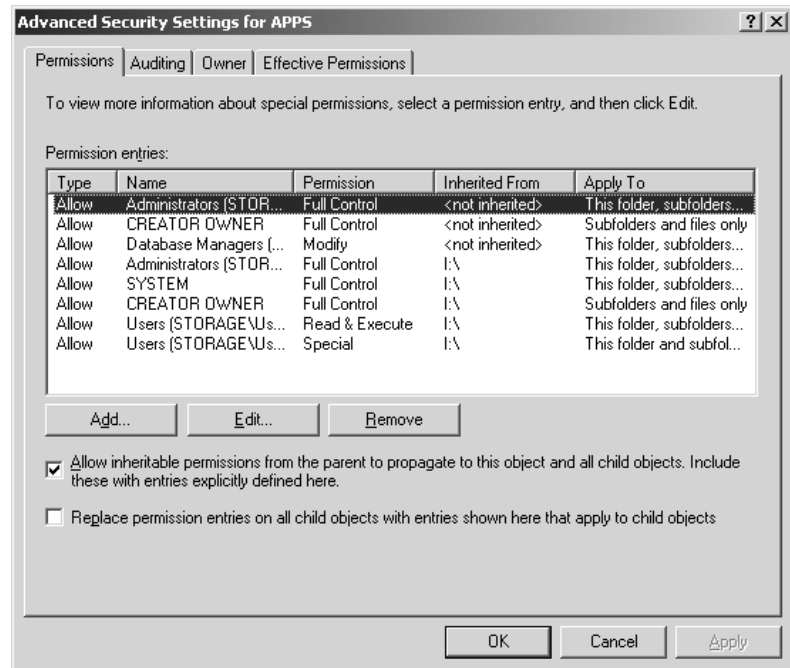

For this example, you want to allow Read and deny Write. When you click OK to have these new permissions take effect, you'll get a warning that tells you that Deny permissions override Allow permissions. Now, in the case of the multiple-permissions scenario, the Deny takes precedence, and even if the supervisor in question has both Managers and Employees memberships, he'll get cut off with the Deny.

### EFFECTIVE PERMISSIONS

What is the end result of all of these permissions if some are inherited, some are not, some apply to users, and some apply to groups? Who will get to do what and with which files? By now you have seen that permissions can conflict with each other and sometimes have to battle it out to determine the winner. How can you tell what the result of all of these permissions will be for any group, user, or object? Well, Microsoft has included a new tool in Server 2003 that allows you to calculate the effective permissions for any particular user or group on a particular object. Take a look at the dialog box in Figure 11.30. Once again, it's the advanced property sheet for your APPS folder that, by now, you should know well. Remember that Administrators have Full Control, Database Managers can Modify and Users have Read and Execute permissions?

**FIGURE 11.30**

Advanced permissions for the APPS folder

To see how exactly all these permissions work, click the Effective Permissions tab, and you will see the dialog box shown in Figure 11.31. It's simple. Just select a user or group name to view the permissions based on Global and Local group permissions, local permissions, and local privileges.

**FIGURE 11.31**Effective  
Permissions

Of course, you have to have the appropriate rights to view the permissions on whatever resource you are checking, and there *are* some limitations in terms of the factors that are used to determine the effective permissions. For instance, you may not be able to view permissions for every user or group. Consider the local users group on the server called Storage, where your APPS share is located. Because this server is a member of an Active Directory domain, the global group called Domain Users is automatically nested within the local Users group. You can view the effective permissions on the local users group by selecting the local location called Storage (instead of the directory) after clicking the Select button from the screen in Figure 11.31. You get the results shown in Figure 11.32, which were obtained by calculating the permissions for the two entries that exist for the Users group in Figure 11.30.

Because the Domain Users group is nested in the local users group, domain users have the same rights to the folder, barring the existence of any other set of permissions that would conflict with these. But when you try to get the effective permissions for the Domain Users group using this tool, it comes up empty because this tool cannot calculate the effective permissions for domain groups that are nested in local groups.

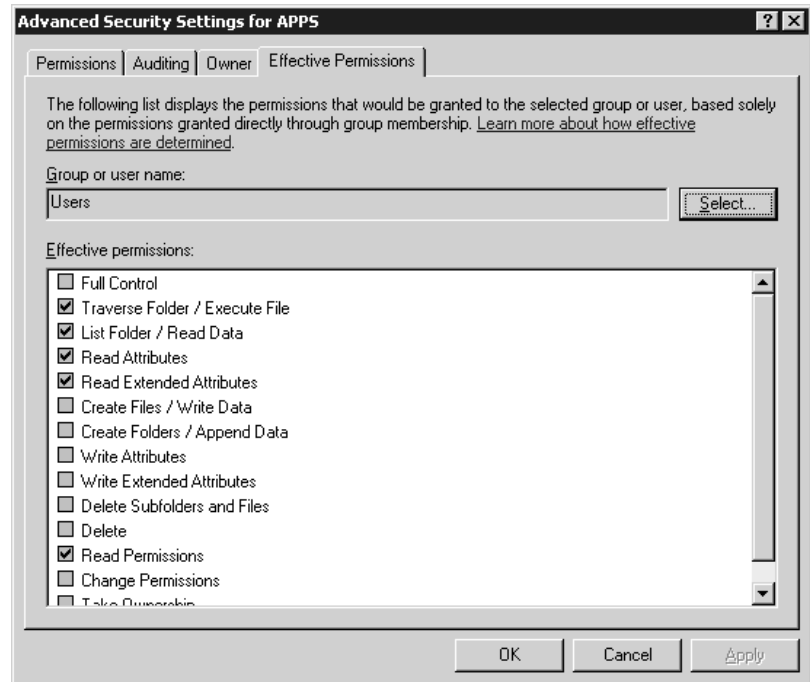

Here are some other limitations:

- ◆ This tool does not take into account any share permissions.
- ◆ It does not take into account many of the SIDs that users have, based on how they are logged in. For instance the Network SID, Terminal Service SID, and many others are not taken into account by this utility.

This certainly limits the effectiveness of the tool, but you can still use it to calculate multiple ACEs for a user or group, as you saw in the previous example.

**FIGURE 11.32**

Effective Permissions for the Users group

## OWNERSHIP

Through the course of assigning and revoking permissions, you are bound to run into the problem where no one, including the administrators, can access a file. And you can't change the file's permissions because you need certain permissions in order to assign permissions. This could be a really sticky situation. Fortunately, ownership can help you out.

There is an attribute of every object called an *owner*. The owner is completely separate from permissions. There will always be *some* owner for *every* object. Yeah, that's great, but how does that help me? Well, the owner of an object has a special privilege—the ability to assign permissions. So if I'm the owner of a file, but don't have access to the file, I can take advantage of my ownership to reassign permissions to myself. Neat-o.

Well, how do I get to be the owner anyway? For starters, whoever creates an object is the default owner. Should that person be a regular user, that's the owner. If there is no apparent creator of the object, which is the case for many system files and folders, ownership is set to the domain's Administrators group.

Here is another problem: The file you are trying to get to but have no permissions for was created by a user and therefore is owned by that user. So you don't have permissions, and you're not the owner, which means that you can't reassign the permissions. Aha. There is a right that is assigned to Administrators that allows them to take ownership of objects. With this right, you can go into that restricted object, seize ownership, and then use that new ownership to reassign permissions.

Let's walk through this whole scenario: I have a share called **USERS**. Under **USERS** is a folder named **Brian**, to which I have installed Full Control permissions for Brian only. While logged in as Administrator, I try to access the **Brian** folder and receive an Access Denied message. The time has

come for me to check out what Brian has been up to. I right-click the Brian folder and select Properties, then select the Security tab. I receive the dialog box shown in Figure 11.33.

**FIGURE 11.33**  
Permissions for the  
Brian folder

Well, I can see that Brian has some set of permissions on this folder, but the check boxes are all shaded, indicating that I have no right to edit these permissions. Let's look at the Advanced permissions dialog box to get more detail. I click the Advanced button and see the dialog box shown in Figure 11.34.

I can see that Brian has full control, but no one else is in the access list at all. But wait a minute, if I'm not in the access list, how am I even seeing these permissions? I select the Owner tab and a dialog box like Figure 11.35 appears, showing my ownership.

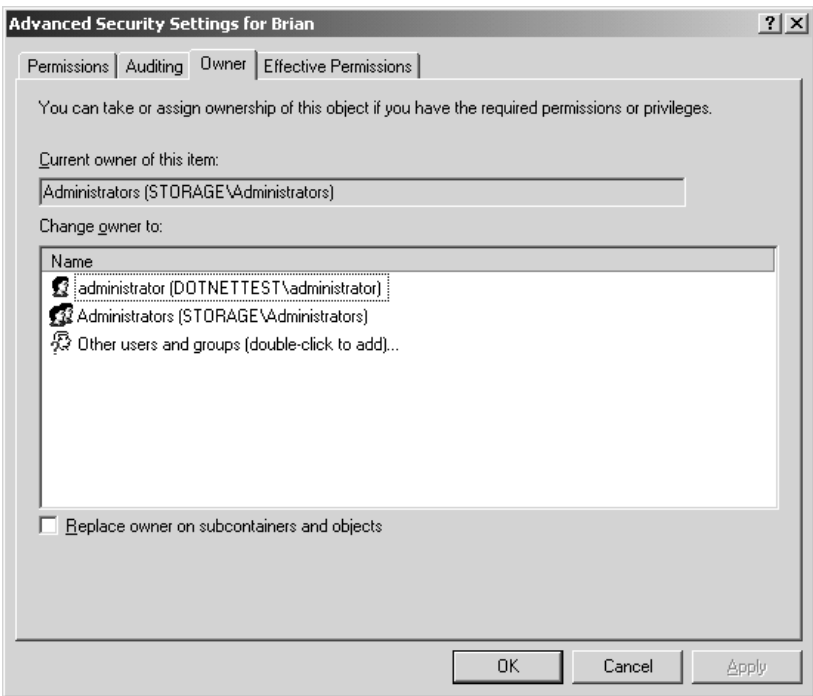

That's right, I was the one who originally created the folder Brian, so I'm the owner. As the owner, I can reassign permissions. That does it, I'm adding Administrators to the access list with full control. I click the Permissions tab to return to the Advanced permissions screen. I select Add, find the Administrators group, and then grant them full control. My permissions now look like Figure 11.36.

**NOTE** If I had initially created Brian's permissions for this folder using the Add button (see Figure 11.33), the Brian entry would have had check marks in all the Allow boxes and I could have edited them from there. But because I created these permissions using the Advanced Security Settings dialog box, all I could see was that there were additional viewable permissions that I'd have to edit in the Advanced dialog box. As I've said, I prefer to manage all my ACEs from the Advanced tab because this initial screen doesn't give you the whole picture, but don't let it confuse you: you can edit these permissions because you are the owner of the file—you just can't do it in the initial screen.

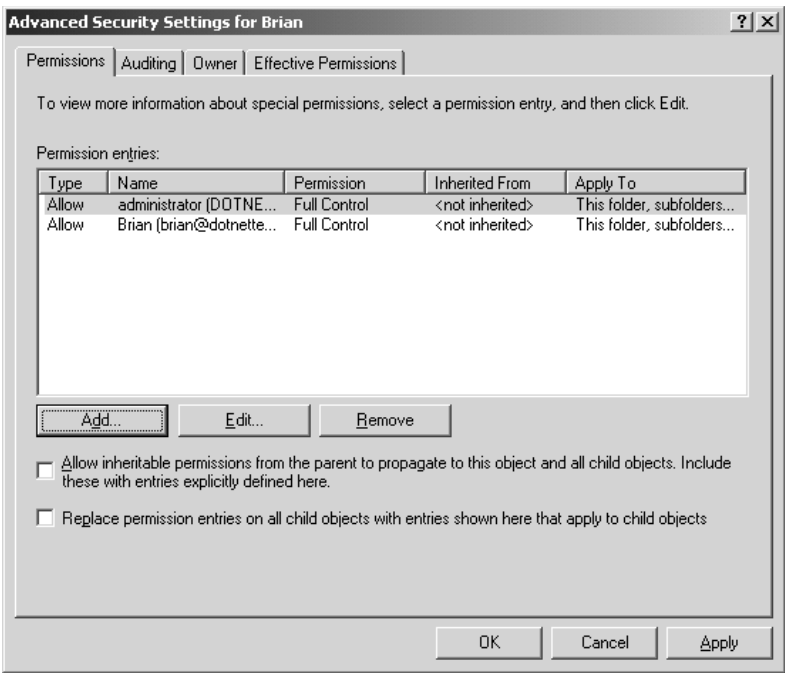

**FIGURE 11.34**  
Advanced  
permissions for  
the Brian folder

**FIGURE 11.35**  
Advanced security  
settings, showing  
current owner

**FIGURE 11.36**  
New permissions

Now, back to Explorer, I click the **Brian** folder and I'm in, only to find a folder that Brian created named **Secret**. I click that folder—Access Denied. Easy enough, I'll just go in and do the same thing. I right-click **Secret**, select **Properties**, and then select **Security**. This time, I get a different message, as shown in Figure 11.37.

**FIGURE 11.37**  
I have no permissions for this folder.

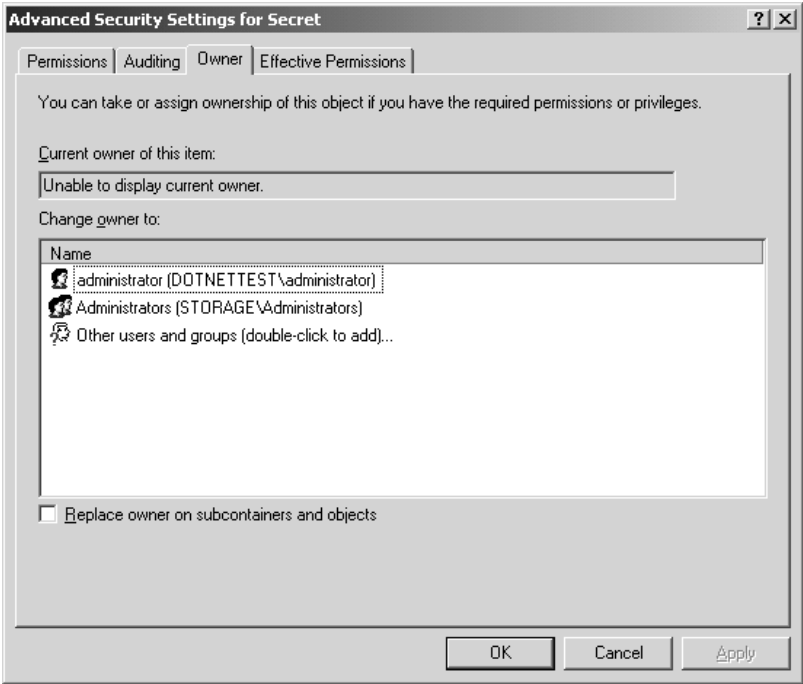

I don't have permissions, but I can take ownership. Why is it different this time? Well, last time I had created the folder named **Brian**, so I was the owner; therefore I could still view and change permissions. This time Brian created the folder, which means that Brian is the owner, so I—Administrator—have no inherent rights to even see the permissions. This becomes obvious when I see the Security properties tab, shown in Figure 11.38.

I am looking at the Security properties tab, but I can't see who has what permissions. I also can't add or change permissions. In fact, everything in this dialog box is grayed out, except for the **Advanced** button. Well, let's hit it. Under the advanced properties, I see a similar sight—the advanced Permissions tab options are grayed out entirely. So I select the **Owner** tab (see Figure 11.39).

**FIGURE 11.38**  
Permissions as  
viewed when not  
the owner

**FIGURE 11.39**  
Unknown owner

I can't tell who the owner is, but it is safe to say that it isn't me. From here, I want to take ownership. Under the Change Owner To box, you will see the different users or groups that I belong to who have rights to take ownership. As you can see, I can select either Administrator or Administrators. Do I want to use the individual Administrator account or the Administrators group? In this case, I won't want every administrator on the network to be able to view Brian's secret folder, so I'll select Administrator. If I simply select Administrator and hit OK, I'll be given rights to the folder, but I will probably run into the same roadblock with subfolders and files. To get it all over with in one shot, I click the check box next to Replace Owner on Subcontainers and Objects. A translation of this into old Windows NT terms would be Replace Owner on Subdirectories and Files. I hit OK and see the dialog box shown in Figure 11.40.

**FIGURE 11.40**

Taking Full Control of the folder can be automatic.

What this is telling me is that, even though I am making the move of becoming an owner, I will still have no access to the folder until I give myself some rights. If I click No, then I will have to manually go in and give myself Full Control permissions on the folder. Here, Server 2003 is saying that it will do it for me. This is an improvement over Windows 2000, where it was a two-step process. I click Yes and return to the less helpful dialog box from Figure 11.38, but now I'm the owner and I have full control over the folder. Now when I click OK to finish out the task and try to access the folder, presto, I'm in!

This will also pass my new permissions down throughout the entire `Secret` directory structure, so I shouldn't have to worry about anything Brian might create in the future.

## Auditing File and Directory Access

Security's no good unless you use it. Who deleted that file out of the common share? Who modified that file? You can use NTFS's permissions to track that stuff to the event log.

There are two steps to logging file and directory access: First, you've got to tell your computer to enable auditing, and, second, you've got to tell your system which files and directories to audit.

### Enabling Auditing

I don't know why you can't simply say to an NT/2000/XP/Server 2003 system, "Log any accesses to this to file," but you can't, at least not without first enabling the whole idea of auditing. I'm guessing it's a performance issue—auditing must be driven by some kind of "watchdog" routine that peeks at file accesses and logs those accesses it's been told to log. But I guess the watchdog must suck up some CPU time, hence disabling auditing by default.

You turn on auditing as you read in Chapter 8, but here's a review. You can enable auditing on a system-by-system basis with the Local Security Policy snap-in, or you can flip it on for groups

of machines via group policies. To turn it on for a particular system, click Start/Programs/Administrative Tools, then Local Security Policy. Then open up Local Policies and then Audit Policy. You'll see something like Figure 11.41.

**FIGURE 11.41**  
Auditing options

To track file and directory access, double-click the Audit Object Access item, and you'll see a dialog box like Figure 11.42.

**FIGURE 11.42**  
Enabling object auditing

Notice that, as you learned in Chapters 8 and 9, any domain-based group policies will override local group policies—but of course if you don't have an Active Directory, there won't *be* any domain-based group policies.

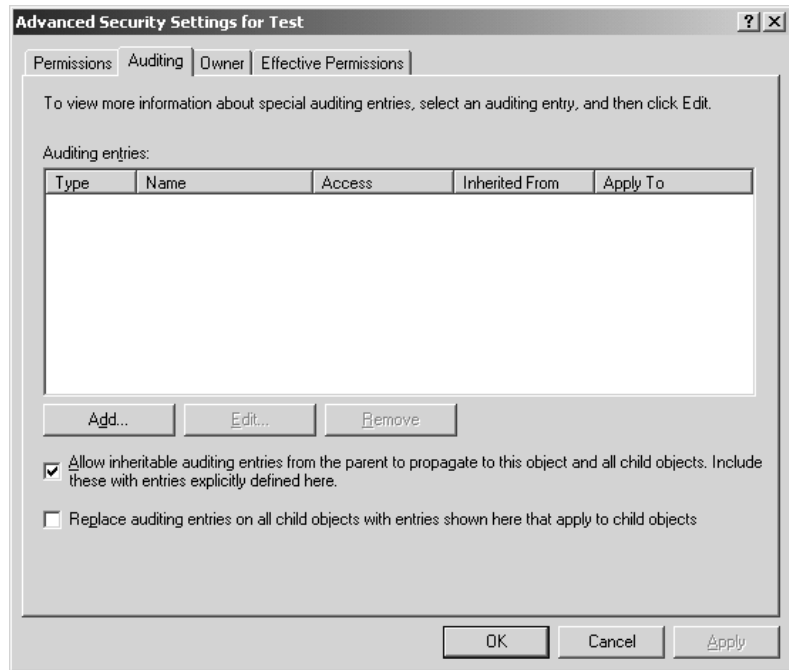

To enable auditing using domain-based group policies, create a group policy object and look in the Computer Configuration/Windows Settings/Security Settings/Local Policies/Audit Policy. Apply that object to the particular domain or OU for which you want to enable auditing.

All you've done at this point is make auditing *possible*. Now tell the system which files you want to audit. Do that by getting to the Security tab of any file or folder (right-click the file or folder and

choose Properties, then the Security tab) and then the Advanced button to raise the Advanced Security Settings for *objectname* property page. That will have four tabs: Permissions, Auditing, Owner, and Effective Permissions. Remember this box? We've already looked at three of those four, so let's look at Auditing. Click Auditing and you'll see something like Figure 11.43.

**FIGURE 11.43**

Auditing  
property page

Note that inheritance applies to Auditing as well as permissions. The two check boxes are the same ones you saw earlier in this chapter, and they work the same way here.

Click Add and you'll be prompted for the users to audit—you've seen this dialog box before, so I'll spare you the figure—and you can say that you only want to watch a particular user (you've always had your eye on that Peter character, haven't you?) or a group, including local and domain groups. You *then* see the atomic permissions dialog box, which, again, you've also seen before. But where the previous atomic screen shot gave you an Allow or Deny check box for each type of permission, this one gives you a Successful and Failed check box.

Thus, you could decide that you only want to know when someone transfers ownership of a file and don't care if someone tries and fails to modify ownership. The atomic permission is Take Ownership. You'd check the Successful check box because you only care if someone actually *changed* ownership—if he failed in his attempt, then you don't care. (Understand that I'm not *recommending* you only audit ownership changes; this is just an example.)

Once you've set up auditing on a directory (or a file), you can see who's been working with it by looking in the security log. For example, an event type 560—a file write—shows the following information:

Object Open:  
Object Server: Security

```

Object Type:   File
Object Name:   D:\test\test.txt
New Handle ID: 208
Operation ID:  {0,5892625}
Process ID: 1208
Primary User Name:  panderso
Primary Domain:   BIGFIRM
Primary Logon ID: (0x0,0xE90B)
Client User Name: -
Client Domain:   -
Client Logon ID:  -
Accesses      READ_CONTROL
              SYNCHRONIZE
              ReadData (or ListDirectory)
              WriteData (or AddFile)
              AppendData (or AddSubdirectory or CreatePipeInstance)
              ReadEA
              WriteEA
              ReadAttributes
              WriteAttributes

```

You see from this that you're opening a file named `D:\test\test.txt` and the person doing it is named `panderso` in a domain called `BIGFIRM`. You can then see the various atomic permissions that `panderso` exercises (whether he knows it or not) when he closes a file in Notepad that's changed.

Everything that you read in Chapter 8 about auditing applies here: Be sure to do something about managing the logs. They can get large quickly. And remember that logging is of no value if you don't check the logs now and then!

## Hidden Shares

As you've seen before, once you share a folder out to the network, it becomes visible to the user community. But what if you don't necessarily want everyone to see the share? For example, I have created an installation source share on my server so that whenever I go to a user's workstation, I can install whatever applications I need to without having to bring CDs. It's really just a convenience for me, but at the same time, I don't want the users clicking away through the shares, installing every program they can get their hands on. Sure, I could limit the share to allow permissions only to me, but that is kind of a pain, too. I don't want to log off the user and log in as myself every time I do an install, especially if user profiles are being used. This is where creating hidden shares can help. I want the share to be there and available, but just not as easily visible. Although not a completely secure solution, it is a deterrent to the overly browse-active.

To create a hidden share, proceed as normal in sharing a folder, but place a dollar sign at the end of the name. That's it. Now, whenever the server registers its information to the browse list with its available resources, it simply will not register that hidden share.

The share that I am creating will be called `INSTALL$`, which will be shared from `D:\Install`. I create the share as normal, making sure to call it `INSTALL$` instead of `INSTALL` (see Figure 11.44).

**FIGURE 11.44**

Creating a hidden share

Now, from my client workstations, I will not see the INSTALL\$ share listed in the browse list, but I can still map a drive to the INSTALL\$ drive connection if I manually type the share name, as I've done in Figure 11.45.

**FIGURE 11.45**

Mapping to a hidden share

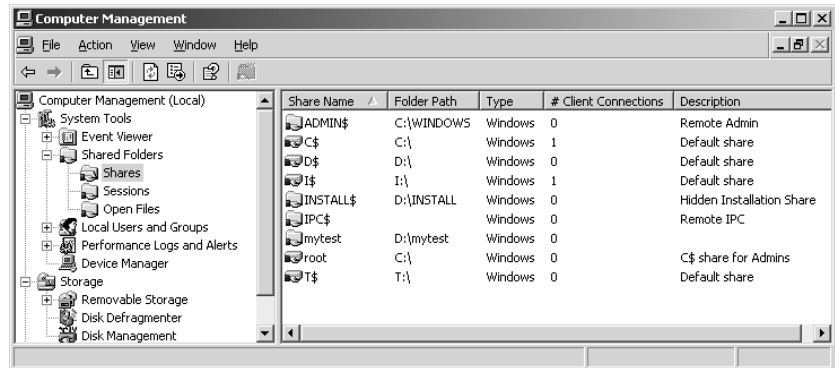

Although the hidden share will not show from your Explorer browse list, the share is visible through the Computer Management Console. This helps keep you from forgetting which hidden shares you have created.

## Common Shares

In Windows Server, you may find that several common shares have already been created for you. Most of these shares, you will find, are hidden shares (see Figure 11.46).

**FIGURE 11.46**  
Common hidden shares

## C\$, D\$, and So On

All drives, including CD-ROM drives, are given a hidden share to the root of the drive. This share is what is called an *administrative share*. You cannot change the permissions or properties of these shares, other than to configure them for Offline Files (we'll talk about Offline Files at the end of this chapter) and if you try to stop sharing these administrative shares, you will see the message shown in Figure 11.47. As soon as you reboot the computer or restart the server service, they will automatically be shared again. These shares come in handy for server administrators who do a lot of remote management of the server. Mapping a drive to the C\$ share will be the equivalent of being at C:\ on the server.

**FIGURE 11.47**  
You can only stop sharing administrative shares temporarily.

**NOTE** Only administrators or backup operators can connect to administrative shares.

## ADMIN\$

ADMIN\$, like its C\$, D\$, and other drive share counterparts, is an administrative share. This share maps directly to your system root, or where your Server 2003 operating system resides. I installed my Server 2003 operating system to D:\Windows, so that's where my ADMIN\$ maps to.

Why is this necessary? Let's say I manage 50 servers, and I want to copy an updated INI file to all servers to have them configured differently. (Of course, I have already tested the configuration

change thoroughly. The last thing you want to do remotely is change the configuration of an operating system without knowing exactly what is going to happen when you reboot or otherwise initiate the change.)

The problem is that about half of my servers are new Server 2003s with the system installed into C:\Windows. The other half are a mixed bag of old upgraded servers and random installs performed by different admins, so my system root can be anything from D:\Winnt to C:\Windows2k to who knows what. Thus the ADMIN\$ share. I have one common connection point that I can connect to across the board, with no guesswork required.

## PRINT\$

Whenever you create a shared printer, the system places the drivers in this share. See the chapter on printing services (Chapter 13) for more information.

## IPC\$

The IPC\$ share is probably one of the most widely used shares in interserver communications. You know how you can map a drive letter to a share on a server and use that drive to access files and folders. What about other resources? How do you read the event logs of another computer? You don't actually map a drive, you use *named pipes*. A named pipe is a piece of memory that handles a communication channel between two processes, whether local or remote.

## REPL\$

Whenever the replication service is used, a REPL\$ share is created on the export server. The export server sends a replication pulse to import servers. The individual import servers connect back to the export server to get a replicated set of the data. This REPL\$ share is where your import computers will connect. This share is a critical element of replication, so it's best to leave it alone.

## NETLOGON

The NETLOGON share is used in conjunction with processing logon requests from users. Once users successfully log in, they are given any profile and script information that they are required to run. This script is usually going to be a batch file. For example, I have a common batch file that I want all of my users to run every time they log in. This allows me to have all clients run a standard set of commands, like copying updated network information, mapping standard network drives, and so on. These batch files, scripts, and profiles go in the NETLOGON share. The NETLOGON share is required on all domain controllers.

## Connecting to Shares via the Command Line

Now that you have these shares, how do people use them? Assuming that I've got a share called APPS on a server called STORAGE1, how would someone attached to the network get to that share? There are several ways to use the GUI to get to shares:

- ◆ Right-click My Network Places or My Computer and choose Map Network Drive, then follow the wizard that starts.

- ◆ Browse the network from My Network Places.
- ◆ Look for a share in the Active Directory.

All of those techniques are convenient, but they require a fair amount of network “superstructure”—they only work well if the network’s working well. But sometimes you need to attach to a share when things aren’t working so well—in fact, sometimes you need to attach to a share specifically *because* things aren’t working so well, and the share contains some tools to help you get it working right. That’s where the command line comes in handy.

## Introducing *net use*

The command I’m talking about is **net use**. In its basic form, it looks like this:

```
net use driveletter \\servername\sharename
```

For example, to attach to the share APPS on the server named STORAGE1, and then to be able to refer to that share as drive V: on my system, I’d open a command prompt and type this:

```
net use v: \\storage1\apps
```

If I didn’t want to worry about figuring out which drive letters are free, I’d just use an asterisk instead of a drive letter, as in the following:

```
net use * \\storage1\apps
```

**net use** will then just choose the first available letter.

## Using a Different Account with *net use*

Sometimes you’re logged in to one account and need to connect to a share, but you only have permissions to access that share from another account. In such a case, you can tell **net use** to try to connect you with the share while using that different account with the `/user:` option. With this option, **net use** looks like this:

```
net use driveletter \\servername\sharename password
  /user:domainname\username
```

So, for example, if I were logged onto a domain named CANISMAJOR (note we’re talking older NetBIOS-type domain names here; although **net use** has been improved to understand the newer DNS-type names in Server 2003) under an account named Joe, and I wanted to access a share named DATA on a server named RUCHBAH on a domain named CASSIOPEIA, then I might have a problem, particularly if the CASSIOPEIA domain doesn’t have a trust relationship with CANISMAJOR. But perhaps I have an account named Mark on the CASSIOPEIA domain, with password “halibut.” I could then type this:

```
net use * \\ruchbah\data halibut /user:Cassiopeia\mark
```

You needn’t type the password, in case you’re concerned that someone might be watching. Leave it off, and **net use** will prompt you for it. Also, since **net use** now understands the new DNS-type names, you could substitute either `/user:dotteddomainname\username` or `/user:username@dotteddomainname` in the above example.

## “A Set of Credentials Conflicts”

Sometimes when you’re trying to attach to a share, you’ll get an error message that says something like, “A set of credentials conflicts with an existing set of credentials on that share.” What’s happening there is this: You’ve already tried to access this share and failed for some reason—perhaps you mistyped a password. The server that the share is on has, then, constructed some security information about you that says that you’re a deadbeat, and it doesn’t want to hear anything else about you. So you need to get the server to forget about you so that you can start all over. You can do that with the `/d` option. Suppose you’ve already tried to access the `\\STORAGE1\APPS` share and apparently failed. It might be that you *are* actually connected to the share, but with no permissions. (I know it doesn’t make sense, but it happens.) You can find out what shares you’re connected to by typing just **net use** all by itself. Chances are, you’ll see that `\\STORAGE1\APPS` is on the list. You have to disconnect from that STORAGE1 server so that you can start over. To do that, type this:

```
net use \\storage1\apps /d
```

But then do another **net use** to make sure that you’ve got all of those connections cleaned up; you may find that you have *multiple* attachments to a particular server. *Then* your **net use** will work. Or... in a few cases, you may have to disconnect *all* of your file shares:

```
net use * /d
```

## net use-ing over a WAN

Now we are into one of our most difficult networking areas: connecting to your resources across long distances and great unknowns. If you’ve ever had to rely on remote computing, you know well not to rely on it. We have a new little function set in our **net use** arsenal that takes a lot of the “unknown” out of the picture. Instead of relying on getting to the appropriate name resolution server, getting through to that server, and getting accurate reliable resolution over an inaccurate and unreliable network link, you can now just map a drive straight to your server via its IP address. Granted, you now need to know that IP address, but it is a good failsafe. In my case, I work from several different locations connected with frame relay WAN links. My Network Places isn’t always so good about being able to convert server names into IP addresses, so **net use \\storage1** usually tells me that my machine couldn’t *find* `\\STORAGE1`. Even if it *does* work, name resolution—converting a name such as STORAGE1 to a network address—takes time.

If you know the IP address of the server that you’re trying to contact, then you can use the IP address in lieu of the server’s name. I know that STORAGE1’s IP address is 134.81.12.4, so I can simply type this:

```
net use \\134.81.12.4\apps
```

And, as you’re probably connecting from a different network, you might have to add the `/user:` information. And it’s never a bad idea to add `/persistent:no` so that your system doesn’t spend five minutes trying to reconnect to it the next time that you start up. So, for example, if STORAGE1 is a member of a domain named dotenetttest.loc and I have an account on dotenetttest.loc named “boss,” I could ensure that STORAGE1 will know who I am and log me on like so:

```
net use \\134.81.12.4\apps /user:dotenetttest.loc\boss /persistent:no
```

Know the **net use** command; you’ll find it useful.

## The Distributed File System

If you haven't started playing around with Distributed File System (Dfs), you should. Although Windows NT4 with SP3 can host a stand-alone Dfs root, the tool really became useful with the release of Windows 2000 and Active Directory. And in Server 2003, there are even more enhancements that we will explore in more detail in this section. What is Dfs, you ask? Well, with Dfs, you can create a single share that encompasses every file share-based resource on your network. Think of it as a home for all the file shares on your network with a "links" page that points the clients to the particular server or servers that actually house those shares. Under this one root share, you create links that point to all of your other shares across numerous servers, one link per share. Now, using this Dfs share, your users only need to remember one place to connect.

Let's say you had the following set of shared resources across the network:

UNC Path	Users' Mapping	Resource Description
\\DC1\APPS	G:	All generic applications
\\RESOURCE1\APPS	G:	The same applications as \\DC1\APPS
\\STORAGE\SALES	S:	The corporate sales data
\\STORAGE2\USERS	H:	All user directories
\\STORAGE\FINANCE	Q:	The corporate financing data
\\RESOURCE2\APP2	P:	Miscellaneous applications

This could become a real pain for users (not to mention administrators!), who have to remember where to go to connect to their various resources. Here, there are five different servers housing resources. This also means that if a client needed to access APPS, SALES, USERS, and FINANCE all at the same time, they would be required to make three different connections. Well, three doesn't sound too bad, but I have been in large networks where there were literally no more available drive letters left on clients to map another share; every single letter from A: to Z: was mapped to something. You also have to remember which clients connect to \\DC1\APPS and which connect to \\RESOURCE1\APPS, which are identical shares housed on two different servers. Again, it's not a big deal in this particular example, but if you had 50 servers containing the same set of APPS, this could become a nightmare to keep track of.

**NOTE** As you can probably see, Dfs is most beneficial in large enterprises and probably not worth the effort in small office networks.

Now, let's put this same scenario into a Dfs instead. You would have one Dfs Root—we'll call it CORP—with all of your corporate shares listed within. I'll show you how to do all of this later, but your end result will look like Figure 11.48.

Now, isn't that pretty? All those resources, no matter where they reside physically, show up under the domain's Dfs root volume named CORP. The links to the shares show up to the users as subdirectories under CORP. Users don't know, see, or ever care what server each of those subdirectories

point to, nor will they ever even need to know that there *are* other servers involved at all. To them, it is one big share with everything they need.

**FIGURE 11.48**

Dfs root view

Understand, though, that Dfs isn't a new kind of file server. In a sense, it's not a file server at all—it is, instead, a way of putting a kind of “table of contents” on a bunch of existing file shares and pointing the clients to that source of information when they need to connect to a share that is referenced in that table. Dfs does *not* create file shares; you must create all of the file shares on the various servers first, *then* use Dfs to impose some order. To underscore that point, here's another fact about Dfs: the file shares needn't be NT or 2000 or Server 2003 file shares. If you had Unix NFS, Banyan VINES, and Novell NetWare client software on your computer, then you could actually create a Dfs “share” that only points to NFS, VINES, and NetWare volumes!

But does that mean that this new Dfs root—this “table of contents”—constitutes a new single point of failure? If that one server that houses the root—the place where all of our users go to find their resources—goes dead in the water, so do our users, right? Not necessarily. Combined with the Active Directory, Dfs roots can be made to be fault tolerant. Instead of the actual, physical root being housed on one server, it can be stored in the Active Directory, which is maintained across all domain controllers. Now, if one of those servers housing the root—in the Active Directory—goes down, our users are automatically directed to another location to retrieve root information without even a hiccup.

Again, let's stress the function of Dfs. “Fault-tolerant Dfs” doesn't mean that you're backing up the data in the file shares. It only means that the “table of contents” that is a Dfs root gets backed up, so that if the computer hosting the Dfs root goes down—and sorry to be stressing this point, but again there's a good chance that the machine hosting the Dfs root *does not contain one single byte of shared files*, just the pointers to the servers that contain those files—then there's another computer standing by to assume the role of “table of contents server” or, in Server 2003-ese, the Dfs root.

But *can* you somehow protect those file shares and their data with some kind of fault tolerance? Yes, with *link fault tolerance*. You saw earlier that you had two different servers with an APPS share. Assuming that those servers contain identical sets of APPS data, there is no need for them both to be listed in your Dfs. Remember, under the Dfs root, you create one Dfs link per share? Well, if you want to house identical information for both of these shares called APPS, then there is no need to create two links.

You can have one APPS link listed, which is pointed to two targets, which point to the actual file shares. Then the users are referred to either one of the targets or replica sets when they are looking for the APPS share. I say replica sets, because if you have two identical shares, then you can set up your Dfs, in conjunction with the File Replication System (FRS), to actually replicate the data within those shares, ensuring their consistency. It's a great way of streamlining your network, and you can even choose or customize your replication topology, which was impossible in Win2K. You can also use Sites in Active Directory to ensure that your clients are not directed to a share over a slow line if a faster one is available.

Using the File Replication Service, Dfs can keep all copies of replicated targets in sync with each other. With your two APPS shares, you make a change on one share, and Dfs takes care of getting those changes out to the other targets. Again, this has shortcomings—this time in principle, not in the technical details. If you have dynamic data within a link at all—and by dynamic I mean anything that changes as the users access it, such as Word documents, spreadsheets, databases, or anything else that requires users to change data on the server—you probably shouldn't replicate it. Let's say Jane and Bob are both editing the same document, but both are editing different replicated copies on two different shares. Jane makes her changes and closes the document, then Bob makes different changes and saves his version. Who wins? Bob will win because he saved it last. Once saved, the document is replicated to the other share, overwriting Jane's changes. So, remember, if a user is editing a document and they are accessing that document on a link that is a replica, their changes will get overwritten next time the replication occurs. Use caution when using link replicas and replication.

## Dfs Terminology

Before we go much further, you need to understand the terminology of Dfs. Just like learning to understand Active Directory, a whole new set of concepts and terms comes into play.

You start with a *root*. This translates roughly into the share that will be visible to the network. In the example, CORP was the root. You can have many roots in your site, and with Server 2003 one server can now hold more than one root, which was a limitation in Win2K. A root is shared out to the network, and actually operates like any other share. You can have additional files and folders within the shared folder.

Under a root, you add *Dfs links*. The link is another share somewhere on the network that is placed under the root. I guess the term *link* is part of our never-ending terminology shift. In this case, it seems to be shifting to more of an Internet nomenclature. Picture the Dfs root as a Web home page with nothing on it but the name of the page and a bunch of links to other Web pages. The links within the Dfs hierarchy are like hyperlinks on a Web page that automatically direct you to a new location. You, the user, don't need to know where that link will take you, as long as you get the Web page you were looking for. Once you find your home page (the Dfs root), you will be directed by those hyperlinks (your Dfs links) to any other Web site you want (your shares).

A *target* or *replica* can refer to either a root or a link. If you have two identical shares on the network, usually on separate servers, you can group them together within the same link, as *Dfs targets*. You can also replicate an entire root—you know, the table of contents—as a *root replica member*. Once the targets are configured for replication, the File Replication Service manages keeping the contents of roots in sync.

## Stand-Alone versus Fault-Tolerant Dfs

Before you begin making a Dfs, you need to decide which kind of Dfs you want. This will be primarily decided based on whether you have an Active Directory. The big difference is going to be on the root of the Dfs. In an Active Directory–based Dfs, or fault-tolerant Dfs, the root itself can have replicas. In other words, that one single point of failure—the root—has been spread out into the Active Directory. Using root replicas, if you have 27 servers housing the Active Directory, you have 27 places where the Dfs information lives. Well, not all Dfs information, just enough information to point clients to one of the Dfs root replicas. With that, as long as the Active Directory is alive and available, the Dfs is too. Also, when integrated into the Active Directory, link replicas can be configured to use automatic replication. With automatic replication, the File Replication Service takes over the synchronization of the contents of replicated folders to ensure that all replicas contain the same information. It might be safe to say that if you have an Active Directory–based domain, you should choose the fault-tolerant Dfs.

But here’s the really cool part of an Active Directory–based Dfs. If I host my Dfs in the Active Directory of the `dotnettest.loc` domain, not only do my users not need to know which server a particular share is on, but now they don’t even need to know which server the Dfs itself is on. Instead of having to map a drive to `\\servername\dfsname`, my users could map a drive to `\\dotnettest.loc\dfsname`. Now, using the same logic a client uses to find an available domain controller for the Active Directory, it can search for a host of the Dfs. If one fails, the client just calls on another.

A domain-based Dfs automatically publishes its topology in the Active Directory. What this means is that the actual Dfs hierarchy—the root(s), links, targets—is published into the Active Directory so that all domain controllers will know where the Dfs lives, what it looks like, and how to get to it. It *doesn’t* mean that every domain controller is a Dfs root replica server.

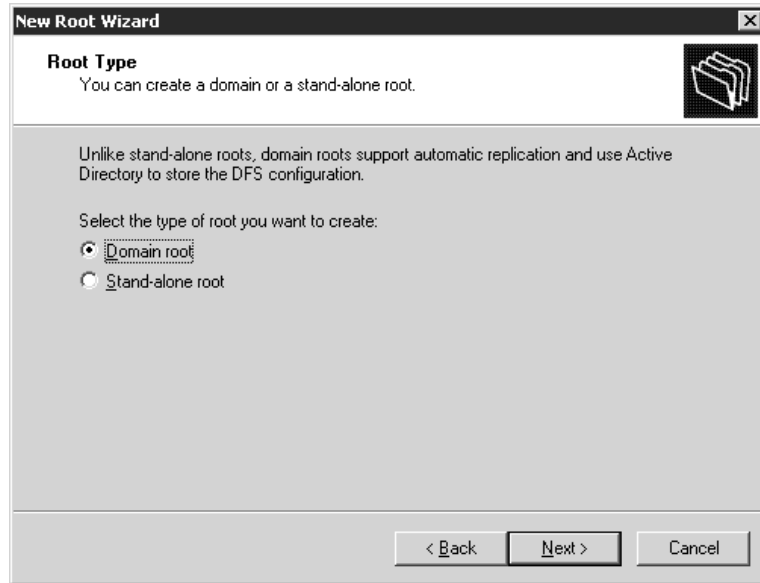

If you’ve gotten this far, you probably don’t have an Active Directory to publish to. What about the non-AD-based networks? Some companies have migrated to Active Directory (and most others are at least in the planning stages, since support for NT4 is ending). Some have at least put up a few member servers here and there. For those who have not gone through the process of migration, the Dfs provides an enhancement to the basic file server that lets an enterprise step out of its physically bound shackles into a more user-friendly and manageable state. A stand-alone Dfs is a solid step forward into the world of Windows 2000 or Server 2003, without requiring a major Active Directory initiative. With a stand-alone Dfs, you don’t get the nice fault tolerance of the root itself, you don’t get the automatic replication, and you don’t get the Dfs published in the Active Directory. But you still get all the other goodies, like combining all of your network shares into a single namespace and finally killing the dependency on physical server names and locations when it comes to getting your users to their resources. In just a little bit, I’ll talk about how these new benefits brought to you by the Dfs can be put to use in a practical environment—with or without an Active Directory—but first, let’s jump into learning how to actually build these things.

## Creating a Dfs Root

To get to the Dfs management console, select Start/Administrative Tools/Distributed File System. Now, the first thing you need to do is create the root. Right-click the Distributed File System in the left pane and select New Root. Of course, a wizard greets you. Select Next at the welcome screen, and you are then asked which kind of root you want to create (see Figure 11.49).

**FIGURE 11.49**

Select the Dfs root type.

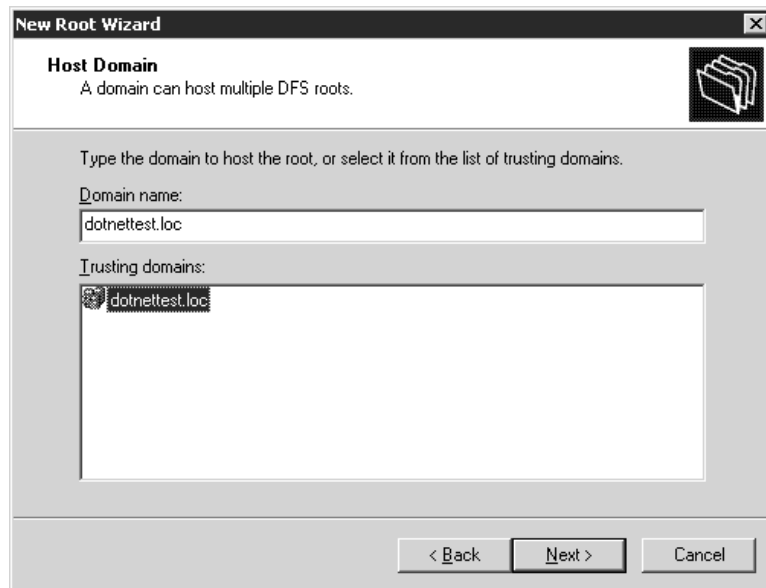

Your choices for the Dfs root type are domain root and stand-alone root. A domain root will publish itself in the Active Directory, while a stand-alone root will not. This fundamental difference is the deciding factor on how much functionality you will receive. Keep in mind that a domain Dfs root must be hosted on a domain controller, so that there is an Active Directory to post to. One of the most important benefits of being published in the Active Directory is that domain roots can have replica roots. Again, a root replica lets you have any domain controller host the root, which greatly improves fault tolerance. Because the roots require the Active Directory to be replicas at this level, stand-alone roots cannot be nor have replicas. Because my test server, DC1, is already a domain controller, I'll choose a domain root.

The next step is choosing a domain that will host the Dfs, as shown in Figure 11.50. If you were to select a stand-alone Dfs, you would not get this option.

The purpose behind selecting a domain to host the Dfs is to publish the Dfs into the Active Directory. This clues you into yet another *big* advantage of using fault-tolerant roots. Jump forward in your mind, if you will, to what this may look like to the clients later on. If you publish this root called CORP into the Active Directory on the domain dotnettest.loc, you will later see this shared out to the world under the name of dotnettest.loc\corp, as well as dc1.dotnettest.loc\corp. If you were using a stand-alone root, you would only be able to see this as dc1.dotnettest.loc\corp. How does this help? This is one less thing you have to configure at the workstation level. Simply point all of your clients to dotnettest.loc, and they never need to worry about which server houses which resources.

**FIGURE 11.50**

Select a domain to host Dfs.

After you select which domain will host the root, click Next so you can select the server that will host the root, as shown in Figure 11.51. This is where the actual resource will reside.

**FIGURE 11.51**

Select a server to host Dfs.

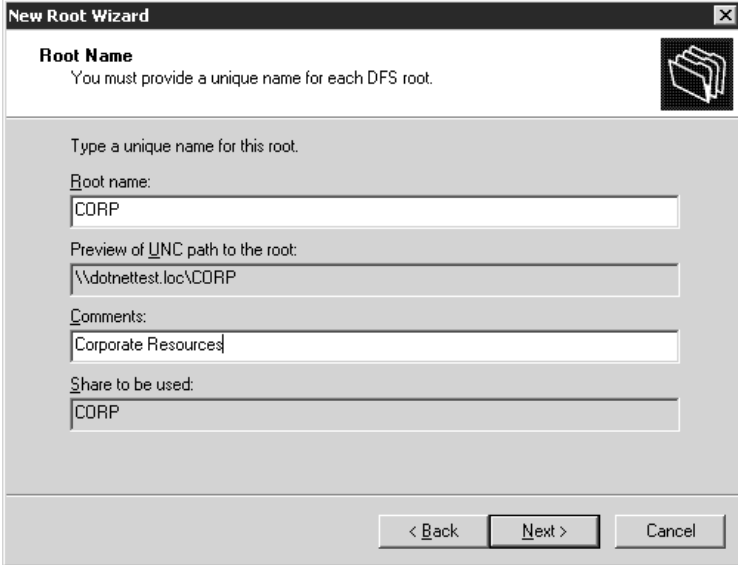

Click Next to provide a Dfs root name and a description as shown in Figure 11.52. The name for each root must be unique for the domain. Unlike shares, whose names can be the same as long as they are on different servers, there can only be one CORP Dfs root per domain. This is a side effect

of having the Dfs root accessible from the domain instead of the server, and I would say that this is a very acceptable side effect.

**FIGURE 11.52**

Select a root name.

**New Root Wizard**

**Root Name**  
You must provide a unique name for each DFS root.

Type a unique name for this root.

Corporate Resources

Share to be used:  
CORP

< Back   Next >   Cancel

The next screen in the wizard allows you to define the actual share for the root. Remember, this can be a regular share. You can select an existing share on your host server to be the root of your Dfs, or you can create a new one on-the-fly (see Figure 11.53).

**FIGURE 11.53**

Select a share for the Dfs root.

**New Root Wizard**

**Root Share**  
The specified share does not exist. Create a new share at the following location.

Folder to share:  
i:\corp

Browse...

< Back   Next >   Cancel

I've decided to make a new share called corp. This is going to be my corporate resource Dfs root. I don't already have one, so I've chosen to create a new share. Since the path for the share I entered does not exist, I am confronted with the dialog box in Figure 11.54.

**FIGURE 11.54**

Dfs will create the share for you.

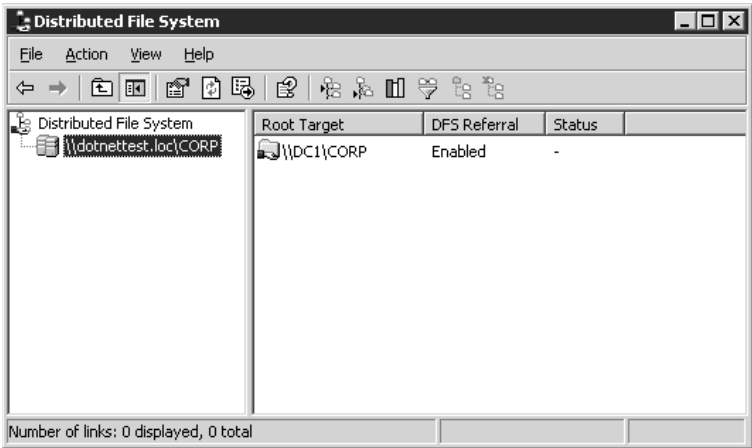

Once I select Yes, the share will be created automatically so don't worry about Alt+Tabbing back and forth just to get your folder set up ahead of time.

Finally, I am shown a confirmation dialog box with all of my selections, and the root is created. When I return to the Dfs Management Console, I see the new root listed as `\\dotnettest.loc\corp`, as shown in Figure 11.55. Notice how the path appears as `\\dotnettest.loc\corp`, instead of `\\dc1.dotnettest.loc\corp` or even `\\dc1\corp`.

**FIGURE 11.55**

The new root

### Adding Links to a Dfs Root

Once you have your root, you need to add your Dfs links. Let's start with APPS. First, you want to select your new root in the left pane of the console. You will notice that in the left pane, the root is `\\dotnettest.loc\CORP`, indicative of its membership with the domain, whereas the right pane shows that the share, or the physical location of the resource, is `\\DC1\CORP`. Right-click the root—that would be `\\dotnettest.loc\corp`—and select New Link. This is where you add another network resource to your Dfs. Start with the `\\DC1\APPS` share (see Figure 11.56).

The first field, Link Name, will be used to reference the network share you are about to add to the Dfs root. We'll call ours APPS. Simply type it in. The second field, Path to Target (Shared Folder), is the name of an existing share on the network. You can enter the UNC for the share, or

browse your network for the share that you want to point users to. Sorry, but you can't create a share on-the-fly here; it must already exist.

**FIGURE 11.56**

Add the Dfs link.

**New Link** ? X

Enter a name and path for the new link. When users open this link, they are redirected to the shared folder you select as the target.

Link name:  
APPS

\\DC1\\APPS Browse...

Comments:  
Applications

Amount of time clients cache this referral in seconds:  
1800

OK Cancel

The Amount of Time Clients Cache This Referral in Seconds value tells the client how long to wait before they check back with the hosting server to update share information. When a client connects to \\DOTNETTEST\\CORP\\APPS, they are told by the hosting server, which happens to be \\DC1, to connect to \\DC1\\APPS, *but* check back with me in 1800 seconds. At that time, the client will call back the Dfs host to see if everything is okay. If you take a link offline—applicable when you have replica links, or if you simply redirect a link to a different share, the client will be told this information at that time and will be directed back to the appropriate share accordingly. Think about this value carefully. The shorter the interval, the more network traffic you will create. The longer the interval, the longer it takes a client to check back for an update. Let's say you have defined an interval of 3600 seconds, or one hour. A client connects to \\DOTNETTEST\\CORP\\APPS at 10:00 exactly, and is redirected to \\RESOURCE1\\APPS. They won't check back until 11:00. At 10:10, you find out that you need to take the server down. You want to take RESOURCE1 offline and redirect all clients to a replica member of APPS on DC1. (I'll cover replicas in a minute.) So you configure your replica set to have RESOURCE1 offline. If you take RESOURCE1 down now, your client who connected at 10:00 could lose data. The best thing to do is wait until all clients have reported back so they can see that RESOURCE1 is offline, and redirect to DC1. This means that you may have to wait the longest possible interval before shutting down your server—an hour. If your interval was 10 minutes, then you could be fairly comfortable that within 10 minutes, RESOURCE1 would be free from any client connections to APPS.

Going back to the network resources given earlier, repeat the above process to create all child nodes—except for \\RESOURCE1\APPS—using the information below:

When a User References	Send the User To
\\DOTENETTEST\CORP\APPS	\\DC1\APPS
\\DOTNETTEST\CORP\APPS	\\RESOURCE1\APPS
\\DOTENETTEST\CORP\SALES	\\STORAGE\SALES
\\DOTENETTEST\CORP\USERS	\\STORAGE2\USERS
\\DOTENETTEST\CORP\FINANCE	\\STORAGE\FINANCE
\\DOTENETTEST\CORP\APP2	\\RESOURCE2\APP2

When you’re done, the Dfs Console will look like Figure 11.57.

**FIGURE 11.57**  
The new child nodes  
in the Dfs console

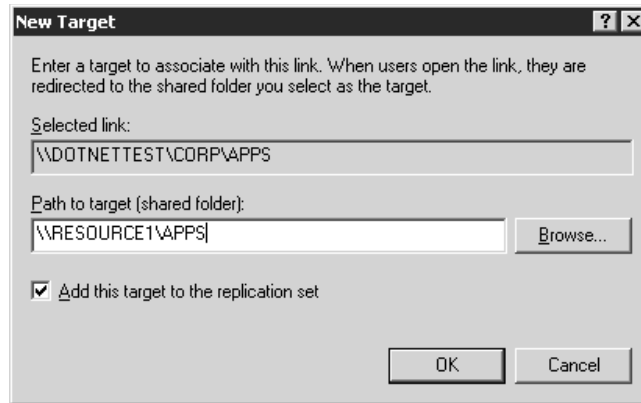

**Configuring Dfs Replicas**

Now you want to make a replica link of APPS. Remember how you had \\DC1\APPS and \\RESOURCE1\APPS? You want to combine those into one logical resource: \\DOTNETTEST\CORP\APPS. Right-click the APPS link and select New Target. What you get is a condensed version of the dialog box that created the Dfs link in the first place (see Figure 11.58).

Enter the path for the next share that is to be available as part of this resource, and check whether you want to add the target to the replication set. The File Replication System (FRS) in Server 2003 works with the Distributed File System to synchronize files on the included shares within the link. If you choose to include the new target in your replication topology, when you click OK you’ll see the dialog box shown in Figure 11.59. Some Server 2003 improvements to the FRS include compression of the replication traffic and the ability to differentiate between necessary and unnecessary replication traffic.

**FIGURE 11.58**

Add a new Dfs replica member.

**FIGURE 11.59**

You are given the option to configure replication when you create a replica.

You can configure replication now or go back and do it later. If you select Yes now, you will start the Configure Replication Wizard. Click Next to move through the initial screen and you will arrive at the window shown in Figure 11.60.

**FIGURE 11.60**

Choosing a master share for replication

One of the shares that you have configured in the replica will need to be initialized as the Master in order for the replication process to start. Once the Master is chosen, replication will become a multi-master process, so this is just a temporary assignment of duty.

Replication for the Dfs has improved in .NET: you can now choose from the various topologies available, including the ability to create a custom topology design for replication. You can view the options in Figure 11.61.

**FIGURE 11.61**  
Choosing a replication topology

Choose a basic ring topology and then click the Finish button, which ends the Configure Replication Wizard and returns you to the Dfs Management Console. You have just added another target to your APPS link and thus have two shares available for users to seamlessly connect to through the Dfs. You can see this by looking at Figure 11.62.

**FIGURE 11.62**  
Viewing multiple shares in the APPS link

You have also configured replication between the shares, so that new applications should only have to be added to one share, automatically replicating to the other. Note that there is now a Replication tab available when you right-click the APPS link and choose Properties (see Figure 11.63). From here, you can reconfigure your replication topology or the replication schedule at any time. You can even decide which specific files or subfolders in the share are replicated, including wildcards like \*.doc, which would include all files with an extension of .doc in the replication arrangement.

**FIGURE 11.63**

Viewing replication properties for the APPS link

From now on, when your clients connect to \\DOTNETTEST\CORP\APPS, they will be directed to either \\DC1\APPS or \\RESOURCE1\APPS.

To remove a replica member from a Dfs link, right-click the member and select Remove Target. If you want to take \\RESOURCE1\APPS out of the replica set, leaving only \\DC1\APPS, you could remove it from the Dfs, just like that. When removing a replica member, however, nothing on the replica member's server is altered in any way. \\RESOURCE1\APPS will still be shared, and all data will still be available within that share. The only thing that is affected is the Dfs topology.

## Understanding Dfs Replication

Replication itself is simple. In a stand-alone Dfs, the replication is manual, and one link replica is the master. In other words, changes from that particular master server propagate to all other replica

servers. If the physical share you want to keep synchronized resides on an NTFS volume on a Windows 2000 Server, replication is automatic and uses multi-master replication. With multi-master replication, you can modify files on any one of the link replicas, and the changes will be automatically copied to the other members. Really, with automatic replication, there is no such thing as a Master after the initial replication. The first replication will need a Master to ensure that all shares have the same starting point. It is advised, though, that you do not mix automatic and manual replication within a single replica set.

To manage replication within the Dfs Management Console, you'll need to change the way you view the console. Highlight the links for which you have enabled replication—you'll see a blue circular icon over the links in the left pane if you have configured replication—then click the Action button from the Console menu. Choose Show Replication Information. This will add a column in the Target window called File Replication, as shown in Figure 11.64. You can also view the status of the targets in your link by highlighting the link and clicking Check Status from the Action menu, but you can only do one of these at a time. You can view either status information or replication information at any one time, but not both.

**FIGURE 11.64**  
Viewing replication information from the console

Each member within the replication set is shown in the Management Console, along with information as to whether replication is enabled. All the members of the replication set will now have their data synchronized, based on the schedule you chose.

### Managing Dfs

After you have configured your Dfs, there are a few steps you must go through to properly manage the roots, links, and the clients that are connected to them.

#### TAKING REPLICA MEMBERS OFFLINE/ONLINE

When you have multiple members belonging to a replica set, you may find occasions to take one offline. Say, for instance, you need to perform maintenance on a server. You don't want to just take a server down and have users lose their connections. You also don't want to go through the process

of dropping a member from the replica set and adding it again later once your maintenance is done. Instead, right-click the member share and select *Enable/Disable Referral*. This will toggle a member's status. You can see that a member is disabled in Figure 11.65, although the machine itself, and therefore its shares, are still online.

**FIGURE 11.65**

An offline member

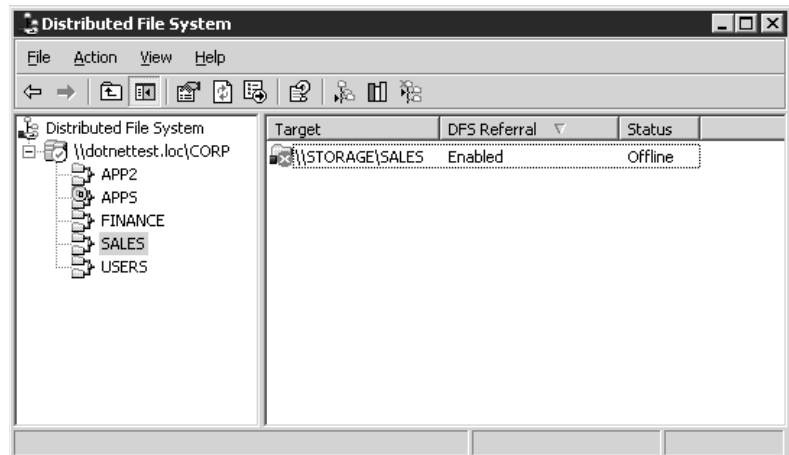

### CHECKING NODE STATUS

Periodically, you should verify the status of each link within the Dfs topology. To check the status of a link, right-click the share in question and select *Check Status* or click the *Action* menu item and choose *Check Status*. Actually, there is even an icon in the Management Console toolbar for this. It looks like a bar graph. A green check mark indicates that the node is working properly. A red icon with an X through it indicates a problem (see Figure 11.66).

**FIGURE 11.66**

A failed node

A failed node indicates that there is a problem accessing the shared folder to which the child node refers. Try checking out the share directly to make sure it is still available to the network. More severely, the entire server that hosts the child node could be down.

### DELETING CHILD NODES

In Figure 11.66, the SALES node has failed. (It really failed because I took down the server that the share resides on so I could show you what it looks like.) Now I want to completely remove SALES from my Dfs. Right-click the link in the left pane and select Delete Link. This will remove the SALES folder from the CORP hierarchy, but will not touch the actual SALES share or any of its data on the remote server. Users will still be able to connect to \\STORAGE\SALES directly. If I wanted to remove the share from the network altogether, I would need to stop sharing and delete the SALES folder from STORAGE.

### CONNECTING AND DISCONNECTING FROM ROOTS

Within the Dfs Management Console, you can connect to any Dfs root on your network to manage. Right-click the Distributed File System line in the top of the left pane, and select Show Root. From there, you can browse your network for roots or type in the location of the root. For my CORP root hosted on DC1, I could type in \\dotnettest\corp or just expand the domain and then the Domain Dfs roots folder, as shown in Figure 11.67. Note that I have two Dfs roots available for management, the one we created called CORP and another root called IT. Click Cancel to return to the Management Console. To remove a Dfs root with the Management Console, you can right-click the root and select Delete Root.

**FIGURE 11.67**

Viewing available  
Dfs roots

### THE PHYSICAL ROOT

One of the problems with understanding this whole concept of a logical root with no physical bounds is trying to figure out what—physically—this Dfs really is. For starters, let's go back to the Dfs we've been creating throughout this chapter. Originally, I put my Dfs root on DC1 in the folder `I:\corp`. From there, I've created links of `APPS`, `USERS`, `SALES`, `FINANCE`, and `APP2`. If you look at `I:\corp`, you see a folder structure like that of Figure 11.68.

**FIGURE 11.68**

The physical root

Notice anything? Those folders were all created automatically under `I:\corp` as I created the links. If I try to look into one of those folders under `I:\corp`, I get an Access Denied because the system has those areas protected in order to handle the Dfs referrals—the process of passing users to a respective link member, rather than the physical subdirectory.

Speaking of referrals, when a client goes to hit the `APPS` folder within the Dfs `CORP`, what exactly happens? Using the Network Monitor, you can trace out the referral process. There are two important transactions between the client and the server. The client initially tries to access `APPS` just as it would any other directory within a share, except the server returns a message that tells the client to get a referral link. Why can't the server just direct the client there in the first place? Well, if you had the root server act as a middleman to the entire process—for every share, folder, and file access—your bandwidth would go through the root to and from that server. You have to force the client to make the connection to the actual link member. By getting this “error” message, the client has to go to Plan B, which in this case is to find out who—if not the root—has the data in question. Now the client sends a Get Dfs Referral message to the root server, requesting a filename of `\DOTNETTEST.LOC\CORP\APPS`. The root server responds to the referral with the actual share name that the client needs to contact. In this case, the server has chosen `RESOURCE1`, so it responds with

\RESOURCE1\APPS. It also includes a Dfs TimeToLive value equal to the parameter configured for the client cacheing interval so the client will know how often it has to check back with the Dfs root for updating information about where to access the file, folder, or application.

### **PRACTICAL USES**

Before you start setting up your root, throwing in some links, and reorganizing the way your users access their resources, let's take a quick look at some good ways that Dfs can actually add value to your network. Remember, it's not about playing with cool new features; it's about making life easier.

#### **Consolidated Enterprise Resources**

The example Dfs we've worked through in this chapter would be a good way to consolidate enterprise resources. You can take all of your shared resources across the network and put them under one logical share. Then, instead of having to know which logical drive a resource resides on, you only need to know the subdirectory. The neat thing is that actually configuring the Dfs has absolutely no impact on the configuration of your network. You can build and experiment with Dfs configurations all day long in a production environment without anyone even knowing that it exists. All of the old shares on your network remain in place, data is untouched, and users don't see anything different. Once you're ready with your new Dfs, the hard part comes in—changing your users' drive mappings from one drive per \\server\share to one drive for all shares. Don't underestimate this task. It's more than just mapping a new drive letter to the Dfs root. All applications need to know that they will no longer be on drive X:, but rather drive Y:.

#### **Life-Cycle Management**

The good news is that with Dfs, this is the last time you'll ever deal with changing drive mappings. If you need to move data from one server to another for purposes of life-cycling a new server in and an old one out, you don't need to play the game of backing up data, wiping the server, rebuilding it new with the same name, and restoring data to make it look like it is the same physical machine. With Dfs, you can set up a brand new server and configure it as an offline link replica for the share you want "moved." After you verify that all data has been ported over successfully, bring it online and take the old one off. The users don't know that they are hitting a new server. The Dfs handles it all in stride.

## **Web Sharing**

Web sharing is a feature that debuted in Windows 2000. It allows you to share folders directly for use via HTTP requests coming from Web browsers.

**NOTE** You must be running Internet Information Services for this option to be available. If your server doesn't support Web access at the server level, it won't matter whether your shares are Web enabled. Your users won't be able to get to those shares through their Web browsers anyway.

Configuring Web sharing is extremely simple. Within your Windows Explorer, right-click the folder you want to share out to the Web and select Sharing. At the top of the folder properties page

that appears, you'll notice a Web Sharing tab (see Figure 11.69). Selecting that tab allows you to configure how this folder will be shared out to the Web. I'm going to enable Web sharing for my Marketing folder.

**FIGURE 11.69**

Web Sharing folder properties

At the top of the Web Sharing tab is a Share On drop-down list. In that list are the different Web sites that have been created via the Internet Services Manager. Select the Web site that you want to add this folder into. For our purposes, I'm just going to use the default Web site, and this is where I will place my Marketing folder.

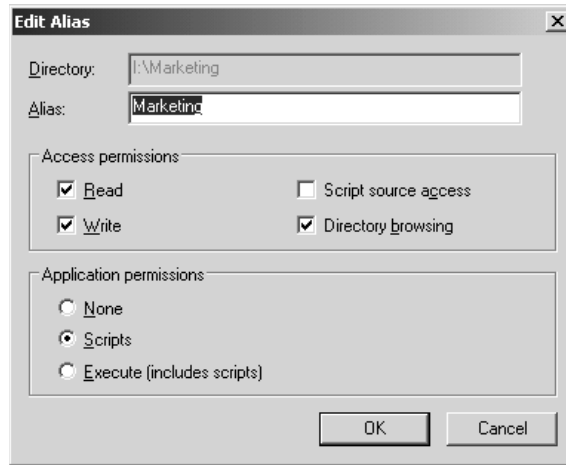

The next step is to select the radio button for Share This Folder. Once selected, a dialog box will pop up to configure the Web alias for this folder, as shown in Figure 11.70.

The alias is what Web clients will refer to in order to access this resource. Choose which permissions you would like Web clients to have for the data in this share. You can select any combination of Read, Write, Script Source Access (which allows clients to execute scripts through this share), and Directory Browsing (which allows clients to see folder lists without being required to enter a valid filename to view). Choose the application permissions level from None, Scripts, and Execute. Once completed, you will be returned to your Web Sharing tab and will have the new alias shown as a configured alias (see Figure 11.71).

You can add more aliases for this folder by selecting the Add button, or remove unwanted aliases by selecting the alias and clicking the Remove button. You can also revisit alias properties by selecting the alias and clicking Edit Properties.

**FIGURE 11.70**

The Edit Alias dialog box

**FIGURE 11.71**

The configured Web alias

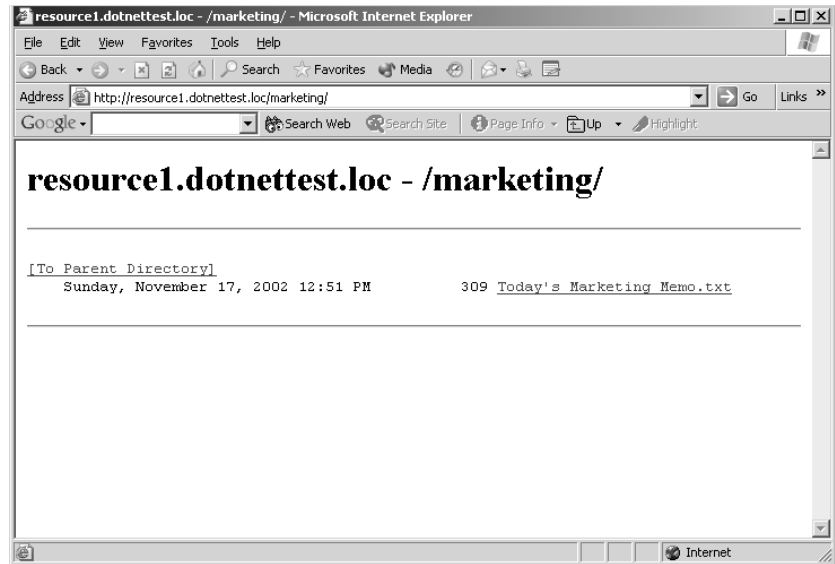

Once you click OK, the alias will be registered to your selected server's Web site and ready for browsing. Go to your Web browser and enter the URL for this alias. On my machine, that would be <http://resource1.dotnettest.loc/marketing/>. Because I enabled directory browsing

for my alias, I can see the files and folders within that folder, and I see the Web page shown in Figure 11.72.

**WARNING** I tried to combine a few of these features into one step by enabling my CORP share—which is my Dfs root—as a Web folder. When I look at \\DOTNETTEST\CORP within the regular Explorer, I can see the full Dfs. If I try to look at my own I:\CORP folder, however, I can see all the directories corresponding to my child nodes, but since they are not real resources on my machine—rather redirections to other shares somewhere else—the server gives me an Access Denied message. When I enable Web sharing for the CORP share on my server, and try to access <http://resource1.dotnettest.loc/corp>, access is denied again. When navigating through the Web browser function, the client never gets a chance to ask for a link referral.

**FIGURE 11.72**

Browsing the  
Web folder

## Using Offline Files/Client-Side Cacheing

As you've seen, the Windows family of OSes file server functionality has grown to include Dfs as well as Web folders, while retaining the old NT file server capabilities. But it doesn't stop there: Not only do some of these features improve the *server* side of file servers, they also jazz up the *client* side. Released in Windows 2000, Offline Files is one of those tools about which I find myself saying, "I could have used this feature a long time ago!"

### Introducing Offline Files

If you have laptop users in your network environment, you'll love the Offline Files, or Client-Side Cacheing (Microsoft uses both names interchangeably), feature. In fact, it will appeal to almost anyone who uses a network. Offline Files provides three main advantages: It makes the network appear faster to its users, smoothes out network "hiccups," and makes the now-difficult task of keeping laptop files and server files in sync simple and transparent.

## How Offline Files Works

Offline Files acts by automatically cacheing often-accessed network files, storing the cached copies in a folder on a local hard drive, a folder not surprisingly called `Offline Files`. Offline Files then uses those cached copies to speed up network access (or apparent network access), as subsequent accessing of a file can be handled out of the local hard disk's cached copy rather than over the network. Offline Files can also use the cached copies of the files to act as a stand-in for the network when the network has failed or isn't present—such as when you're on the road.

Offline Files is a write-through cacheing mechanism; when you write a file out, it always goes to the network, and it is also cached to your local hard disk. And when you want to access a file that Offline Files has cached, then as you've already read, Offline Files would *prefer* to give you the cached (and faster) copy, but first Offline Files checks that the file hasn't changed at the server by examining the file date, time, and size both on the server and in the cache; if they're the same, then Offline Files can give you the file out of the cache without any worries; otherwise, Offline Files fetches the network copy, so you've got the most up-to-date copy.

As a network file could easily be modified by someone else when you're not using it, there's a pretty good chance that the network copy of a file would often be different from the cached copy. But if *that's* the case, then what good is Offline Files? After all, if the file changes on the network a lot, then you'll just end up having to retrieve it from the network instead of enjoying the speed of getting it from cache. Offline Files increases the chances that it has the most up-to-date copies of your cached files by doing background synchronizations in several user-definable ways. This synchronization is largely invisible to the user, who simply utilizes My Network Places or a UNC to access network files, as has been the case with earlier versions of NT and NT client software.

**NOTE** *Offline Files only works on Windows 2000 and later machines; you can't get this benefit if you've got Windows 9x or NT 3.x or 4.x on your Desktop. If you are using a Win2K or XP Desktop, however, Offline Files will be useful even if you're accessing a server running pre-Windows 2000 software, such as NT 3.x or 4.x.*

You'll like Offline Files for several reasons. As these oft-used cached files will reside on the local hard disk in the `Offline Files` folder, you'll immediately see what seems to be an increase in network response speed: Opening a file that appears to be on the network but that is really in a local disk folder will yield apparently stunning improvements in response time, as little or no actual network activity is required. It also produces the side effect of reducing network traffic, as cached files needn't be retransmitted over the LAN. Having frequently used files in a local cache folder also solves the problem of “What do I do when the network's down, and I need a file from a server?” If you try to access a file on a server that's not responding (or if you're not physically connected to the network), Offline Files shifts to “offline” mode. When in offline mode, Offline Files looks in your local Offline Files network cache and, if it finds a copy of that file in the cache, it delivers the file to you just as if the server were up, running, and attached to the user's workstation. And anyone who's ever had to get ready for a business trip knows two of the worst things about traveling with a laptop: the agony of getting on the plane, only to realize that you've forgotten one or two essential files, and the irritation of having to remember when you return to make sure that whatever files you changed while traveling get copied back to the network servers. Offline Files greatly reduces the chance of the first of those problems because, again, often-used files tend to automatically end up in the local network cache folder. It greatly reduces the work of the second task by automating the laptop-to-server file synchronization process.

## Enabling Offline Files on Your Desktop: The Basics

When you first install Windows 2000 or XP on your desktop, Offline Files does not work by default. You must turn it on in one of two ways: either by telling Offline Files to keep track of a particular file, or by going to Folder Options—it's available in the Control Panel, or in the Tools menu of any folder window. Then just check the box labeled Enable Offline Files.

Once activated, Offline Files will often *automatically* cache a file just as a side effect of you using the file. (I'll get to why it *often* rather than *always* does this in a bit.) You can, however, tell Offline Files to *ensure* that a particular file or an entire folder on the network is always in the Offline Files folder (recall, the name for the Offline Files cache) in just two steps: First, find the desired file (or folder) in My Network Places. Second, right-click the file. My Network Places will then display the file's context menu with the usual items—Open, Rename, Delete, and the like—but some files' context menus will include the option Make Available Offline, as you can see in Figure 11.73.

**FIGURE 11.73**

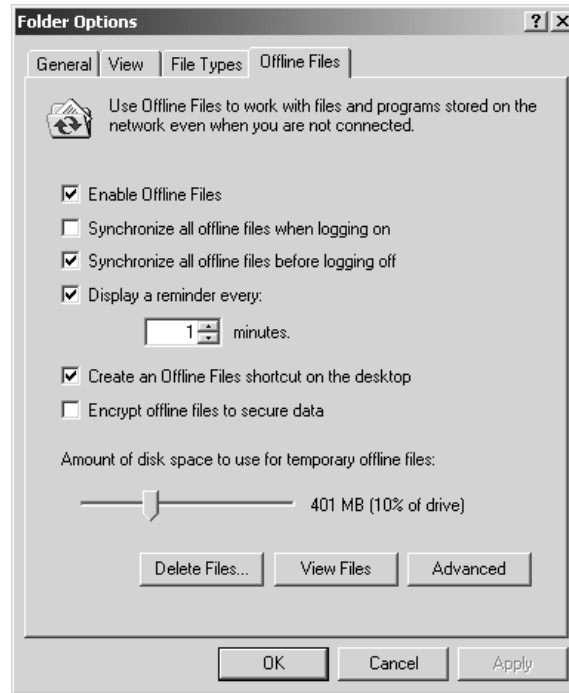

“Pinning” a file so that it is always in the Offline Files folder

Forcing Offline Files to keep a copy of a particular file in the Offline Files folder (that is, forcing Offline Files to keep a copy of a file on the PC's local hard disk) is called *pinning* that file or folder. The first time that you pin a file, Offline Files will start up a configuration wizard, called the Offline Files Wizard, that asks a few questions, then sets up Offline Files to run based on your answers. And although it *sounds* like a great idea, be careful about making entire folders available offline, as that has the effect of copying the entire folder and all of its contents to your local hard disk. That can take some time when it's first set up, and of course it can be a bit irritating when it fills up your hard disk. (Subsequent synchronizations may be quite quick though, as you'll read later.)

Now that you have enabled Offline Files, if you choose Tools/Folder Options from Explorer or My Network Places, you'll see the property page shown in Figure 11.74.

**FIGURE 11.74**Options for  
Offline Files

In the Offline Files page, the first check box tells a Windows 2000 or XP machine to enable its Offline Files capability. The next two tell Offline Files to compare every file in the **Offline Files** folder with the file's "actual" values out on the network servers, forcing Offline Files to synchronize its local file copies with the file originals every time you log on or off. (That's only one of *several* options you have for controlling offline file synchronization, and you'll read more about those options later.) The next check box controls how Offline Files tells the user that one or more servers are not currently available, leading Offline Files to place that server or servers into offline mode. If you'd like, you can tell Offline Files to remind you every so often that one or more servers are in offline mode, with a ToolTip-like balloon such as you see in Figure 11.75. You can also decide whether you want to place a shortcut to your Offline Files folder on your Desktop and whether you want to encrypt the files that you cache.

**FIGURE 11.75**Offline Files  
reminding you that  
you're offline

If you know that one of your servers is about to go offline, or if you're a mobile user about to go on a trip, then you will often need to know whether a particular file is already in your PC's cache,

its **Offline Files** folder. You can see which files are in the local **Offline Files** folder, as well as their status, in a few ways: In the **Offline Files Settings** page, click the **View Files** button. Alternatively, in a check box on the same page, as you saw before, you can direct Win2K or XP to place a shortcut to your **Offline Files** folder right on your Desktop.

While the whole idea of network file cacheing is attractive, there's a built-in limitation to how many files can be cached on a user's local hard drive. There are often tens of gigabytes worth of files out on the network, and usually much less than that available on most workstations. It is entirely possible that you could, in a short period of time, examine more files on the network than would fit on your hard disk. Clearly, if left to itself, **Offline Files** could use up all of your free disk space. You can control how much free space **Offline Files** is allowed to fill up, though, in the **Offline Files Settings** page. However, you can only control how much space **Offline Files** allocates to the automatically cached files, and when that space is exhausted—by default, it's 10 percent of your disk's space—then **Offline Files** just drops the file that hasn't been used in the longest time to make room for more automatically cached files. In contrast, you can pin as many files as you like, forcing **Offline Files** to cache *them*—but you of course could run out of disk space doing that, too. If that happens, **Offline Files** just pops up a dialog box directing you to either unpin some files or to free up some disk space.

## Getting and Keeping Things in the Offline Files Folder

Once you've turned Windows 2000 or Windows XP's **Offline Files** feature on, how do you use it? In a given day, you may access many files on a network—which ones get copied into the **Offline Files** folder?

It's easier to conceptualize how **Offline Files** caches files if you understand that files get into the **Offline Files** folder in one of two ways: either you *direct* **Offline Files** to cache a file by pinning it (recall that you do that by choosing **Make Available Offline** from a file's context menu) or **Offline Files** decides by itself to cache some files without you having to ask it to. **Offline Files** calls these automatically cached files *temporary offline files*.

### SITUATIONS IN WHICH FILES WON'T CACHE

You can't always cache network files, however. Sometimes you'll look at a network file's context menu and the **Make Available Offline** option doesn't appear; when that happens, **Offline Files** won't cache the file either by pinning or by making it a temporary offline file. One of three things causes this cacheing prohibition: First, if the file is on a non-SMB server, such as a NetWare server, then you don't get the option to cache the file. **Offline Files** can only cache files on SMB servers, which means that it can cache files from NT 3.x, 4, and Windows 2000 servers and workstations as well as Windows XP. Files on Windows 9x machines running File and Printer Sharing services can also be cached. (Of course, it can also cache files from Windows Server 2003s.) Second, if you have disabled **Offline Files** by unchecking **Enable Offline Files** in **Folder Options**, the option won't appear. Third, you will not get the option to pin a file if the shared folder that the file resides in has been declared noncacheable by a network administrator. A network admin may declare a share noncacheable in the share's property page at that share's server. They just right-click the shared folder and choose **Sharing and Security**, then click the **Offline Settings** button. A dialog box like the one shown in Figure 11.76 will appear.

**FIGURE 11.76**

Adjusting cache settings for a shared folder

If the network administrator checks the Files or Programs From The Share Will Not Be Available Offline option, then no one will be able to cache files in that folder.

#### MANUAL AND AUTOMATIC CACHEING

Assuming you're working at your workstation and trying to access a network file that *can* be cached, pinning that file will prompt Offline Files to immediately copy the network copy of the file to your local Offline Files folder; a dialog box appears showing you the progress of that copy.

Other files get cached in the Offline Files folder if the files are in a network share on a Windows 2000, XP, or Server 2003 machine and if that share has been designated for *automatic* cacheing. Using the Offline Settings dialog box, an administrator can designate a share so that Only the Files and Programs That Users Specify Will Be Available Offline, which is the default setting. Or you can choose the check box for All Files and Programs That Users Open From the Share Will Be Automatically Available Offline. Selecting the first option will allow the users to choose which files they want to cache. The second option causes automatic cacheing to occur. That means that, when you open any file from a share configured for automatic cacheing, that share's server tells your workstation, "While you're at it, cache this file or program." Your workstation then makes a local copy in the Offline Files folder, noting that the copy is a temporary offline file. The only difference between cacheing for documents or for programs is that Offline Files will run an EXE in a cached-for-programs folder without checking to see whether it's up to date—without synchronizing that file first. It's a bit quicker that way, though of course it could cause trouble if you modified that EXE frequently.

#### HOW OFFLINE FILES MANAGES CACHE SPACE

Offline Files allocates space for pinned files a bit differently than it does for temporary offline files. Recall that the Offline Files Settings page includes a slider that you can use to control how much of your hard disk space to allow Offline Files to use. A second look shows that this amount only applies to the *temporary* offline files. The space taken by the files that you *pin* into the cache does not

count against the space allocated in the Offline Files Settings page. As I said earlier, if the `Offline Files` folder is full and Offline Files automatically caches a new temporary offline file, it must drop one or more older files from the `Offline Files` folder to keep the size of the temporary offline files below the maximum allowed amount given in Offline Files Settings.

And don't bother looking on your hard disk for the `Offline Files` folder—it's actually a series of folders inside `\Winnt\Csc` hidden not with the `Hidden` attribute, but the `System` attribute. You can find it, but first you've got to go to the `Winnt` folder, then choose `Tools/Folder Options`, then go to the `View` tab and uncheck `Hide Protected Operating System Files (Recommended)` and confirm the choice. You'll then be able to browse through `\Winnt\Csc`. What you *won't* find there are useful filenames—all cached files are tagged with long numerical names rather than their actual names. I still haven't found the files in XP, but since they aren't really useful to me, why bother?

**Offline Files in Action: Before the Trip**

Now that you've got Offline Files set up, let's put it to work. It's useful to both mobile and fixed-location users, but its benefits are most dramatic for those mobile users, so here's a step-by-step look at how someone might use Offline Files to make life on the road easier.

**PUTTING THE FILES IN THE CACHE**

A user named Jim is about to go on a trip. He connects his laptop into his company's corporate network and opens a share named `Marketing` on a server named `Resource1`. Jim's network administrator has set up the `Marketing` share with automatic cacheing. `Marketing` contains two files that Jim needs, `file1.txt` and `file2.txt`. Jim right-clicks those files and chooses `Make Available Offline`. Over the course of the day, he also accesses `file3.txt` and `file4.txt`, although he does not pin them.

**ENSURING THEY'RE IN THE CACHE**

Before shutting down the laptop prior to getting on the road, Jim wants to double-check that copies of `file1.txt` and `file2.txt` are on his laptop's hard disk. He opens his `Offline Files` folder and sees a screen something like the one in Figure 11.77.

**FIGURE 11.77**  
Jim's `Offline Files` folder contents after accessing the `Resource1` server

Note that under the `Availability` column, `file1.txt` and `file2.txt` are designated as `Always Available Offline`, meaning that they've been pinned; the little (blue) modification to the files' icons indicates that they are pinned. Note also that `file3.txt` and `file4.txt` are in the `Offline Files` folder, even though Jim didn't pin them—Offline Files automatically cached them. You can tell this

because under the Availability column head, these files are noted as being Temporarily Available Offline. They could end up pushed out of the Offline Files cache without warning if Jim were to exceed the amount of space he originally allocated to his offline files cache by re-attaching to his corporate network and accessing enough other cacheable files.

Note also that the server status of Online means that Jim's still attached to the corporate network and that Resource1 is online. Actually, his laptop will consider Resource1 online until the laptop notices that Resource1 is not responding to attempted communication. Jim can view his **Offline Files** folder via a shortcut on the Desktop (assuming he has configured his system to show one), or he can navigate to the Offline Files Settings page and click the View Files button.

### GETTING THE MOST RECENT VERSION OF THE FILE

If Jim has even more files to synchronize, perhaps entire folders, then he can employ Mobile Sync, available by choosing Start/Programs/Accessories/Synchronize. When started, its screen looks like Figure 11.78.

**FIGURE 11.78**

Choosing shares to synchronize with Offline Files

Mobile Sync lists all of the folders that contain pinned files that Offline Files knows about. Jim can then check the folders he's interested in synchronizing and click the Synchronize button. Clicking Properties just displays the contents of the **Offline Files** folder, and the Setup button allows Jim to configure synchronization when he's *not* traveling (see the later section "Controlling Synchronization for Nonmobile Users").

## Working and Making Changes on the Road

On the plane to a client site, Jim starts up his laptop and opens My Network Places. His Desktop looks the same as it did back at the office, except now his system tray contains a small icon depicting a PC. Moving a mouse over the PC icon gets the message “Offline Files—the network is not available.” Right-clicking that icon offers a context menu that includes Status, which will simply report again that the network is not available; Synchronize, which obviously won’t accomplish much until he’s reconnected to the network; View Files, which opens up the Offline Files folder; and Settings, which brings up the Offline Files Settings page.

### ACCESSING “NETWORK” FILES ON THE ROAD

Despite the fact that Jim is not attached to any network, My Network Places shows a “networked folder” icon for Marketing on Resource1. If he opens up that folder, he’ll see `file1.txt`, `file2.txt`, `file3.txt`, and `file4.txt`, just as if he were connected to the corporate network. He could open a command window and type `net view \\Resource1` to get a list of shares available on Resource1, including Marketing. Or he could find `file1.txt` in the Offline Files folder.

Jim sees a problem with `file1.txt` and edits the file and saves it, and Offline Files allows Windows 2000 Professional (or Windows XP) to make it seem as if he’s attached live on the corporate network. He also makes a few changes to `file2.txt`. After a meeting, he creates a completely new file, `file5.txt`, and saves it in the Marketing volume, again as if he were connected to the company network.

### WARNING: SOMETIMES OFFLINE FILES DON’T WORK

Oh, by the way, this all sounds good, but sometimes it has gone haywire on me. In the typical traveling scenario, I’ve got a laptop and a file server, and I pin some files or perhaps a complete share or folder on the file server. Whenever you pin an entire folder, you have to wait a minute or two while Offline Files goes out and copies all of the files from the pinned folder to your local hard drive. In the case where my laptop is a member of a different domain than the file server, I’ve seen Offline Files look like everything syncs up fine when I pin the folder. But when I disconnect from the network and try to access the files, I’ve gotten error messages like “The network name is not available.” I’ve also had situations where I originally logged in under a particular username and then had to enter a different username to access some share. When I then pinned that share, again Offline Files looked as if it were copying every single file. When on the road, however, Offline Files refused to let me view or work with the file, claiming that it didn’t exist at all. My advice follows in the warning.

**WARNING** *If you are going to depend on Offline Files, make sure that your laptop, file server, and user account are all in the same domain. If that’s not the case, be absolutely sure while you’re still in the office to disconnect the network cable after synchronizing your pinned files and double-check that you can access those files. Offline Files is great, but don’t trust it until you can be really sure of it!*

## Back in the Office: Syncing Up

After Jim returns from his trip, he plugs his laptop into his company’s network and powers up the computer. He has updated `file1.txt` and `file2.txt` and created a completely new file, `file5.txt`, and he wants all three of these new or modified files written to the network servers.

As his laptop's operating system loads, it senses that it's back on the corporate network and tries to update the three files on Resource1's share. The first two we'll look at, `file1.txt` and the new `file5.txt` are no problem—the version of `file1.txt` is the same as it was before Jim left. The file called `file5.txt` didn't exist before, so there's no conflict and Offline Files writes it to the server share. But unknown to Jim, someone *else* modified `file2.txt` and updated the server copy while he was on the road. This presents a conflict to Offline Files, a conflict that it can't resolve by itself, so it prompts Jim for guidance (see Figure 11.79).

**FIGURE 11.79**

Resolving a file version conflict

Jim uses the View buttons to examine both versions and decides that his update has more recent information, so he clicks the Keep Only the Version on My Computer button and then clicks OK. At this point, the files on his laptop and the ones on the network servers are synchronized.

## Applying Offline Files to the Office: When Servers Fail

But suppose you're not a traveling user. What does Offline Files offer you? Greater network reliability and speed would be the primary advantage. By caching commonly used documents, Offline Files offers you a productivity safety net in the event that the network fails.

### BULLETPROOFING WORD WITH OFFLINE FILES

Suppose you're working on a Word document. You keep the DOC file on a server rather than your local hard disk so that you can work on it from any workstation and because it'll be automatically backed up every night. But Word's frequent background saves and AutoRecover writes mean that your workstation must often communicate with the server where the document resides. A network failure or even a short hiccup in network or server response can cause problems that can lead to

Word losing your document. With Offline Files, Word has a much softer landing. Once the server becomes unresponsive, Offline Files automatically shifts all of that server's folders to offline mode. Your first clue that there's a network problem, other than the initial delay from an unresponsive network, is that the Offline Files PC icon has appeared in your system tray, and a balloon message tells you that the server you were working with is now offline. You can continue to work with and save the file, but of course it'll really save to the **Offline Files** folder, at least until you reconnect to the server and synchronize. Additionally, you'll see this kind of network fault-tolerant behavior on *any* cached file, whether a pinned file or a temporary offline file. As you saw before, Offline Files will cache any file that you access on an automatically cached share, or any file that you pin in a manually cached share. This suggests that you should consider either pinning all of the Word files that you use from a server or setting the server shares' caching settings to Automatic Caching for Documents.

### RESUMING NORMAL OPERATION

When the server is available again, Offline Files will sense that and modify its icon to the one shown in Figure 11.80. Click the Offline Files icon, and you'll see a dialog box (Figure 11.81) offering to reestablish connection to the server.

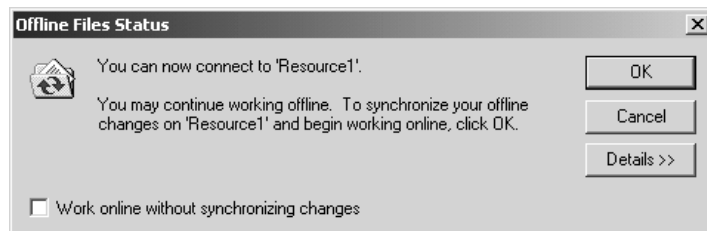

**FIGURE 11.80**

Ready for  
reconnection

**FIGURE 11.81**

Reestablishing  
network connection  
with Offline Files

Click OK and you'll get a warning to close whatever files you are working on, as Windows 2000 and XP will have to close any open files before they can synchronize them.

### Controlling Synchronization for Nonmobile Users

In addition to its fault-tolerant-like benefits, Offline Files's other great strength for nonmobile users is that it can improve a user's network experience by reducing the time between when a user requests a file on the network and when the user gets that file. There's no magic in that quick response, of course: Offline Files gets those files to the user so quickly because the files are already sitting on the user's hard disk in the **Offline Files** folder. But that's really only half the story. Sure, it's nice to get your files quickly—but are they the *right* files? The answer is yes, but there's a lot of underlying machinery ensuring that.

Before offering the locally cached file copy as correct, Offline Files does a quick synchronization with the original network file. That synchronization need not be an entire copy; instead, it is a simple consistency check. For example, try pinning a 100+MB file to your **Offline Files** folder. The initial synchronization will be a simple file copy, and it'll take a good long time. But then right-click the large file and do a synchronization, and you'll see that synchronization finish in seconds. This is true even for large files; for example, in one test, a 4MB JPEG file on a network server was pinned to a workstation's **Offline Files** folder, then the JPEG file was modified by another workstation, reducing its size by 30 percent. Synchronizing the first workstation to the JPEG file's new size took less than 5 seconds.

So you might find when accessing a file via the **Offline Files** folder that there is a short delay while your workstation synchronizes with the offline file's original copy. That might be acceptable, but Offline Files improves further upon that performance by periodically resynchronizing its offline files *before* you need them.

In addition to the synchronizations that occur when you reconnect after being offline, when actually accessing the file, or after choosing **Synchronize** on a pinned file's context menu, you can also configure your Windows 2000 or XP workstation to synchronize at logon, at logoff, when the workstation is idle, or at particular times of day. You configure these synchronizations either by starting **Mobile Sync** via **Start/Programs/Accessories/Synchronize** and then clicking the **Setup** button, or by opening a folder and choosing **Tools/Synchronize** and then clicking the **Setup** button on the resulting page. You get a properties page like the one shown in Figure 11.82.

**FIGURE 11.82**

Initial synchronization configuration screen

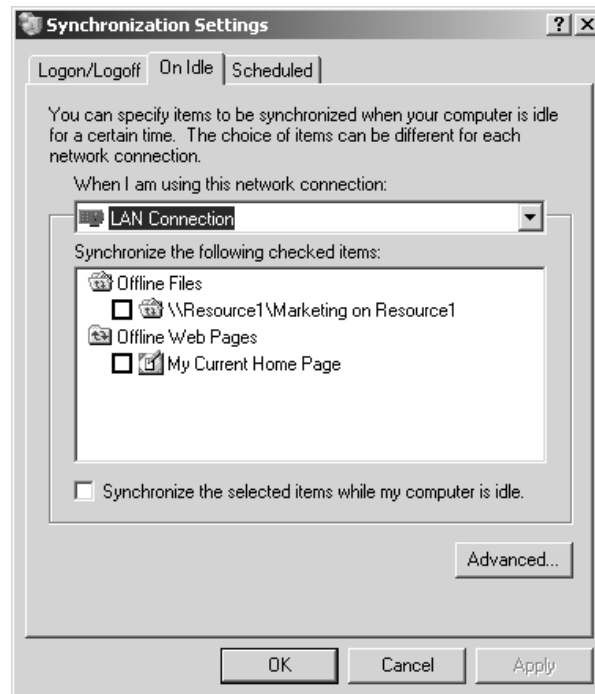

There are three tabs on this properties page: Logon/Logoff, On Idle, and Scheduled. The first two have a single-selection drop-down list box, When I Am Using This Network Connection, that allows you to specify whether you want this synchronization done over a LAN or WAN connection.

In the first tab, you can instruct Offline Files to synchronize at logon or logoff or both. And if you think that synchronizing might be a lengthy process and would like to be able to skip it, you can select the Ask Me Before Synchronizing the Items option, and Offline Files will display the Mobile Sync screen, letting you choose which—if any—folders to synchronize.

The second tab allows Offline Files to essentially synchronize in the background, waiting until your computer sits idle (see Figure 11.83).

**FIGURE 11.83**

Controlling foreground/background synchronization

As with the Logon/Logoff tab, you can specify which folders to synchronize. The Advanced button lets you control how long your workstation should be idle before synchronizing, and how often to synchronize if the computer is idle for long periods of time. You can also indicate that you don't want synchronization to occur when the computer is running on battery power.

The final tab, Scheduled, lets you set up synchronization activity for particular times of day. You can tell it to synchronize every *n* days, every day, or every weekday.

## Cleaning Out Offline Files

Sometimes Offline Files won't go away, however. Say you once connected to a server named MANGO and pinned a couple of files. You'll never see MANGO again and the files aren't important any

longer, but the system wants to synchronize with MANGO and you get an error message every time you log in or log off. What to do?

Simple. Go to the `Offline Files` folder and unpin all of the files (or perhaps folders) in MANGO. Alternatively, you should be able to do that in `My Network Places`. Unpin everything related to MANGO, reboot, and you *should* hear no more about MANGO. Sometimes, however, it just stays around forever. In that case, zap *all* of the cached files. (Be sure to synchronize the folders that are still relevant first!)

You might want to flush out all offline files for several reasons. You might be about to give a laptop or desktop to someone and don't want them poking around inside your `Offline Files` folder or `\Winnt\Csc`. Or maybe you've just gone a bit pin-crazy and have so much stuff cached that you don't have any hard disk space left. In that case, unpin what you can first. But finish the job by choosing `Start/Programs/Accessories/System Tools/Disk Cleanup`. You'll notice that one of the things that Disk Cleanup will do is to wipe out your offline files.

**WARNING** *Again, make sure there's nothing cached that you want to synchronize with the file server before doing this; if you've made changes and haven't synchronized, cleaning out the `Offline Files` folder will lose your changes!*

You'll probably first notice Offline Files when you see how much easier it makes keeping laptop files and network files in lockstep. But you may soon notice that your in-house network is a bit snappier, and that the occasional network failure doesn't keep you from getting work done. And if *that* isn't a killer app, what is?

## Chapter 12

# Software Deployment

IN A PREVIOUS CHAPTER the wonders of RIS were covered in glorious detail. No doubt you already have plans for all the free time you'll now have. Finally, you too can do what previously only people who had the budget to buy third-party products could do. Not only can you do unattended installs, but you can build Windows Workstation (or Server) images, each with applications installed to perfection.

Can I get an alleluia?

Not to burst your bubble, because RIS is great, but what if:

- ◆ The mixed bag of workstations in your network don't all have PXE-capable network cards?
- ◆ Those machines don't even have network cards that are included in the RIS boot disk utility?

And, even if you have RIS-compatible network cards, what if the users actually save data to their machines (even only temporarily)? If you image their systems over the weekend, come Monday the users are going to be mighty upset when they find out their data's gone.

Hmmmm, that *is* a bummer.

Now, what I'm going to talk about is not interested in hardware. It'll get the software where it needs to go, without wiping the machines' hard drives, and without stopping to inspect your network card. And it's all managed through the Active Directory.

I'm talking about software deployment, baby.

Say you manage to get an operating system on the user workstations. But now your manager wants you to make sure everyone has Office XP so they can use the new Word templates from corporate. No hurry, tomorrow would be good.

RIS isn't going to cut it. So it looks like you're going to have a long night ahead of you.

Nope. Maybe an hour or so of your time, a few test runs, and voila, it's all good.

I'm not saying it doesn't take some forethought. I'm not saying it doesn't take some planning. But I am saying it may not be as bad as you think it will be. Realize something up front: not only are you going to be expected by said manager to install the software immediately, but you are probably also going to have to uninstall it when he changes his mind. And if management doesn't change its mind, what about updates and patches later on; are they going to be managed from Active Directory too?

You betcha.

Isn't that what it's all about? Working the system, rather than it working you? So sit back, turn some pages, and learn how to make your life just a little bit easier. . . .

## Windows Installer and Group Policies

Basically software deployment depends on three components: the installation file itself, Windows Installer (currently at version 2.0 with Server 2003), and group policies.

### The Windows Installer Package

Let's start at the beginning. It doesn't start with group policies, it doesn't start with any special service, it starts with the installation file. In order to install any software you need to have the setup file for it. In the good old days (okay, maybe not so good) it'd be called `setup.exe` or perhaps `install.exe`. It was basically up to the programmer as to what the file would be called. It was also up to him as to how it worked. In other words, not a lot of standards were followed. It was something of a free-for-all.

Now, imagine if you wanted to customize the install a little. For example, ensuring that an application saves its user preferences to a particular network path rather than locally. Well, with the old-fashioned setup files, you'd be out of luck because they were all one nonstandard object.

That also meant, if you hadn't noticed, that uninstalls were problematic, because the software setup made some assumptions and installed files, and then the operating system made some assumptions and wrote over those files, then other installed software packages made assumptions and wrote over those files again. Pretty soon things got confused and the uninstall program would fail to delete everything. Or worse yet, it would delete something that another program assumes will be there and then that program wouldn't work. Happens all the time.

That's why Microsoft is focusing on an install file standard. One where the install files are packaged in such a way that all the components are independent. You can check them out, tweak them, choose to load them locally, or not at all. This standard is known as Windows Installer or the Microsoft Software Installer (MSI) package. The MSI package is a database of all of the changes that are made during the install, including files copied and folders created. These installs can then be undone with more success than most uninstalls I've ever seen.

An MSI file is called a *package* because the actual executable information (the code and data that *is* Office) is packaged with its install database into one object. This does not mean the MSI package is the only file needed for the install, like setup files of old; it can still refer to additional files around it. You'll see that when you set up some administrative installs later in this chapter.

Windows Installer can only really recognize a few file types:

**MSI** The Microsoft Software Installer file extension and one of only two main file types that Windows Installer can deploy.

**MSP** The Microsoft Software Patch file.

**MST** The Microsoft Software Transform file, which allows you to modify the install data of an MSI file.

**AAS** The AAS file, an install script that gets stored with the Group Policy object.

**ZAP** The extension recognized for a text-based file you create to get legacy `setup.exe`-based installs onto user machines. You cannot uninstall them or have them install in the background, however. And they're not self repairing. More on that later.

Products like Microsoft Office XP are packaged as MSIs, ready for easy install. In this chapter, we are going to be using Office extensively, so that's convenient. The PDF reader we will be using

(Adobe Acrobat), on the other hand, will not be packaged as an MSI, seeing as it is not yet a Microsoft product. (By the way, why did I choose to use Office as my primary example? Most businesses I know use it. So I figured it might be useful for you too....)

## Windows Installer, How It Really Works

Now let's talk about how Windows Installer really works. Every user and every computer can have an account in Active Directory. These accounts can have group policies applied to them. In the same way, you can create a group policy that applies software installation packages to the account. There are two ways that a software package can be applied using Windows Installer. It can be assigned or published.

Publishing, the more optimistic of the two, is when the software is made available to the user through Add/Remove Programs. These published software packages can then be installed at will. The users might think of it as a lottery approach to software installation—it can keep them looking in Add/Remove Programs hoping for a prize. Another nice feature is auto-install. An application can be the default program to open a particular file extension (such as `.doc` or `.pdf`). When the user double-clicks on a file with that extension, the system will install the required software package automatically, just as if the user had gone into Add/Remove Programs themselves.

Assigning, on the other hand, is when software gets installed automatically without any user intervention. Instead, the software is pushed onto the local system during login, when an associated file is accessed, or when the application icon is first clicked.

Both types of installation use the MSI file extension and come with some nice advantages. These advantages include giving the software packages the ability to link to their install source for reinstalling, uninstalling, or repairing themselves should the software become corrupt.

In general, I assign most of my software packages. Why? Well, convenience, really. Say a user accidentally uninstalls a package that had been published to them. The next day, they go to use the software, and it's not there. All the user knows is that the software is not there, and all they remember is that it's your job to put it there. So they call your boss, who calls you, wondering where the software is that the user needs for their big presentation. If that package had been assigned, then on login the user would have had the package reinstalled. No phone call would have been made, at least, not that day for that reason.

Published packages are not considered *resilient* in that way. (I love the way Microsoft interprets the word “resilient.” Software that can repair itself when it's broken or even reinstall itself when it's uninstalled is *resilient*. I wish I were that resilient.)

**NOTE** *Keep in mind, computers have accounts just like users, and as such, they too can have group policies that run Software Install packages. Logically, they cannot have software published to them (no computer I know can go check out Add/Remove Programs and decide what software it wants to install that day), so packages can only be assigned to computer accounts. Again, you can only assign software to a computer, but you can either publish or assign software to a user account.*

ZAP-installed files are even less resilient than a published MSI file. At least published packages are still MSI packages. They still link to their source and can repair themselves (or be repaired from Add/Remove Programs). A ZAP file is a text file that just points to a common everyday `setup.exe`. Because a ZAP file installs in the foreground, it requires user participation. It therefore must be

published and not assigned. And since a ZAP file doesn't have a nice organized database of Registry changes and added files, it cannot be repaired or easily uninstalled. If it breaks, however, you can just reinstall it.

If you assign a piece of software to an account, and that user or computer does not have that software the next time the applicable group policy gets checked (at login/start up), it will get reinstalled, period. No questions asked. No phone calls made.

I don't like the phone. I don't publish packages unless I have no choice.

But that's just me.

## Using Group Policy to Do Deployment

Now that you know what a Microsoft Software Installer (or Windows Installer) package is, and you realize you can apply it to either users or computers, it's time to think about how and to whom to deploy the package. This does take some forethought, because unexpected things can happen if you lose track of what is getting installed to whom and where. It's always a good idea to think before you click. Just like any group policy, there is an order of application (local, site, domain, OU), and the last one done is the one that is applied. If you install Office XP at the domain level and you uninstall it at the OU level, somebody might not get Office, depending on inheritance and overrides. (Not sure about that sort of thing? Check out Chapter 9 for more details)

Generally, users are organized by what they do. Therefore, users in one OU tend to all need the same software. That's convenient. You also may want to organize the computers themselves by location or type of use, for the same reason. Once you know how the user and computer accounts are organized, deploying software is much easier. There are some caveats though. What if you need to deploy a service pack for Windows XP Professional domain wide? You may expect to keep it simple and apply it to all of the computer accounts. But what if some of those computers are *not* running Windows XP? What if they are running Windows 2000 because their hardware doesn't support the newer OS? What do you suppose will happen to those Windows 2000 machines when you apply a service pack for the wrong operating system? Pandemonium perhaps? It's hard to say....

And, since computer accounts tend to be organized by where they are located or who uses them for what, you may find Windows XP Pro workstations all over the place in Users and Computers. So what can you do, other than pick and choose machines individually? The answer is to put them in groups. Computers have accounts, accounts can be added to groups, and groups aren't affected by the boundaries of something as simple as an OU. I know, I know, group policies aren't applied to groups, they are applied to containers like OUs. Apply the policy to the domain, then go to the Security tab and uncheck the Apply Group Policy check box for all groups but the computer group of your choice. Ta-da, all done, time for a latte.

## DEPLOYING TO USER ACCOUNTS

Microsoft had to make a decision about how software was actually going to be deployed to the users. If it's published, that's easy. The software doesn't get put on the user's system until they ask for it from Add/Remove Programs. Even if you choose to have it auto-install when someone opens a file that has an extension associated with it, Windows Installer will just look in Active Directory for it and install from the path there.

Assigning software, now that's tricky. Microsoft could have made the assign feature force Windows Installer to deploy the product whole hog onto the user's machine, but that would take a long time

when the user first logs in and possibly take up too much space. Or Microsoft could have made an educated guess as to what parts of Office users utilize the most and only install those features, something like a “standard install.” But what if they were wrong?

Instead, Microsoft chose to do something similar to publishing and install only enough of the package to invoke a full install when the shortcut to the application is double-clicked. That way, the software gets “installed” onto a user’s system really quickly when they log in. And that way, no one yells at anybody.

Okay, so this means that the first time someone really uses the product is when the package spends the time to install. And, of course, that’s when the user is always in the biggest hurry. But at least this way, if a user never uses Access it never has to get installed. No wasted space, no wasted time, and no wasted network bandwidth while installing it. That is why, even when assigned, the software isn’t really installed on the computer until it is invoked by the user. Ahhh, that’s why those shortcuts on the Start menu, or Desktop don’t actually point to any software. Ever check out the properties of a shortcut that hasn’t had the software installed for it? It’s not pointing to a target that’s on the system. No siree. As a matter of fact, when I checked online to see if I could find a way to sneak a peek at the source for the shortcut, all I found was an article about how to write a short C++ program that would find the source.

Cool. I guess.

(Maybe I’ll just double-click the thing and find the source that way...)

Because software is not installed locally from the start by default but only when the user “asks” for it, it is considered “advertised.” You know, the user account knows where to get it if it needs it, as if it heard it on TV.

## DEPLOYING TO COMPUTER ACCOUNTS

Notice in the last paragraph I said user account. Unlike software assigned to a user account, when a computer gets software assigned to it, the package is really installed. Also, since it is assigned to the computer account (and essentially belongs to the computer), the user can’t uninstall it unless they have the appropriate privileges. Something to think about if you are in a situation where avoiding uninstalls is important.

Because you can apply an application to both a computer and a user, it may be tempting to sort of “overapply” software to guarantee that it gets installed. Don’t do it. What do I mean by that? I mean that you should *not* do either of the following:

- ◆ Create a single group policy that assigns the same software packages to both computers and user.
- ◆ Create a group policy that assigns software to a user, and create another group policy to assign the same software package to a computer the user is likely to use.

Among other things, either of these actions can cause the system to remove and then reinstall the software *every time* the user logs in to that computer, potentially just repeatedly uninstalling and reinstalling so that the processor can’t be bothered to let the user get to the Desktop for more than a few seconds at a time. I’ve experienced that one in my travels, and it is pretty unmistakable. If you have a user (or user group) in need of a software package and they always use the same computer (or group of computers), do not have Windows Installer deploy the package anew each time a person logs in—that’s not nice. If they need the package, deploy it once to the computer account(s) and be done with it.

## A Quick Look at What Everything Does before You Start Clicking

I don't know about you, but I really can't just do things by rote. If I open a dialog box, I want to know what all the check boxes mean and what all the buttons do (or what dialog box they open up) before I blindly commit to anything.

Before you start clicking, let me show you what software deployment looks like and what everything can do. Then, once you've seen all the buttons, you'll actually do it.

I am taking it for granted that you either have already used group policies or have read Chapter 9 of this book. Even so, you may not have really gone into software installation, so I'll cover that. If you are confident you know the SI (software installation) portions of the Group Policy, feel free to skip this part and move on to the deployment scenarios.

Let's start by looking at an important item, the Options button. It is located under the Group Policy tab of the container (such as an OU) properties in Active Directory Users and Computers (see Figure 12.1).

**FIGURE 12.1**

OU properties,  
Group Policy tab  
dialog box

You know how easy it is to create a new Group Policy Object (GPO), look at its properties, edit it, and delete it, but what is often overlooked when it comes to setting up a GPO is the Options button. Within the Options button's dialog box (see Figure 12.2), you can choose to have no other GPO override the one you have selected, or you can disable the selected one.

Why would you want to disable a GPO? Three reasons:

- ◆ First, if you are having problems with an account in the container and you think that a GPO might be causing it, as a last resort you can disable it and see what happens.
- ◆ Secondly you could leave an old, no longer relevant, GPO linked to the container so you know where it is if you need to recycle it later.

**FIGURE 12.2**

The GPO Options dialog box

- ◆ Finally, and most importantly for software installation, disabling lets you pre-create your software-installing GPOs in an afternoon of setting up network shares, writing ZAP files, and performing administrative installations before deploying any of them. It also lets you make sure you clicked the correct check box or radio button before it's too late and the software is pushed to the entire network. I don't like to enable the GPOs until I'm good and ready and not a moment sooner.

The next interface you need to be familiar with is the Group Policy Management Console (see Figure 12.3). This console is covered in great detail elsewhere, but I want to focus on the software installation here. The Software Installation icon is located right beneath the Software Settings folder in the list on the right side of the window. It looks like a blue box with a CD coming out of it (or going into it...you never know). Because you can assign software to a user or computer, there are configuration options for both. As in much of Windows Server, the context menu is where to go to do anything. If you right-click the Software Installation icon (not the Software Settings folder), you can add any crucial new package that you'd like to deploy. The Software Installation object itself has properties that can be used to set the default deployment options for any package that gets linked to it (see Figure 12.4). Let's look at that dialog box before moving on.

On the General tab, there are a few items of interest. The Default Package Location can be useful if you have (or plan to have) all of your MSI files stored in one place.

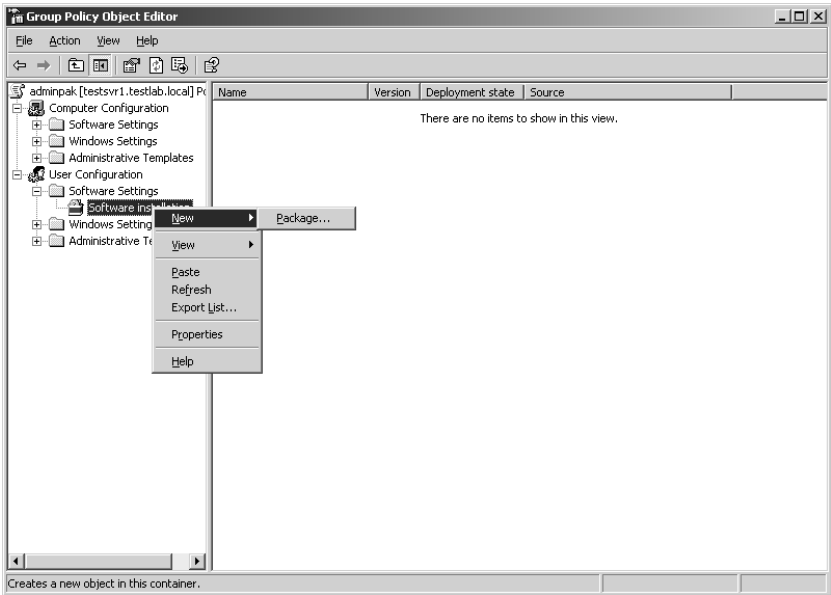

Surprisingly, the Browse button on this dialog box is network aware. When you click it, it immediately looks across the network. If you go to the folder where you store your packages, it will in fact realize that it requires a network path. This is not that common. Most of the location fields in the dialog boxes you will come across may need a network path, but generally default to looking for files on the local drive.

Also under the General tab you can set default information about deployment, such as the options for the Deploy Software dialog box. The Deploy Software dialog box pops up after you've added a new package to a GPO and allows you to choose whether to publish, assign, or do more advanced deployment. You can choose not to display the Deploy Software dialog box and instead have one of the two deploy choices (Publish or Assign) apply immediately. Or, you can choose Advanced. Advanced deployment will allow you to set each package's deployment options in more detail before deployment occurs. I actually prefer the advanced setting, since I have grown comfortable with all of the options, and tend to tweak as I go. For this chapter, though, assume that I have left it in its default, Display the Deploy Software Dialog Box.

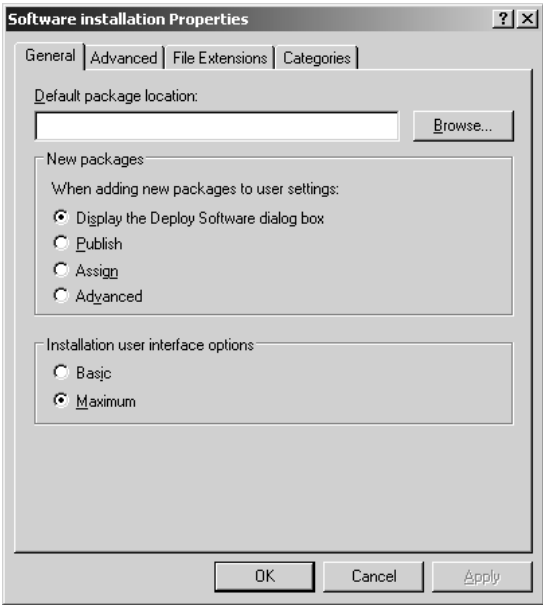

At the bottom of the General tab are the Installation User Interface options. You can choose Basic, which means that the users will see as little as possible of the install process, or Maximum, which means that the users will see as much as possible of the install process (some might say too much). For

some reason, Maximum is selected by default. I always go Basic. Remember though, that this choice doesn't affect ZAP files. They go through their setup as they normally would.

**FIGURE 12.3**  
Group Policy  
Management  
Console

**FIGURE 12.4**  
Software Installation  
default properties

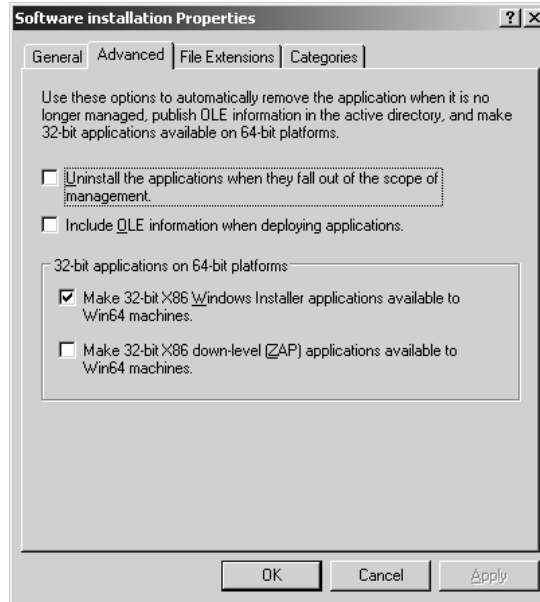

Under the Advanced tab (see Figure 12.5), there are several check boxes. The first allows you to uninstall applications (note the plural) when they fall out of scope of management. That means if

the GPO client user or computer were to be removed from the container or group that this GPO applies to, the installed package would be removed from the machine and would no longer be advertised to their account. This is a great feature and I always have it on by default.

**FIGURE 12.5**

Software Installation properties  
Advanced tab

**NOTE** To ensure that software is removed properly after it has been deployed, make certain that the *Uninstall the Applications When They Fall Out of the Scope of Management* option is checked before the package is first assigned or published. If that option is checked, Windows Installer will write the package uninstall information to the account profile. That way, if the account loses access to its source MSI package for any reason, it will still be able to uninstall itself using the account profile information.

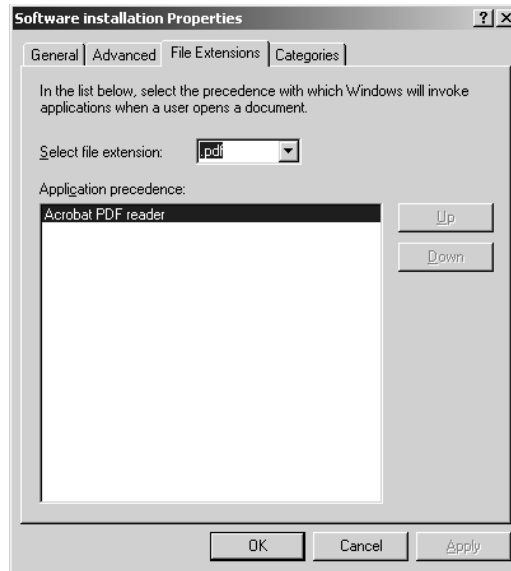

The second check box allows you to include OLE information if the application being deployed has special COM components it needs to access from Active Directory. And the last two check boxes allow you to have 32-bit applications work if you are installing them (as either MSIs or ZAPs) onto 64-bit machines running 64-bit enabled Windows.

The next tab is File Extensions (see Figure 12.6). Here you can view the list of file extensions that will be associated with all the packages added to the GPO. There is nowhere within the individual package properties dialog box to specify extensions—the MSI file lists its associations in its database, and you manually specify associated extensions in the text of a ZAP file. Therefore, this tab is here to help you avoid conflicts if two added packages activate on the same extension. This is particularly important if the extension is contested, such as MP3 or MPG. You can move the packages listed up or down to enforce precedence, with the item closest to the top getting first dibs.

The last tab, Categories, (see Figure 12.7) is used to organize the view of installed packages in Add/Remove Programs. If you would like to associate categories with your packages, you must create them in this tab of the Software Installation properties before they can be listed in the packages' own properties.

**FIGURE 12.6**

File Extensions tab

**FIGURE 12.7**

Categories tab

That's it for the Software Installation properties. Now, on to the package properties.

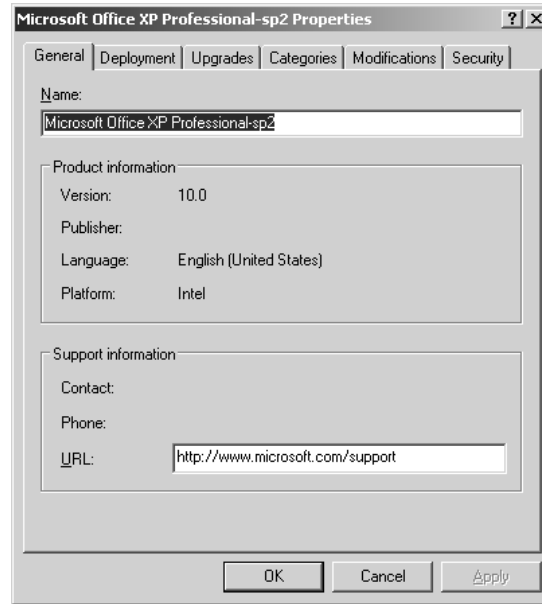

You can get to the package properties page in two ways: by right-clicking a pre-existing package and selecting Properties, or clicking Advanced during the deployment of a newly added package. Either way, you'll end up in the same place.

In the General tab (see Figure 12.8) is the Name field for the package. This field is self-explanatory, but it's useful if you have multiple deployments of the same software with different configurations.

Also under this tab is product information and a support URL field. This field is usually filled in with the package maker's URL (usually Microsoft, whatta surprise), but it is editable. This URL field also shows up under support information in the clients' Add/Remove Programs, so it might be useful to enter the URL to your intranet support page.

**FIGURE 12.8**

Software Installation  
package properties

The second tab is Deployment (see Figure 12.9), which looks similar to the Software Installation properties dialog box. Which options are available under this tab depends on whether you are assigning or publishing and if the package is a ZAP file.

In the Deployment Type section, you can choose Assigned or Published. Only those two options are listed because this *is* advanced deployment. Under Deployment Options you'll see the default settings made in Software Installation properties (you can of course change them, they are only defaults). The first option is Auto-install This Application by File Extension Activation. If this option is checked but grayed out, chances are the package has added its associated extensions to the software installation list. If you were to go back and check the Software Installation's File Extensions tab after you finish with your package, you'll probably find it listed with at least one file extension associated with it. Also the Uninstall This Application When It Falls Out of the Scope of Management option is here (instead of under Advanced as it is in software installation). Notice it is singular, but the Software Installation reference to uninstalling is plural.

The Do Not Display in Add/Remove Programs option makes it a little more difficult for the users to uninstall their software and prevents them from repairing the package if it isn't working properly.

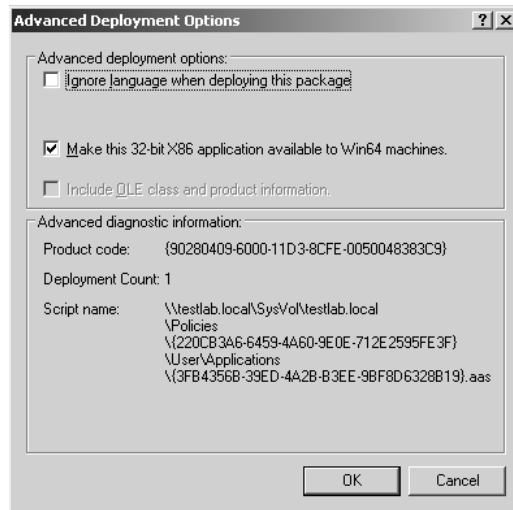

And finally, the brand new and much-needed Install This Application at Logon option. This makes certain that the package is not advertised to install on first use but actually goes ahead and installs the whole package when the client logs on. Of course, this means that it will take quite a while to log on when the package deploys. But no more waiting for clip art to install when the user tries to use it for the first time. Of course, you can't choose this option if you publish the package rather than assign it.

**FIGURE 12.9**  
Deployment tab

Now for an option most people don't even know is available. If you click the Advanced button, you'll bring up the Advanced Deployment Options dialog box (see Figure 12.10). From here, you can choose to ignore language and make a 32-bit application available on a 64-bit machine. (If it wasn't set as a default, you can turn it on here.) My favorite part of this dialog, however, is the Deployment Count. By keeping an eye on this, you can keep track of how many times you have had to redeploy a package. In some circumstances, this can come in handy.

**FIGURE 12.10**  
The Advanced  
Deployment Options  
dialog box

The next tab is Upgrades (see Figure 12.11). If the package you are deploying is supposed to upgrade or replace a previous version, use this tab to make sure it happens. The first section is the list

of packages to be upgraded. If you would like the package to sense and remove previous versions of its software that may not have been installed by deployment, select the Required Upgrade for Existing Packages check box. At the bottom of the page is the list of packages within that GPO that are set to upgrade this package. Obviously, the packages that are going to be upgraded are expected to have been previously deployed, so if you click Add to bring up the Add Upgrade Package dialog box (see Figure 12.12), expect to have to browse through GPOs to find the package that is going to be upgraded. Once you have selected it, you can choose to have your new package upgrade over that older version, or have the older version removed and replaced by the new install.

**FIGURE 12.11**

Upgrades tab

**FIGURE 12.12**

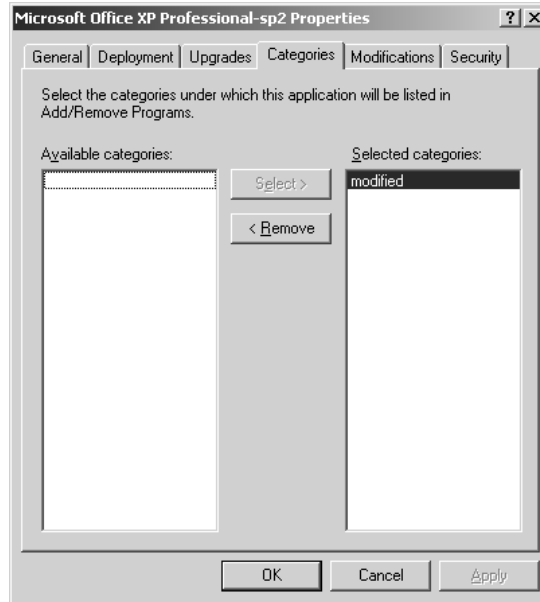

Add Upgrade  
Package dialog box

The next tab is Categories (see Figure 12.13). It has two columns: Available Categories on the left, lists the categories that were created in the Software Installation properties page, and Selected Categories on the right, lists the categories that the package has been assigned to. And there are the obligatory Select/Remove buttons that move items from the available categories to the selected categories (or just get rid of categories you may have assigned the package to by mistake).

**FIGURE 12.13**  
Categories tab

On to the Modifications tab (see Figure 12.14). This tab is where you go if you have created a file that customizes an MSI install. The MST file is used during installation to tell the MSI package the particulars about how to install components, modify application settings, and such. Because it is only used at installation, it stands to reason that you can only add an MST (or several of them if you'd like) to a deployment before it runs. If you click OK before you finish adding your transform files, you're out of luck—it's all or nothing. This is definitely not something to come back to later.

**TIP** *In my experience, the special voodoo that gets software installation to really work is to do everything you intend to do before you deploy the package. If the client gets the deployment and it works fine, they may not check back with the server to see if there have been any changes, so it's better not to make any after deployment. This is another reason to use the Advanced Deployment option as a default. It'll give you a chance to double-check your settings before clicking OK.*

And finally we come to the Security tab (see Figure 12.15), where you can choose permissions that are appropriate for the package file itself. Remember, if you want to check out the permissions to whom this GPO will apply, you will have to go to the GPO's properties.

**FIGURE 12.14**  
Modifications tab

**FIGURE 12.15**  
The Security tab

Phew. I'm glad we got that out of the way. I just can't leave a button unclicked....

## The Scenario: What You Can Do with Software Deployment

Now let's look at a scenario that might lend itself to the kind ministrations of software deployment:

- ◆ An IT staffer has complained once too often, and you decided to publish administrative tools to all IT personnel so they can have them no matter where they log in from. That should make them happy.
- ◆ Well, it should have made them happy, but they are too lazy to go to Add/Remove Packages, so you end up assigning it and redeploying it instead.
- ◆ Then the IT staffer who first made the suggestion is found abusing the administrative tools. He gets moved to sales. Obviously he shouldn't have admin tools anymore.
- ◆ The CEO hears about the IT staffer's indiscretions and decides administrative tools cannot be deployed to any workstation other than those in the secure network room. You will need to remove the tools and assign them only to the secure network room computers.
- ◆ Then your boss wants you to upgrade Office 2000 to Office XP, Service Pack 2, on every machine in the building. He also wants you to change the default location of the Microsoft Word Workgroup Templates to a shared folder on the server. No hurry, tomorrow would be fine.
- ◆ The corporate office sends out a memo demanding that all Windows XP Professional workstations have Service Pack 1 installed before the end of the week.
- ◆ The sales staff needs to be able to read PDF documents, but the PDF reader your company bought has an EXE install file.
- ◆ Oh, and all users need to be able to create self-extracting ZIP files for non-Windows XP clients. But that program doesn't use an MSI, and not all users can use Add/Remove Programs.

Alrighty then, I think we've covered the basics. Now that you know where I'm going with this, let's get down to it.

### PUBLISHING AN MSI PACKAGE

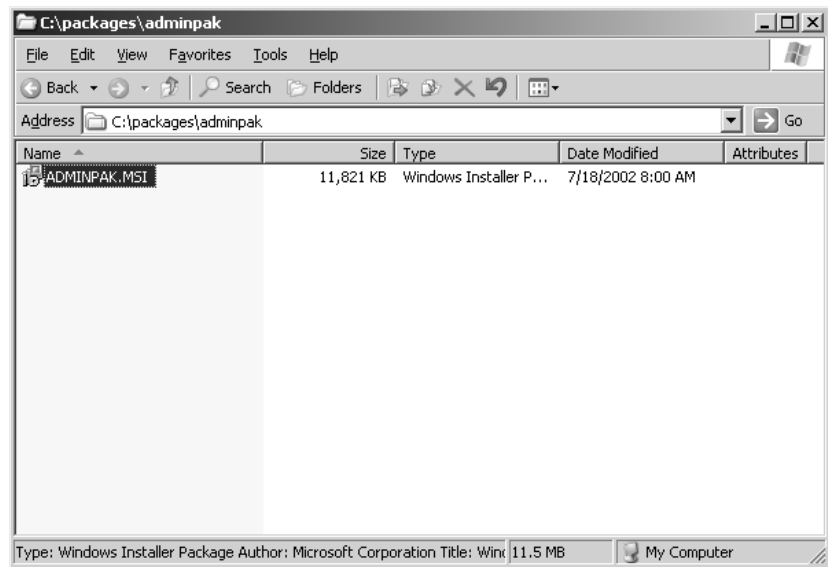

In the preceding scenario, the first thing you need to do is publish the administrative tools to all of the IT staff accounts. To start, you need to find the MSI file for the software. It just happens to be called `adminpak.msi`, and it is located on the Windows Server CD, in the I386 folder (`x:\I386\adminpak.msi`). This MSI package is considered "flat" because it can be deployed as is. That is, it stands alone, unmodified, with no administrative intervention needed before applying it. That being said, you can just put it in a shared location, link it to a GPO, publish it, and it's done.

Seriously. I'll show you:

1. Copy the file `adminpak.msi` to a shared folder on the server. On my server I organize all of my MSI packages in their own folders under a folder called, creatively enough, `packages`. On the server it would be `C:\packages\adminpak\adminpak.msi`, as shown in Figure 12.16.

**FIGURE 12.16**

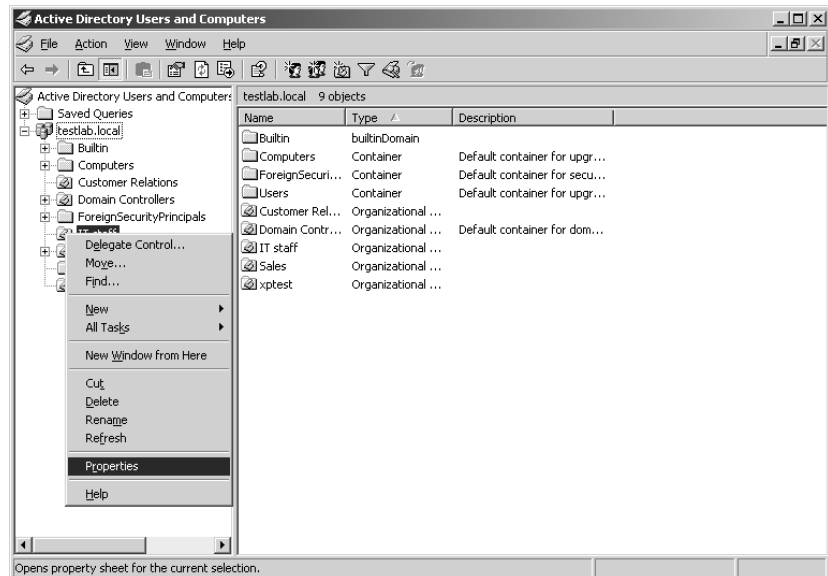

Saving the `adminpak.msi` file to a shared folder on the server

2. Open the Active Directory Users and Computers MMC. As you can see in Figure 12.17, there are a few organizational units, and one of them is called IT Staff. Not surprisingly, that is the organizational unit that the `adminpak.msi` is going to be published to. To get to the properties and add a group policy, right-click the IT Staff OU.

**FIGURE 12.17**

Right-click the OU in Users and Computers to create a new group policy.

3. Take a look at Figure 12.18. On the properties page, click the Group Policy tab. Click the New button. It will put a new, unnamed Group Policy object in the list area. Name it adminpak. Click the Edit button.

**FIGURE 12.18**

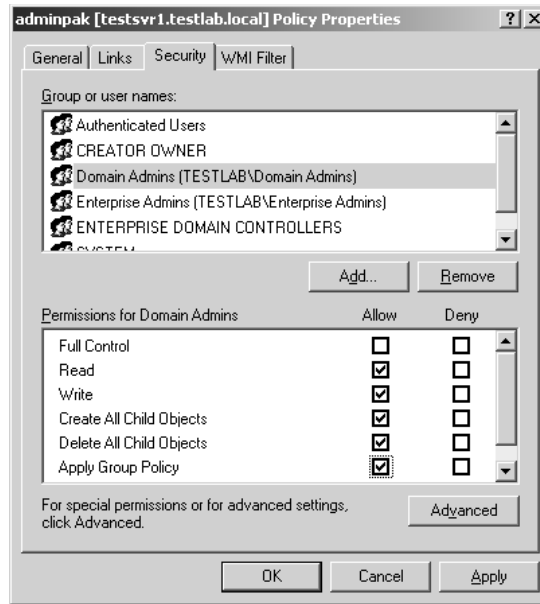

Edit the new  
Group Policy

4. At this point, I always check to see what groups of users this GPO actually applies to. It's always good to pay attention to who has the Apply Group Policy permission. Right-click the adminpak group policy icon at the top of the list. Select Properties. In the properties page (see Figure 12.19), go to the Security tab. Click Domain Admins and notice that Apply Group Policy is not checked in the list of permissions. They can read it, but they don't have to obey it. To make sure the group policy applies only to them, check the Apply Group Policy box, and make sure it is unchecked for your general authenticated user. That way, if someone accidentally gets moved to the IT Staff OU, they won't have administrative tools.
5. In the Group Policy Management Console, you can see that there are two basic configurations to choose from on the left: User Configuration or Computer Configuration. Since the adminpak.msi is going to be applied to the IT staff user accounts, it stands to reason that you should go for the User Configuration. Before you add a new package though, make sure that it will uninstall if a user leaves the IT staff. Beneath User Configuration, click the plus sign next to Software Settings, and right-click Software Installation. In the pop-up menu, click Properties. Click the Advanced tab (see Figure 12.20) and make sure the Uninstall the Applications When They Fall Out of the Scope of Management option is selected. Click OK. Now any package added to this software installation configuration will bear this option.

**FIGURE 12.19**

Verifying that the Domain Admins have Apply Group Policy permission

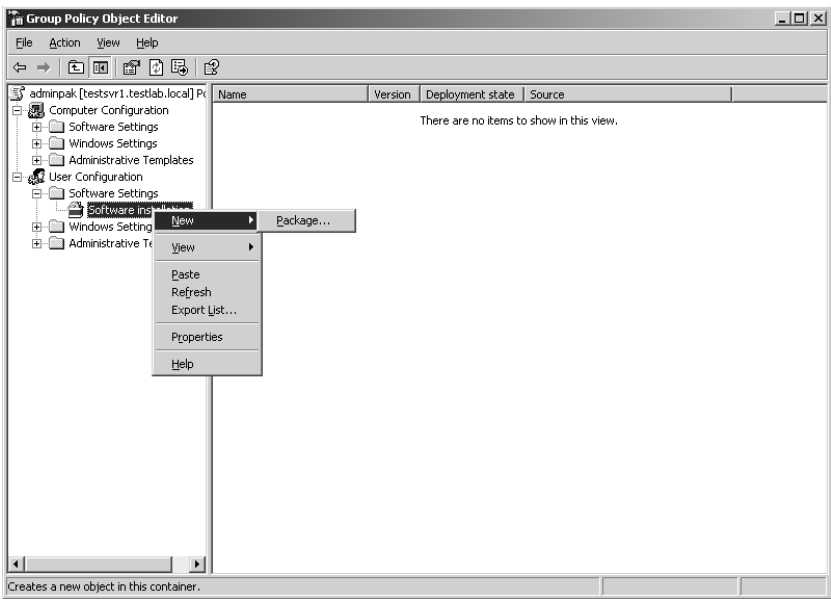

**FIGURE 12.20**

Ensuring that the package will uninstall if a user leaves the IT staff

- Now it's time to create the package. Right-click Software Installation and go to New\Package (see Figure 12.21).

**FIGURE 12.21**  
Create a new software installation package

7. The dialog box obviously means for you to click the location where the file is currently located. *Do not do that.* The temptation is there, but you must remember that you are setting up the path to the MSI file that will be accessed across the network. Be sure to type in the full path to the package. (As you can see in Figure 12.22, in my case it is `\\tstsvr1.testlab.local\packages\adminpak\adminpak.msi`.) Then click Open.

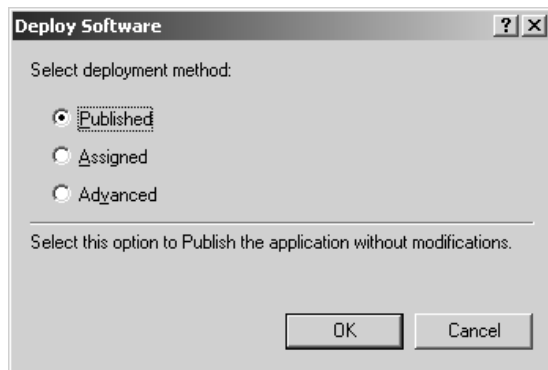

**FIGURE 12.22**  
Type in the full path to the MSI package

8. That's it, the package is linked to the GPO. Now you have to decide how to deploy it. In this example, you are going to publish. In the Deploy Software dialog box that pops up (see Figure 12.23), make sure that Published is selected and click OK.

**FIGURE 12.23**

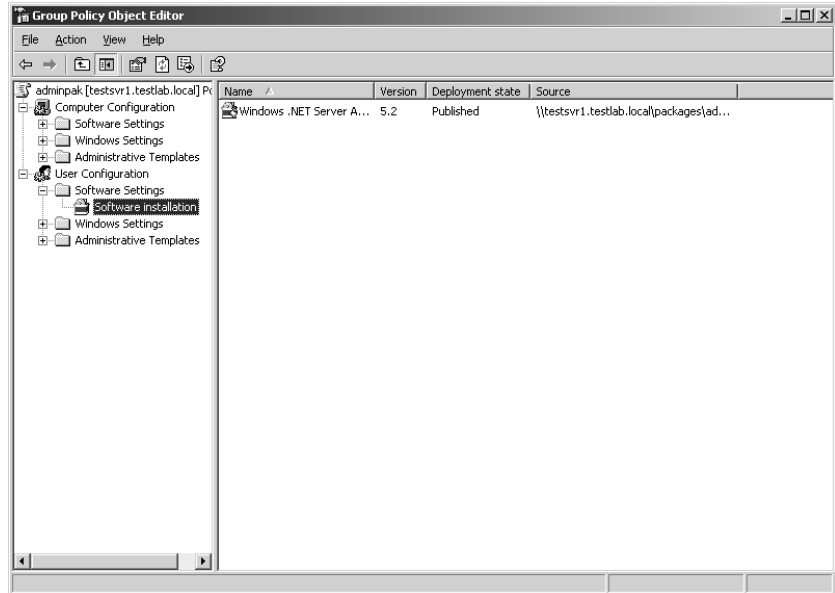

Deploying a package by publishing it

9. Voila. The package is there. Take a look at Figure 12.24 and check out the new administrative tools package on the right side of the window. Notice that under Deployment State it says Published. Also, check your path and make sure it is correct.

**FIGURE 12.24**

New package to publish

10. That's it. Now when an IT staffer logs in, they can go to Add/Remove Programs and add administrative tools from there (see Figure 12.25).

**FIGURE 12.25**

New administrative tools are now available for installing in Add/Remove Programs

**NOTE** It is in Add/Remove Programs that all installed software is listed (unless you set it to not display under Deployment Options in the package properties). It's also where a user can go to manually try to repair an installed software program if it is not working properly. By clicking the Click Here for Support Information option, the user can then click Repair, and the corrupted or missing files will be replaced by the source MSI file.

Again, the basic steps to publishing an MSI package are as follows:

1. Copy the MSI file to network share.
2. Make the group policy. Make sure it applies to the users you want it to.
3. Link the MSI to the group policy.
4. Choose to publish it and make sure it uninstalls if it goes out of the scope of management.
5. At the next login, the user will have the option of installing the program from Add/Remove Programs or whenever they activate an associated extension.

#### **REDEPLOY (IF AT FIRST YOU DON'T SUCCEED...)**

Within days of publishing the `admi npak.msi` to the IT Staff, you realize something important: People are generally lazy. You have gotten three e-mail messages asking if you could just assign the MSI rather than making them perform the extra steps to install it. You decide you might as well, because you'd rather the tool kit be used than neglected.

There are several good reasons to redeploy software. One is that you should assign software to people's machines rather than publishing it. And, although you might think changing the deployment state from Publish to Assign is enough, I think that it's a better idea to redeploy the package to apply the change. Why? Because it ensures that the installed copy on the user machine changes

its deployment status as soon as possible, rather than waiting to get around to it when it needs to repair itself.

**NOTE** Remember: If you are going to make any changes to the deployment state or options of a package, make sure that the accounts that are to be affected have logged off and on (or shut down and restarted) at least once after you make any changes. If they don't do this, the clients may not be aware of the change and will remain unaffected.

Another reason to redeploy is if the MSI file has been updated or modified in some way that requires that a changed version be installed on the users' systems. The problem with redeploying is that it does force a reinstall of the software all over again. This can take up network bandwidth and may frustrate the users temporarily, but if it makes work better they will eventually forget about it.

1. To redeploy the `adminpak.msi` file to be assigned rather than published, go to the appropriate GPO, and edit it (by right-clicking the container, going to Properties, going to the Group Policy tab, selecting the adminpak GPO, and clicking the Edit button). Then right-click the MSI package and choose Assign (see Figure 12.26).

**FIGURE 12.26**

Assigning adminpak

2. The Deployment State of the package will go from Published to Assigned. Right-click the package again, go to All Tasks (you'll see that Publish and Assign are listed here too for your convenience. Assign, of course, is now grayed out.), and select Redeploy Application (as shown in Figure 12.27).
3. After you redeploy, there will be a warning dialog box (see Figure 12.28), and it is serious. Redeploying software can take up bandwidth on a busy network. Click Yes if that's not an issue. That will redeploy the `adminpak.msi` file as assigned. No more manually installing administrative tools.

**FIGURE 12.27**  
Redeploying  
adminpak

**FIGURE 12.28**  
Redeployment  
warning

**SCOPE OF MANAGEMENT**

Now, there was a reason I wanted you to make sure the Uninstall This Application When It Falls Out of the Scope of Management check box was checked when you first set up the adminpak for deployment. As I mentioned earlier, when a software package is added to a GPO and deployed to an OU, its scope of management is limited to that OU. When a user is moved out of that OU, they fall out of that GPO’s ability to manage that software. Because the Uninstall This Application option was checked before the package deployed, the software will be uninstalled from the user’s machine if they move out of the OU, and will no longer be available to that user for as long as they are no longer in the OU. Remember the scenario? The very person who wanted administrative tools wherever they log in has been caught being naughty (they abused the admin tools). So (instead of being fired) they have been transferred from the IT department to the Sales department.

You already set the software to be uninstalled if someone moves out of the OU; so when the staffer is moved from the IT Staff OU to the Sales OU, they will no longer have administrative tools.

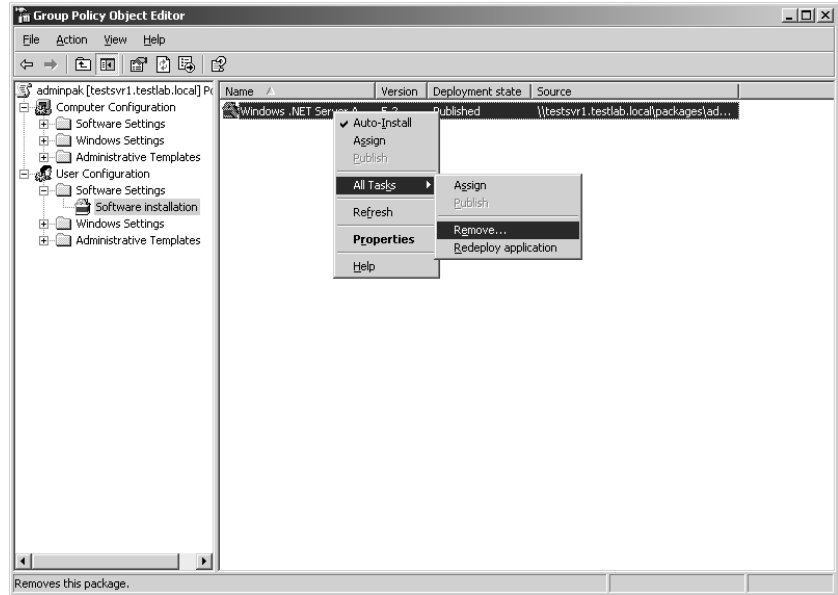

**REMOVE A MANAGED MSI PACKAGE**

Of course, because one bad apple spoiled the barrel, you now have to essentially do a recall on the very administrative tools you recently deployed. As you may remember, the CEO now wants to

be sure that no one outside of the secure network room has those tools. So step one is just removing the software from everyone's systems. We'll worry about getting the admin tools back later....

1. Go to the properties dialog box of the IT Staff OU and click the Group Policy tab. Select the adminpak GPO. Edit it. Right-click the administrative tools package. Select All Tasks from the popup menu (see Figure 12.29) and choose Remove.

**FIGURE 12.29**  
Removing a package

2. The Remove Software dialog box, which comes up as soon as you choose to remove a package (see Figure 12.30), gives two options: to uninstall the software immediately, or allow the copy to remain on the user's machine, but prevent new installations. Choose the option to immediately uninstall (no time like the present, I always say). Click OK and the package disappears. If an IT staffer logs on now, their admin tools will be gone and there'll be no possibility of reinstalling.

**FIGURE 12.30**  
Removing the  
package immediately

**WARNING** To ensure that software is removed properly after it has been deployed, make certain that the *Uninstall This Application When it Falls Out of the Scope of Management* option is checked before the package is first assigned or published. If that option is checked, Windows Installer will write the package uninstall information to the account profile. That way, if the account loses access to its source MSI package for any reason, it will still be able to uninstall itself using the account profile information. How can software lose access to the source MSI? If a package has been recently deployed and you remove it before the affected accounts have had a chance to log on and log off, the clients may not have had a chance to check the server and notice the change so they may not update their own information to reflect the change. If the software later realizes that it should be uninstalled, but it can't find its source installation information, then it also can't find its source uninstall information. At that point, it is considered orphaned. It remains on the system, must be uninstalled manually, and, of course, can't self-repair. Despite the fact that the point of uninstalling applications when they fall out of the scope of management was to ease the administrative burden of managing the software of users that are promoted, demoted, or transferred, it also, inadvertently, helps manage any piece of software that might someday be removed.

### ASSIGN AN MSI PACKAGE TO A COMPUTER

Well, the CEO did say that the IT staff *could* have administrative tools in the network room, so let's assign an MSI package to some computer accounts.

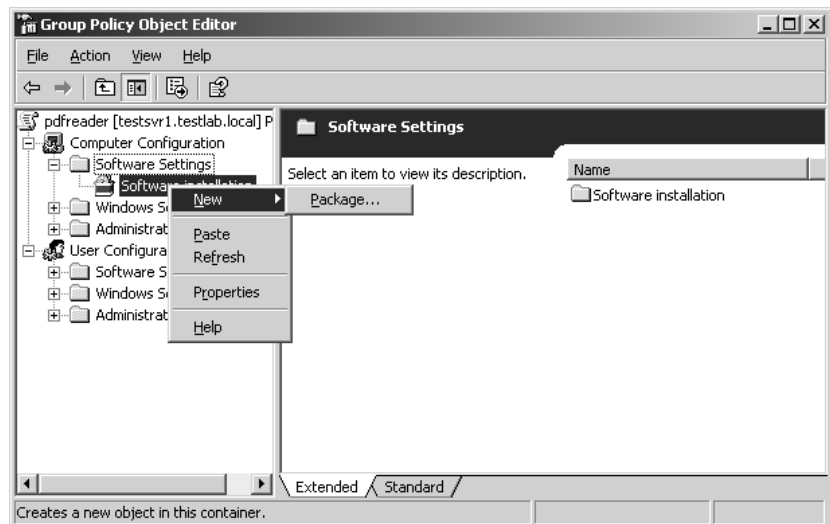

The beauty of computers, as opposed to users, is they (usually) don't roam and if they start acting strange, they aren't considered to be eccentric, they are broken. And they can't leave voice mail. I love assigning packages to computers. Software that is assigned to a computer is installed, period, on that system at startup. No one is going to be idly uninstalling the software because the software is not assigned to its user account. It belongs to the computer's account.

The adminpak GPO still exists but it's not deploying software anymore. Let's use it to deploy the administrative tools to the computers in the IT Staff OU. Waste not, want not.

1. Go to the properties page of the IT Staff OU. Select the adminpak GPO. Edit it. Right-click Software Installation under Computer Configuration (see Figure 12.31) and from the context menu, choose *New\Package*.

**FIGURE 12.31**

Computer software installation

2. Add the `adminpak.msi` file as a new package. You must choose Assign as the deployment method.

That's it. The package is now assigned to install at startup for all computers in the IT Staff OU.

### COMPLEX DEPLOYMENT AND CUSTOMIZATION

The next thing to take care of in our scenario is that Office XP needs to be installed and available to every user on the network. In addition, it needs to be patched, and the install needs to be modified to point to a shared `Template` folder. This process obviously has several steps. First, the software needs to be made available to the users. Second, the software itself needs to have the necessary service packs applied to it (currently up to SP2). Third, the software install needs to be modified. We'll start with making the software available.

#### *Administrative Install*

Before you create the Software Installer GPO, the Office XP MSI package must be prepared to be an administrative install.

"What?" I hear you ask? "Why do I need to do that? I didn't have to do that with the `adminpak`." I know. That's why `admin tools` is so easy to use as an example. Unfortunately, Office is one of the more popular MSI package that gets deployed and managed.

The Office MSI is not a flat MSI. It refers to files outside of itself, it's filled with components both independent and shared, and it can be customized like crazy. It's not an "as-is" item. Because of this, Office XP requires more explanation than just share and go.

Back when Office 97 came out, it had a special network install you could perform so you could accept the EULA, type in the product key, and enter the company information so the users didn't have to. This made it possible to install Office 97 on every user machine without having to type in anything. Heck, just not having to hand out the product key was more than enough reason to use the administrative install version rather than just sharing out a folder that had the contents of the Office 97 CD in it.

Microsoft, like most of us, tends to keep a good thing. So Office XP has an administrative install that does basically the same thing the Office 97 version did.

The files that actually get installed on the user workstation are system file-sensitive. This means the installer has different files (such as DLLs) for different operating systems. To get the installation to work reliably on a workstation, it needs to be administratively installed from that workstation (or a spitting image of it).

Doing the administrative install is really easy:

1. Make sure there is a shared folder on the server to use as a network sharepoint (as you can see in Figure 12.32, mine is under the shared `packages` folder, in a folder I named `OfficeXP`) for the new MSI and its accompanying files.
2. Go to a workstation that has the same operating system on it as the machines you will be deploying to. Make certain the workstation has network connectivity and can see the sharepoint. Oh, and have the Office XP CD handy.
3. Make sure you are logged in with at least enough administrative rights to run software on that machine and to write to the sharepoint.

**FIGURE 12.32**  
Administrative  
install sharepoint

4. Put the CD in the CD-ROM drive, go to Start\Run, type `x:\setup /a` (where “x:” is the CD-ROM drive letter), and click OK (as shown in Figure 12.33).

**FIGURE 12.33**  
Running  
administrative  
install

The administrative install will begin. It has a few wizard steps to go through, most notably when it asks you where to put the administrative files (remember that you should choose the shared folder on the server—mine is in the `OfficeXP` folder under `Packages`—and be sure to use the full network path). It also asks for company name, product key, and prompts you to accept the EULA by proxy for anyone who uses the product from your install (see Figure 12.34).

There are quite a few files in the sharepoint (see Figure 12.35), but `propplus.msi` is the important one. This is the administrative-install type of MSI file that looks for the information you gave during setup. Because an administrative install is aware that it will be a standard copy used by multiple clients, it was designed with convenient, centralized customization and updates in mind.

Updating and customizing is what you’ll do next. Remember, always do everything you can with the file before you deploy it.

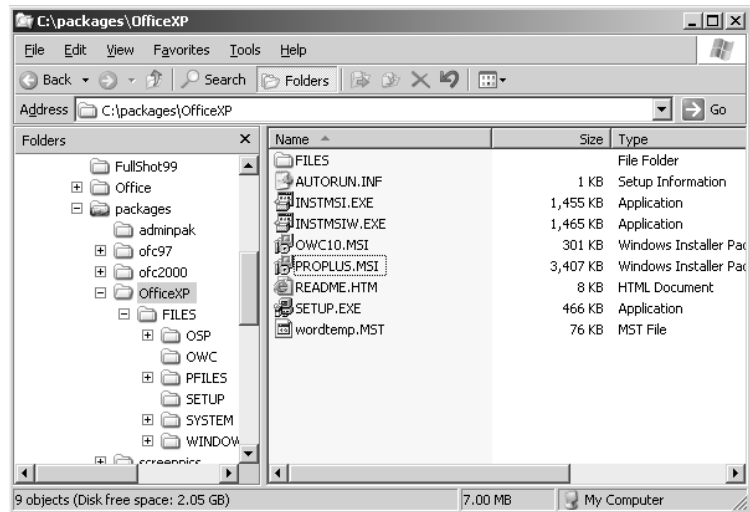

So let’s do the service packs and modifications first. We’ll finish with the easy part, the deployment.

**FIGURE 12.34**

Administrative installation in progress

**FIGURE 12.35**

Administrative install sharepoint contents

### Updating an Administrative Install

Because the boss wants you to install Office XP with Service Pack 2, you should probably apply SP2 before you deploy the software. Updating the administrative install is a convenient way of updating the software on the client computers. After the update, just redeploy the package, and it should reinstall the updated version of the software when a user logs in.

To apply a service pack to an administrative install, you need to download it (unless you have it on CD) and be sure you get the *administrative* version. It is the version that was designed specifically to be applied to an administrative install. The service pack I am using, SP2a, is called `oxpsp2a.exe`.

1. When the service pack is on your system, double-click it to allow it to self-extract. Choose a location to extract it to (see Figure 12.36). This can be a local path because it does not need

to be accessed across the network (notice that it says “location,” not “path,” in the dialog box). For simplicity’s sake, I used `c:\adminupdates`.

**FIGURE 12.36**

Service Pack self-extraction

2. Go to the `adminupdates` (or whatever name you gave your location) folder and you’ll see that it has two MSP files. The one I am going to use is `mainisp2ff.msp`.
3. To apply the patch to the administrative install, you will need to run the `MSIEXEC` command to specify which MSP you would like to apply to what MSI. In the Run box (see Figure 12.37), type the following:

```
MSIEXEC /a c:\packages\officexp\proplus.msi /p
c:\adminupdates\mainisp2ff.msp shortfilenames=1
```

Click OK.

**FIGURE 12.37**

Applying Service Pack 2 to the administrative install

**NOTE** *MSIEXEC is a command-line tool for working with MSI files locally. It cannot do network deployment, but it is powerful to say the least. An entire chapter alone can be dedicated to using MSIEXEC.*

4. What looks like a software installation will start. It will ask you to confirm your organization name, product key for the product it is updating, and EULA confirmation. Then it will install.
5. When the administrative install is updated, just go to the Group Policy Management Console for Office XP’s GPO and redeploy the Office XP package. If all goes well, when the users log on they will be redeployed the updated version of Office XP. To confirm that the update worked, open any Office XP feature, such as PowerPoint, and go to the About box under the Help menu. The service pack will be listed (as shown in Figure 12.38).

**FIGURE 12.38**

An updated  
Office XP  
application

### AN ALTERNATIVE METHOD OF UPDATING IF CLIENT SYNCHRONIZATION IS AN ISSUE

There are several reasons a client may fall out of sync with its source MSI—one of the biggest is if the version of that MSI changes. Applying service packs to an administrative install would do just that.

On a fast, smooth-running network, if all of the computers run well, and the users log in and off on schedule, and the machines are restarted regularly, then there are no problems with lack of synchronicity.

If your network is not a fast, smooth-running machine with orderly shutdowns and logoffs, then when you change the administrative install of a package and do a redeploy, some users may log in and see a dialog box asking to install Office from a CD. Heck, that may happen even on the smoothest, fastest running network.

If this happens, do not despair. First, try having the user log off and log back in again. Sometimes there is simply a delay between the redeployment and the client realizing that the software has changed. If logging off and on a few times does not work, however, you have two options to fix it: a short one and a long one.

The short option is to create a logon script that has the client accounts recache and reinstall the software to apply changes. By using MSIEEXEC, you can rerun the install by pointing to the path of the administrative install MSI file and tell it to REINSTALL whatever features (such as Word or Excel) you'd like, or just do ALL to reinstall all the features (which is what I do). Then specify the switches you'd like to apply to the REINSTALL. The switches I suggest are vomus—I know that looks like a Latin word for a gross bodily function, but it actually stands for a list (or “stack”) of switches (notice that there are no forward slashes for these switches):

- ◆ v = Run from source and recache the local package
- ◆ o = Reinstall if file is missing or if an older version is installed

*Continued on next page*

**AN ALTERNATIVE METHOD OF UPDATING IF CLIENT SYNCHRONIZATION IS AN ISSUE (continued)**

- ◆ m = Rewrite all required machine-specific Registry entries
- ◆ u = Rewrite all required user-specific Registry entries
- ◆ s = Overwrite all existing shortcuts

Using all of those switches might seem like overkill, but it's better to be safe.

The syntax for this MSISEXEC command line is as follows:

```
MSISEXEC /I "path for the admin install MSI" REINSTALL= "featurelist or ALL"
REINSTALL= vomus
```

You only need to run the MSISEXEC once, at the logon following your modification of the source MSI. After you are sure that all users have been reached and won't be orphaned, remove the script. Otherwise, it will recache and reinstall every time the user logs in.

If you think MSISEXEC won't work in your circumstance, there is a longer method that is also effective. This option also helps ensure that no client ends up trying to refer to the wrong version of the MSI source. It is a bit clunky, but it gets the job done.

Before any updates are applied, make a copy of the administrative install folder. Make your changes to the copy (such as hot fixes or service packs). Create a new GPO that has the exact same settings as the current GPO—that is, add the changed MSI, MSTs, categories, and whatever else is necessary to get it to match the current Office XP deployment.

If your environment allows it, you can also check the Install This Application at Logon box in the package properties. It will cause slow logins (especially if everyone logs in at the same time). However, it may be worth the wait to ensure that no lingering component of the prechanged MSI is left behind on the client to cause problems later, especially if being out-of-sync is a consistent problem in your environment.

Then make sure (before you click OK) that the new, changed package upgrades the current Office XP GPO package and that the current package is removed by the upgrade.

Disable the current GPO and move the new GPO up the list until it is above the current Office XP GPO (remember order counts, from the top down).

Then wait and see if any users have problems. Notice that the current GPO wasn't removed, but it won't advertise its version of the MSI to any new users. Leave it that way for a while, and make sure every user has logged in several times. Give every account every chance to upgrade of its own free will. That's the trick: making sure no one has missed the upgrade train. Then delete the no-longer-current GPO for Office XP and delete the old administrative install. No one should be pointing to it anymore.

This method might seem a little extreme, but it is only one extra GPO to ensure peace and harmony throughout your kingdom. It may be worth it. And, if someone who was out on leave logs in and can't get Office XP to work because it keeps asking for the install disk, you can just restore the old administrative install so the client can point to it. It may take a few logins for an account to realize it has a new GPO (usually two), but it will get upgraded. Then you can delete the original administrative install again.

### Customizing an MSI

Your boss has decreed that Word XP needs to point to the `Template` folder on the server. How can you change that in the administrative install to apply the customization to every users' install? It's easy.

To customize Office XP, you need the Custom Installation Wizard. It is located in the Office XP Resource Kit, which can be found either on the Office XP CD or on Microsoft's Web site in the Downloads section. The Office XP Resource Kit file on the CD is called `ORK.msi`.

The Custom Installation Wizard creates a modifier file, like an INI, that the MSI refers to during install to customize Office. The customization file is called a Transform file and its extension is `.mst` (one of the few files that Windows Installer recognizes, as you may recall).

The Resource Kit is a collection of really cool Office tools that are beyond the scope of this chapter (books have been written about them). We only need the CIW to change the default template path, so none of that other stuff is for us.

Download and install the `ORK.msi` file. It does not need to be run from a workstation, the server is fine, because it doesn't need to check the system files. It'll add several nifty Office management tools, but the only one you need is Custom Installation Tools. Select that from the Start menu to get started.

1. The wizard introduces itself with a standard welcome screen; click Next. On the Open the MSI File screen (see Figure 12.39), type in the network path of the MSI package for which you are going to make a transform file. Note that no MSIs are harmed in the making of this MST. Click Next.

**FIGURE 12.39**

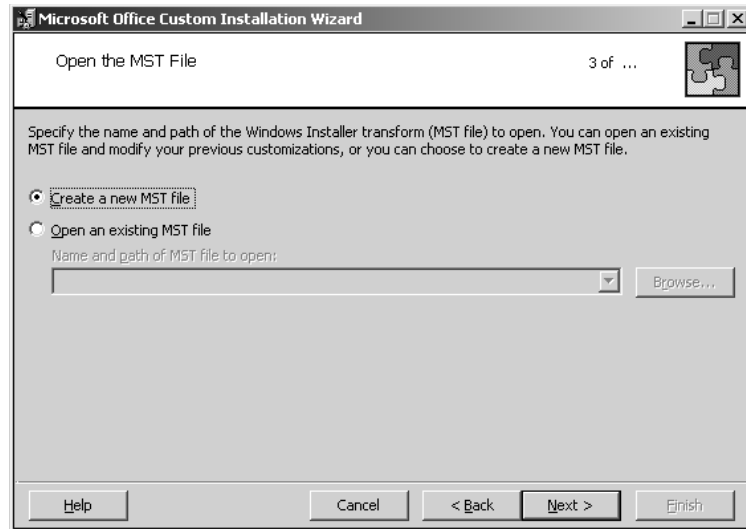

Specifying the MSI to customize

2. The Open the MST File screen (see Figure 12.40) lets you specify whether you are creating a new MST file or editing an existing one. (This is a nice option to know about if you forget something. Remember though, if it is already linked to an MSI package that has been deployed and you make a change, you must redeploy it.) Select Create a New MST File and click Next.

**FIGURE 12.40**

Create a new MST.

3. The Select the MST File to Save screen (see Figure 12.41) will name the MST and specify the path for it. Whenever a dialog box or wizard says “path,” it never hurts to assume they mean full network path. It’s also a good idea to keep MSI files and their MSTs in the same folder. Because this MST will specify an alternate network path for Word templates, I’ve named it `wordtemp.mst`. Click Next.

**FIGURE 12.41**

Supply a name and location for the new MST.

4. In the Specify Default Path and Organization screen, you can change the default folder location for the client installation, but for this exercise, the default install location is fine. While you’re at this screen, however, notice the page number drop-down button at the top

right. If you click its down arrow, you'll see a list of the upcoming steps of the wizard (see Figure 12.42); move to the screen that is relevant to you. This is a time saver, since there are 22 screens and you only need to change the location of one folder. Click Next.

**FIGURE 12.42**

Drop-down list of wizard screens

5. The Remove Previous Versions screen gives you a chance to remove previous versions of the software (see Figure 12.43). It is a good idea to avoid version conflicts, so removing the previous version (but keeping user preferences and such) is always a wise choice. However, for this example, let's have Windows Installer handle it during deployment. Click Next.

**FIGURE 12.43**

Remove Previous Versions screen

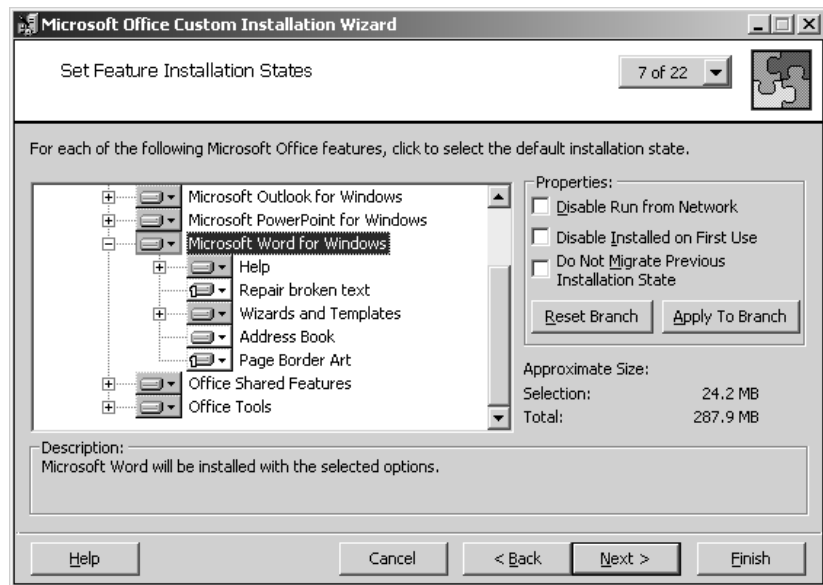

One reason not to manage upgrades with an MST is that you can also manage them as part of software deployment. If you use both methods, you may find yourself being redundant, telling the MST to upgrade any older version of Office, and adding packages to upgrade in the package properties. Try to choose one or the other—that way, if something goes wrong, it's easier to troubleshoot.

6. In the Set Feature Installation States screen (see Figure 12.44), you can choose which applications and their components get installed and how they install. The items that are gray have additional components under them; white items are single components with no subordinates. You aren't going to do anything here, but it's a nice option to be aware of. At this point, use the page number drop-down button to skip to screen 9, the Change Office User Settings screen.

**FIGURE 12.44**

Setting feature install states

7. Here's the screen you've been waiting for (see Figure 12.45). Here's where you can set up the workgroup (shared by everyone) Template folder on the server so Word users have only one place to go to get new corporate forms.

There are many things you can customize from this screen, but you only need to set the workgroup Template folder. Because templates are shared by several Office applications, it's located under Microsoft OfficeXP (User). Choose Shared Paths\Workgroup Templates Path. Double-click it to bring up a dialog box in which you can type the path to the shared folder that is to be its new home. I chose \\testsvr1.testlab.local\wordtemplates (as shown in Figure 12.46). I know that applications other than Word use the Templates folder, but it needs a name that will remind administrators why it's there.

**FIGURE 12.45**

Changing office user settings

**FIGURE 12.46**

Setting the workgroup template location

8. That's all you need to do with this MST, so click Finish. The wizard displays a screen about how to apply your transform file if you are not using group policies (see Figure 12.47), but you are, so you're finished.

**NOTE** You can change many things in an MST. You can even go back and edit it later. That means you can create one big MST file that includes many different modifications and deploy it, or you can make many smaller MSTs with a single change and add them all at the time of deployment. It's up to you. A single MST for an MSI package is easier to handle, but if you forget what you clicked while making the MST, you'll have to search through all of those components to find every one of them. Just a thought.

### Deploying Office XP with Its New MST and Service Pack

This deployment is going to be more particular than any of the others because of the MST. While you are configuring the options of the new package, do not click OK before you add the MST file to the modifications list. I'm serious: *do not* click OK. Clicking OK before you add your MST to the modification list will render the package deployed without it. As far as Windows Installer is concerned, a modified MSI is a fundamentally different beast than an unmodified MSI. Because of that, once you deploy a package, you can't go into its properties and add the MST file. If you try, the Add button on the Modifications tab will be grayed out. If you do click OK on the properties page before you add the MST, the only way to modify the package will be to either remove the package and start over, or create a different GPO with the modified package to "upgrade" the one you just messed up. This is one *big* reason I like to disable my GPO before I add a modified package (an MSI that has an MST), so that I don't deploy anything to anyone until I am positive that the package is configured correctly.

That being said, go ahead and create a new GPO on the domain container called ofcxp-wdmst. You can disable the GPO by right-clicking on it and selecting Disabled from the pop-up menu, or by clicking the Options button and checking the Disabled box. It will be marked Disabled in the dialog box, as shown in Figure 12.47.

**FIGURE 12.47**

Disabling the new GPO

1. Edit the GPO, which opens the Group Policy Management Console. Since the package is going to be assigned to users, right-click Software Installation under User Configuration.

2. Before you make a new package, you might want to check the default options, if only to add any categories you might want to assign the package to. Go to the properties page and make sure that the package will uninstall when it falls out of the scope of management, will install with a basic interface, and the category you want it to be listed under in Add/Remove Programs is there (This is very helpful for modified installs, as they will be organized by category, so you can clump them together for easier identification. The category name I've chosen to add for this example is Modified.) Never hurts to check your defaults.

**FIGURE 12.48**

Adding a category  
to default Software  
Installation  
properties

3. Now it's time to add the new package. Right-click Software Installation and, from the context menu, choose New\Package. Type in the network path for the MSI file and click OK.
4. In the Deploy Software dialog box, you must select Advanced (see Figure 12.49). If you do not, the package will deploy without its MST.

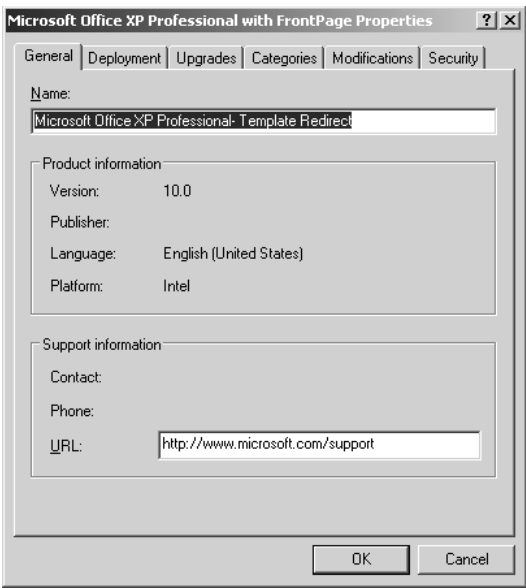

**FIGURE 12.49**

Advanced  
deployment

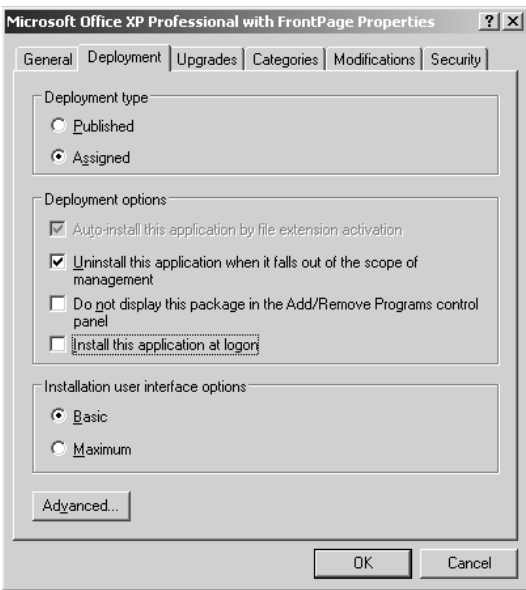

5. On the General tab (see Figure 12.50), which is often overlooked, edit the display name of the package, which will show up in Add/Remove Programs. Specifying the modification is a good idea, as in my example, Microsoft Office XP Professional—Template Redirect. Not catchy, but it does the job.
6. On the Deployment tab (see Figure 12.51), make sure that Assigned is selected. Under Deployment Options, make certain that Uninstall This Application When It Falls Out of the Scope of Management is selected and, under Installation User Interface Options, that Basic is chosen.

**FIGURE 12.50**  
Changing the  
display name

**FIGURE 12.51**  
Deployment settings  
for modified  
Office XP

7. On the Upgrades tab, you can upgrade a previously deployed version of Office. In this example, it will be Office 2000. Click Add to specify what packages this MSI will upgrade (see Figure 12.52). You can choose to either have the package upgrade or remove and replace the previously deployed versions. I prefer to remove and replace to ensure that no stray bits of the previous version will

remain. If the previous versions were not installed by Windows Installer, you can require an upgrade (which basically removes and replaces) by checking the Required Upgrade for Existing Packages check box under the Add button back on the Upgrades tab.

**FIGURE 12.52**

Adding the upgrade package

8. Assign the modified category to the package, as shown in Figure 12.53. The category that you created in the Software Installation properties page should appear in the left column. After you select the category, add it to the right column to make sure that it has been applied.

**FIGURE 12.53**

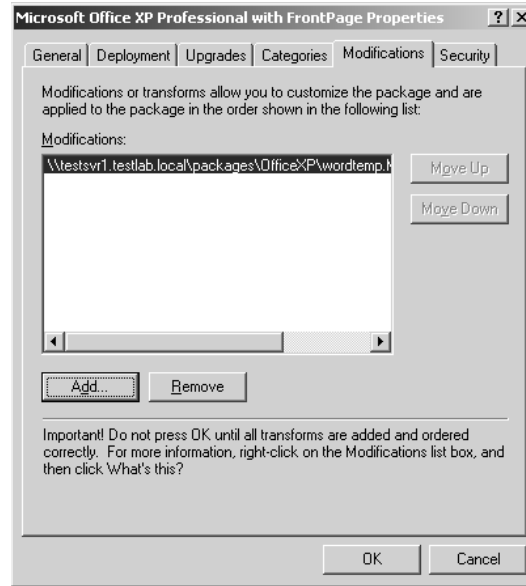

Adding a category

9. Okay, this is the important part of the operation modification. Notice the warning at the bottom of the Modifications tab that says not to press OK until you're sure you've made all the appropriate modifications. Heed this warning. Click Add to get the MST. Make sure to type in the full network path. Click Open. As shown in Figure 12.54, the MST will be listed in the Modifications list box.

**FIGURE 12.54**

Adding the MST  
modification file

10. Take a deep breath; you're done. Click OK. The package is ready to deploy. Close the Group Policy Management Console and go back to the domain properties page. You can check the Security tab to make sure everyone who should be getting the install is listed with the Apply Group Policy box checked. Then go to the Group Policy tab, and uncheck the Disable This GPO check box. If you are superstitious, click Apply, otherwise just click OK.

It's enabled. Now, when domain users log on, they will be getting the service-packed, modified Office XP.

### DEPLOYING OPERATING SYSTEM UPDATES

Next on the list is installing Service Pack 1 for Windows XP.

No problem.

You can force users to be unable to do automatic updates on their computers with a group policy. Although it is a good idea to control which version of what the users have on their systems (especially since patches can be great little carriers of viruses), it does mean that you will have to patch their systems for them. To this end, Microsoft has made life easy. A little quirky perhaps, but easy.

Remember, service packs affect computers, so do not deploy them to users. Also, do not apply a service pack for one operating system to a computer that is running a different operating system. In

Active Directory, I created a group for XP Professional computers and a group for 2000 Professional (the two OSes I have on my network). To apply a group policy, I only need to add the Windows XP group to the security list in the GPO properties, and make sure that no other group is checked to apply group policy.

1. Download the network installation version of the service pack and extract its contents to a folder. For convenience, download it onto the machine that you are going to extract the contents to. You'll see why in a moment. For Service Pack 1 in this example, the filename is `xpsp1_en_x86.exe`, and I downloaded it onto `testsvr1`.
2. In the Run box, type `xpsp1-en-x86.exe /u`. No matter what path you give the service pack to extract to, it will create a randomly named folder on the C: drive and extract to that (see Figure 12.55). Maybe later service packs won't behave this way, but this one does.

**FIGURE 12.55**

Service pack extraction to a random folder

While it's extracting, make note of this random folder name. When it's done, go to the folder and check to make sure that the extraction worked (see Figure 12.56). An example of a problem would be if the folder were empty.

**FIGURE 12.56**

Random folder on the C: drive

3. Copy the contents of the random folder (in it will be many files and folders; don't leave any behind) to the folder from which you want to share the service pack (in my case, it is in the 1-sp folder within the service packs folder, under the packages folder).
4. From here, it is just a matter of creating a GPO for the domain, going to the GPO's properties, and making sure that under the Security tab no one but the XP computer users are going to have this group policy apply to them. I do this by adding my domain local group XP Machines and ensuring that no one but that group has the Apply Group Policy permission checked (as shown in Figure 12.57).

**FIGURE 12.57**

Filtering the GPO to apply only to XP machines

5. Edit the GPO and right-click Software Installation under Computer Configuration. Add the update.msi package. In this example, it's stored in the Update folder among the extracted files, which are located in \\testsvr1.testlab.local\packages\service packs\1-sp\update\update.msi.
6. You have to assign the package—no publishing to computers is allowed. Click OK.

You're done. Now you just have to wait for the Windows XP Professional computers to restart a few times to ensure that the GPO has been applied.

### CREATING AND DEPLOYING A ZAP

The next thing on the boss's list is deploying the PDF reader. Funny, the easiest thing to deploy is the most limited. To support legacy installation files, Windows Installer recognizes the ZAP file. A ZAP file is a simple text file, like an INI or unattend.txt, that points to an executable file and runs it. It's that simple.

ZAP files, as you may recall, cannot be assigned, upgraded, reliably uninstalled, or anything else that requires extensive rollback information. It can only be published. That's it. But you can publish service packs that you want users to install. You can publish any setup file that you can get in its entirety. I have even published self-extracting zipped files containing anything from templates to backgrounds. The point of a ZAP is to get an application to the users. Nothing fancy, but it works.

To create a ZAP file, open Notepad. The file must be a simple text file, no Word documents here, no formatting. Just words.

This sort of file is broken into sections. The section names are in square brackets ([ ]), such as [application]. The syntax is simply *command* = *thing that applies to the command*. The command itself must be one word and cannot contain spaces. If it's a two-word command, the command becomes a compound word, for example, **setupcommand**. And, like any good batch or INI file, comment lines are always preceded by a semicolon (;). An underscore (\_) is used as a continuation symbol if you need a path to be read as if it were all one line, but it's too long to fit.

Another interesting syntax point is the extensions section. To indicate an extension that is associated with the program you're installing, type the three-letter extension and an equal sign, for example, **zip** =. That's it—there's nothing after the equal sign. (I always end up wondering, "Equal to what?") If you type something after the equal sign, it will be ignored.

**NOTE** *The ZAP file points to the actual setup file in order to run it. Make sure the setup command line truly equals the setup's location in relation to the ZAP file. Don't move it after the ZAP file is made and expect the ZAP to work. I, being lazy, always make sure the setup file and its ZAP are in the same folder. That way, I don't have to type in any long paths to show the setup command location.*

Here's an example of how easy it is to make a ZAP file:

1. Open Notepad and type in the following, which is two sections, four command lines and some comments (see Figure 12.58).

```
;Zap file for Adobe Acrobat Reader 5.0.5

;the application section is required

[application]
;friendlyname and setupcommand are required, displayversion is just for
;my convenience. It shows the version in add/remove programs

friendlyname = "Acrobat 5.0.5"
setupcommand = ar505enu.exe
displayversion = 5.0.5

[ext]
;this section is optional
PDF =
```

Remember that the extensions you add to the [ext] section will be the auto-install file associations.

**FIGURE 12.58**

Acrobat ZAP file

```
;Zap file for Adobe Acrobat Reader 5.0.5
;the application section is required

[application]
;friendlyname and setupcommand are required, displayversion is just for
;my convenience. It shows the version in add/remove programs

friendlyname = "Acrobat 5.0.5"
setupcommand = ar505enu.exe
displayversion = 5.0.5

[ext]
;this section is optional
PDF =
```

2. Save the file with a `.zap` extension; for example, `Acrobat.zap`. Make sure that the file does not end up being saved with the `.txt` extension tacked on to the end, such as `Acrobat.zap.txt`. The file must have a `.zap` extension at the end of the filename.
3. To deploy it, just add the ZAP to a GPO for the Sales OU, as if it were an MSI. Then publish it.

Pretty easy, huh? It works really well when the EXE file must get out to the clients as quickly as possible—as long as it can be published, that is.

But what if you need to *assign* an EXE to the clients? Or maybe you need to deploy the software by computer account? What then, are you doomed to manual installs?

No, you'll just have to make your own MSIs. That's right, make your own. For free too. It's a little time consuming and a little detail oriented, but it can be done.

### HOW TO TURN AN ORDINARY INSTALLATION FILE INTO AN MSI

The last item in the boss's scenario is to give the users the ability to create self-extracting ZIP files for their clients. Sounds like a job for ZAP, doesn't it? Except for one small thing: the users cannot be depended on to (or should not) go to Add/Remove Programs and install their own software, so the software should not be published.

You could just have the users invoke the software by opening a previously zipped file, but they are not using the software to open ZIP files, they are using it to create them, and there's a chance they will have to create the self-extracting ZIP before they end up opening one. So, publishing the software and hoping that the users invoke it properly can't be guaranteed to work either. This looks like a job for (drum roll, please) an MSI assigned to the user accounts. Thus, the need to make your own.

The point of making an EXE file into an MSI is to be able to handle the installation as if it were a native Windows Installer package. It sounds almost too good to be true, and yes, there are some wrinkles in the system, but all in all it works pretty well.

Also, you can't publish to a computer account, so if a standard installation absolutely, positively must be on every machine in your company, you have to use a MSI, because a ZAP must be published. That's why Microsoft and a company called OnDemand Software got together to bundle a free MSI

package creator with every copy of Server 2003. Now, be aware, as of this writing, OnDemand Software has not released the current version of their product, so it may not be on the Server 2003 CD. Instead, you will have to download it (check the Server CD for details). It'll be free either way, though.

What is this nifty free MSI packager called, you ask? It's called WinINSTALL LE (Lite Edition) of the full-blown WinINSTALL 8. Despite its "lite" designation, WinINSTALL LE is a surprisingly useful piece of software.

The concept is pretty straightforward. For an MSI to function, it has to have a table of information (and access to the files themselves) about what files get added to a system upon installation, what files get deleted, and what Registry changes get made. But with standard installation files such as `setup.exe`, there is no list of what those changes were or copies of what files were added for recovering from corruption.

Hmmm, EXEs change things upon execution, and MSIs change things *and* keep a database of those changes. The only difference, really, is that there is a record of what was changed along with the actual executable itself.

What if I took a snapshot of a workstation before I run an installation file like `setup.exe`, and took a snapshot after I ran it, then compared the two and created a big, detailed table of all the things that were changed? That would include all the added files, all the deleted files, and any other changes, like shortcuts and Registry alterations. I wonder if that would work?

Yes, it would. As a matter of fact, that is what WinINSTALL LE does. Of course, it's not absolutely perfect. Because there are so many different kinds of programs out there, especially ones with copy protections and other security features, no one can be ready for everything. Some products frequently alter what WinINSTALL LE would consider static (like time-sensitive security information that might change every time the computer reboots). This makes the package keep reinstalling itself because it thinks that the changes mean something has gotten corrupted. For that reason, products with these kinds of features are not candidates for packaging into an MSI (or as Microsoft calls it, "repackaging").

To make sure it won't miss anything, WinINSTALL LE tends to be *too* thorough and records hardware changes or system information that is not necessarily something it needs to worry about. That's why you need to be familiar with what gets excluded and included in any MSI that WinINSTALL LE builds. It's a pretty easy fix and a really convenient way to make do-it-yourself MSIs without having to be a programmer.

The Server 2003 version of WinINSTALL LE has not been released as of the writing of this chapter, but OnDemand Software assures us that there will not be that many interface changes, so ignore the fact that my version has Veritas written all over it (not to mention subtle references to Seagate Software, from which Veritas was spawned), and that yours will probably say OnDemand Software. (That's because Veritas bought it from OnDemand Software, and then OnDemand Software bought it back. Such is business.)

**WARNING** *WinINSTALL LE isn't without its quirks. The most significant is its tendency to not save the changes it has made to the Registry. This means that, at login, the software might query its MSI to update the Registry for each user every time they log in. On occasion, it may even do a query when the software is opened for the day. This may be irritating and is therefore worth mentioning. To avoid this problem, you might want to have Windows Installer install software with elevated privileges (to allow programs installed at the user level to write to the Registry). Elevated privileges can be abused by knowledgeable users, so it may not be the most secure thing you could do, but it is a workaround.*

I happen to know that WinINSTALL LE works well on those little things that everyone needs, like WinZip and Acrobat Reader. I have also used it to deploy things like MP3 players (other than Media Player, of course), screenshot packages, and such. But, because WinINSTALL LE essentially records and then plays back *anything* that was changed between snapshots, you can do more than just make MSIs of installs. You can change the toolbars of the product being installed, add shortcuts to the quick launch area of the Taskbar, remove shortcuts from the Desktop, change preferences and options within the product, and do anything else you could think of that you would like to have set up before deploying the package to the user. It is a lot like working with an MST.

But there's more. What if you want to add a folder with a handbook, forms, phone directory, and other things in it, to the Desktop of all new employees? If you don't want to write a login script for these users, you can create an MSI using WinINSTALL LE. Just make a snapshot of a workstation, create the folder with the files in it on the Desktop, then do the After snapshot. Then, after making sure it does work fine (sometimes you have to make sure that it isn't trying to handle extraneous information, like computer names), deploy it to the users of your choice. Even if the users delete it, it will come back at their next logon. WinINSTALL LE is a pretty flexible and very useful tool, despite its simplicity.

Let's create an MSI package for WinZip. Remember, everyone in the company must be able to create self-extracting ZIP files, so this is it. To create an MSI, you need four things:

- ◆ The installation file upon which you are basing the MSI.
- ◆ The network sharepoint where the MSI will be stored.
- ◆ A "clean and quiet" workstation to create the snapshots on. This workstation needs to have the same OS (including service packs) as your user workstations and network access to the sharepoint.
- ◆ WinINSTALL LE itself, with its discovery program accessible from the clean workstation.

The frustrating thing about using WinINSTALL LE is that the workstation that the snapshot will be taken on *must* be perfectly clean. What that means is it needs to be stripped to the bare operating system with whatever service packs the user machines will have. No fancy wallpaper, no mapped drives, nothing. This is the snapshot you will be making a record of the complete state of the system. To be sure that no DLL file or system tray doodad is picked up that may conflict with something that could be installed on the target computers when the new MSI gets deployed, there must be no extraneous fluff on the snapshot workstation.

Now, that may sound easy, but it means that every time you create a new MSI and you install software on the clean workstation, the software needs to be removed completely. You'll have to wipe and reinstall the workstation every time you do a new snapshot, because it has been tainted with files that might distract WinINSTALL LE from its job. This is why it is a *really* good idea to create an image (using something like R1Prep, for example) for the clean workstation you will be working with. It makes it much easier and faster to make several MSIs in a day without spending hours wiping and reinstalling. Other than that, the rest of the process is rather easy.

Before you can use WinINSTALL LE, it has to be installed, of course. Chances are you will need to use the link provided either in the help files on Server 2003 or on the CD to download the necessary installation file. Be sure to install it on any other network accessible machine *except* the clean workstation. Quite logically, WinINSTALL LE is not going to be on the users' workstations, so it should not be part of an MSI snapshot. For this example, I downloaded it to and installed it on my Server 2003.

WinINSTALL LE comes in two parts: the discovery executable (called DiscoZ, interestingly enough), and the Software Console. The discovery program is what takes the snapshots and must be accessible from the clean workstation, so it should be located in a sharepoint. The Software Console is the program that makes it possible for you to view and edit the MSI's contents. It does not need to be accessed from the clean workstation, although it may be convenient to be able to do so.

**TIP** I tend to share out only the folder with the discovery program in it. If rights to that share were to fall into the wrong hands, those hands would still not be able to access the MSI editor.

Once everything is in place—WinINSTALL LE is installed, your shares are set up, and the clean workstation is ready and imaged—you can get started.

### Creating the MSI

The first half, the actual MSI creation, happens at the clean workstation. Make certain you are logged in with an account that has the right to write to the sharepoint where the MSI will be saved, access and execute the DiscoZ discovery file, and install software on the clean workstation. Generally, this is an Administrative account.

After you log in, you can either go to Start\Run and type in the network path to the discovery program (mine is `\\testsvr1.testlab.local\wininstall\discoz.exe`), or browse to the share containing DiscoZ. The icon is a magnifying glass (see Figure 12.59). Double-click it.

**FIGURE 12.59**

The DiscoZ  
discovery executable

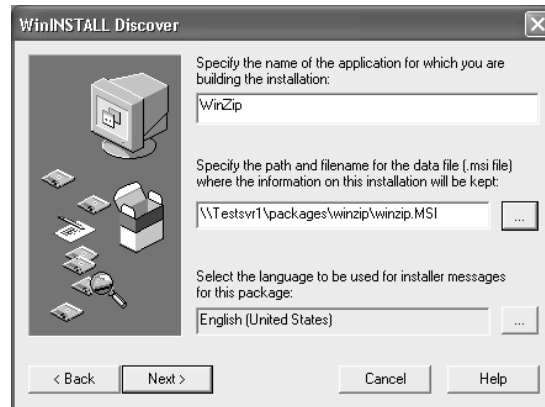

WinINSTALL LE's Discover Wizard will open. Close any windows you may have been browsing through before moving on—you want your Before snapshot to be as clean as possible (and notice in Figure 12.60 that the wizard basically says the same thing). To begin the discovery process, click Next.

**FIGURE 12.60**  
Discover Wizard

At this screen (see Figure 12.61), you will need to specify the installation file you are building the MSI for, the filename and location where the MSI (and its associated files) will be saved, and what language the installer dialog boxes should be in. My installation name is WinZip and the location of the MSI is `\\testsvr1\packages\winzip.MSI`, and, not surprisingly, the language I need for my dialog boxes is English. Click Next.

**FIGURE 12.61**  
Specifying the MSI  
name and path

**WARNING** Do not neglect this part of the MSI building process. Because the MSI will be referred to by the client installs, it will explicitly record its location in its own database. Changing your mind and moving the MSI after it has been created is a bad idea. Although you can move the MSI and edit it later to point to its new location, it's better to keep it simple and do it right the first time.

At this point (see Figure 12.62), you'll need to select the drive where Discover will store its temporary files. When the discovery process is over, these files will be removed. Unless you are really short on space, I suggest keeping the default C: drive selected. Click Next.

**FIGURE 12.62**

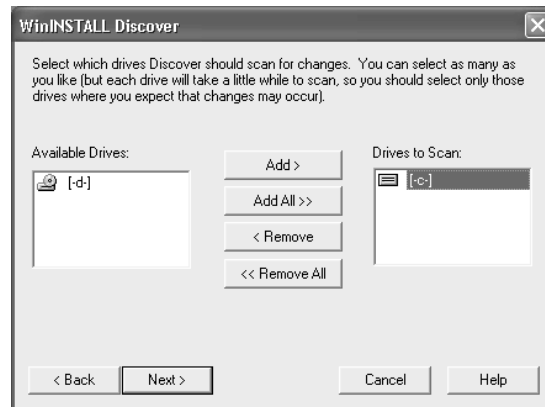

Choosing where to put Discover's temporary files

At this screen (see Figure 12.63), you choose which drives WinINSTALL LE will scan for changes. Select the drive(s) of your choice on the left and click the Add button to move it to the list on the right. Be sure to choose only the drives that are necessary. Unnecessary drives will slow down the process and will probably cause WinINSTALL LE to erroneously record changes that aren't really relevant to the install. Click Next.

**FIGURE 12.63**

Choosing drives to scan

The next screen lets you specify what files and folders to exclude from the Discover scan. Here you can ensure that the My Documents folder will be ignored (should WinZip really care if you delete a file from the My Documents folder?), in addition to the Recycle Bin, temp folders, and swap files. If there are folders or files that you definitely want ignored during the scan, this is where to add them. The defaults are generally more than adequate, so if you are not sure what to exclude, stick with what's already there.

As shown in Figure 12.64, at the top left of the screen is a drop-down box. This is where the drives that you chose to be scanned are listed, one drive at a time. Each drive can have files and folders that need to be excluded. Beneath the drive drop-down box is the list of all the directories available for the selected drive. Faithfully following the theme so far in this wizard, on the right is the list

of items actually selected to be excluded. Below that list of exclusions is a check box for Enhanced Registry Scan. Because the Registry can be complex, it's difficult to be sure that every single piece of data is caught in the scan. If you feel that you need to be extra thorough, check this box, although it will increase the time that it takes to do the snapshots. However, I find that this option simply creates more entries to go through during the edit phase, so I generally do not check it.

**FIGURE 12.64**

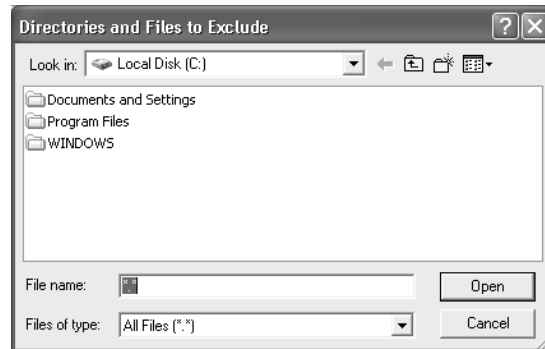

Deciding what to exclude from the Discover scan

Above the exclude list is the Files and Wildcard Entries button. Click this to add a file or group of files (not just folders) to be excluded. Clicking it will bring you to a dialog box, shown in Figure 12.65, that will give you ample opportunity to browse through and select the files and folders you'd like to exclude from the Discover scan. If you do not wish to exclude any wildcard entries, click Cancel to return to the exclusion dialog.

**FIGURE 12.65**

Directories and Files to Exclude dialog box

If you have nothing else to exclude that isn't already listed by default, click Next.

Immediately, the scan will start (see Figure 12.66). You can watch and see what files and Registry keys are read. A dialog box will come up, announcing that the Before snapshot is complete and asking for the setup program before completely closing out. Click OK and it will give you an opportunity to browse to the setup file and open it. In the example, my copy of the install file for WinZip is on the Server 2003, so I just browse to it and double-click.

**FIGURE 12.66**

The scan before  
software is installed

Again, immediately, the normal install process for WinZip begins.

The install finishes and WinZip opens. If you have to reboot after the install, be sure to do it, log back in with the same account (so you will have all of the rights you will need to finish the process), and open the newly installed program.

**NOTE** By the way, although the evaluation version of WinZip is free, the registered version is not, and registration is required to make self-extracting files for distribution. Not only is it really cheap considering how darn useful it is, but you can also purchase a WinZip site license, to make it even cheaper per machine.

Now is the time to modify the install to suit your users. I removed the shortcut from the Desktop, added the Make Exe button to the toolbar, and got rid of the Tip of the Day. This is also the time to run the program through its paces and make sure it works. If it doesn't work now, it won't work when you deploy it. Remember, if it's a product that keeps track of recently opened files and you opened some during this process, clear that list before going any further. Especially if you cannot guarantee that those files will be on the client workstations at the time of deployment.

### A TRICK WITH SHORTCUTS

It is at this point in the MSI building process that I like to do one more thing. You see, WinINSTALL LE sees things in terms of packages, features, and components. Office XP has features like Word, Excel, or PowerPoint, which are separate executables but part of the same package. Each of these features has many components, such as clip art, a spell checker, templates, wizards, etc. Each feature of Office XP has its own shortcut. Well, the same thing is true of WinZip and most other products.

Now, strangely enough, any shortcut that WinINSTALL LE records for any feature does not actually point directly at the executable (as many shortcuts do), but at the feature, which then tells the shortcut where to go. Due to a shortcoming in WinINSTALL LE itself, the actual path to the feature and its executable may not work quite as one would hope. In an unusually complicated way, MSIs indicate location by creating folder properties, so each step in a path to an MSI is a property and doesn't resemble a path in any way that Windows would recognize. Because of this, it's possible that every time you double-click on the shortcut to the program, it will get a bit disoriented and reinstall itself. To prevent this from happening, I make note of every shortcut that WinZip creates; then, when I am in the Software Console, I redirect the shortcuts that I want to keep to point directly at the WinZip executable, *not* at a feature, and delete the ones I don't want. I find this really helps cut down on the times I have to tweak the MSI, reinstall, tweak, reinstall.

Once you've made all the changes that you feel are necessary, it is time to do the scan of what has changed, otherwise known as the After snapshot. Once again, either run DiscoZ or browse to it and give it a double-click. Remember to close all windows before you actually run the After scan.

The WinINSTALL LE Discover screen returns (see Figure 12.67). This time, sensing that a Before snapshot has been taken, it confirms the installation filename, MSI name, and path. If this is the correct information, make sure that Perform the "After" Snapshot Now is selected; otherwise, the Before snapshot will be abandoned and the After snapshot won't be taken. Then click Next.

**FIGURE 12.67**

Starting the After snapshot

**TIP** If you just realized that you are not done configuring your installation, that's okay. Click *Cancel*, make your changes, and run *DiscoZ* again. Canceling does not abandon the process.

The scanning begins (see Figure 12.68). Let it run through its paces. This may take a while, especially if you have chosen to do an enhanced Registry scan.

**FIGURE 12.68**

The scan after software is installed

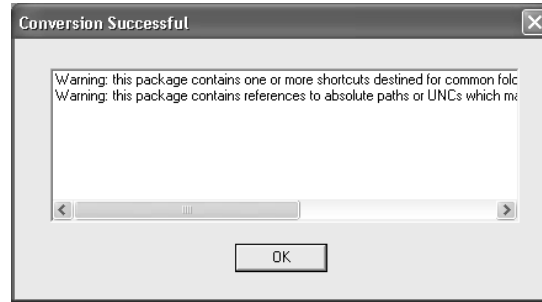

When the After snapshot is complete, you will get to experience a dialog box in conflict with itself (see Figure 12.69). The box will say Conversion Successful in the title bar, but will probably have several warnings listed within. As long as there are no explicit error messages displayed, it's all right. Generally, the warnings are about paths and URLs that WinINSTALL LE is worried will not work (a bit of CYA, I believe) or that should be installed once on a system and made available to all users (that is, assigned to a computer account). Remember that WinINSTALL LE has problems with paths and URLs, and

because the MSI itself needs to be saved to a network sharepoint, there is nothing you can do to avoid having at least one URL warning. Windows accesses resources using paths, period. Make note of the warnings in case you can use the information when checking out the MSI itself, and click OK. You will then get a dialog box announcing that the After snapshot is complete. Congratulations.

**FIGURE 12.69**

Conversion  
Successful  
dialog box

**NOTE** The reason the conversion was successful was because WinINSTALL LE creates a NAI (OnDemand's own kind of installer package) and REG file and then converts them at the last minute into an MSI. Copies of the NAI and REG are kept in the same folder as any MSI that is created by WinINSTALL LE. The NAI refers to the REG (not surprisingly, it has the Registry edits in it) and can be used to recover an MSI that has gone bad. Just close the currently open MSI in the Software Console, go to File, and choose Convert NAI to MSI from the menu bar. During the convert process, just follow the instructions. Be sure to open the NAI in the folder of the current corrupted MSI. Be careful, as always, about where you save the conversion. The converted MSI should be identical to the old one.

### Editing the MSI

The next phase is using the Software Console. Let's take a look at the MSI we just built. Go to wherever you installed the Software Console (I put mine on the Server 2003.) Open the Software Console by going to the Start menu. If you have never used the Software Console before, it should look like Figure 12.70 (if you have used it before, it will open with the last MSI you were looking at still available).

**FIGURE 12.70**

Newly opened  
Software Console

**WARNING** If you have an existing MSI open in the Software Console, be careful. If you accidentally choose *New* instead of *Open* from the File menu, a new package will be created that will overwrite the currently open existing package. Yeah, the interface is a little quirky.

As you can see, there are three sections to the Software Console window: tree view at the top left, list view on the bottom left, and data view, which is the largest section, on the right. The first time you use the Software Console, there is no obvious way to open a file. At first, there is no File on the menu bar. There's no Open icon on the toolbar, either. Here's the trick: click the Windows Installer Package Editor icon in tree view (top left). Then and only then will the menu bar change and File will appear. (You can also right-click the Windows Installer Package Editor and get basically the same result.)

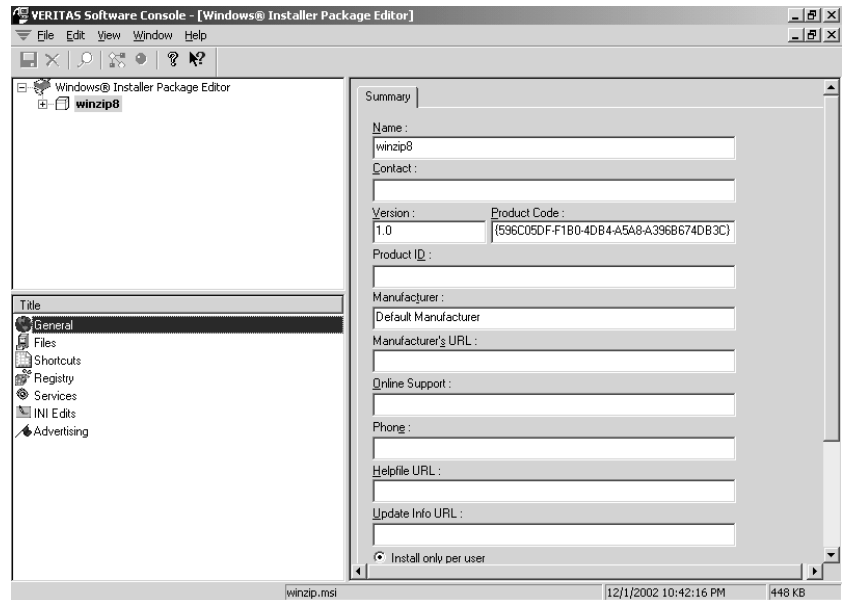

**NOTE** There still is no Open icon on the toolbar of the Software Console, nor is there any Save As option on the File menu.

From either the File menu or the context menu, choose Open. Browse to where you have saved your new MSI (in the WinZip folder under Packages, in the example). Open it.

You will see the new MSI package listed in tree view. There is a plus sign beside it, indicating that there are items under it that haven't been displayed. Those items are separate features and components that help make up the whole package. Each item (from package to component) has properties and objects (such as shortcuts or files) associated with it. If you select the package and look at the list view on the bottom left (see Figure 12.71), you'll see icons representing the different associated properties and objects, such as Registry, Services, and INI edits. These help identify the changes that were recorded as part of the MSI.

**FIGURE 12.71**

The new MSI package in the Software Console

From list view, select General, and on the right side of the window in the data view section, you will see a summary of the properties of the MSI package. The name, version, product ID, even online support and phone number are available to be added. If you scroll down the summary, you will see that you can specify three ways that the package can be installed: per user; per computer; or per

machine, or if that fails, per user. Choosing between installing per user or computer has a pretty big effect on how the MSI handles its Registry entries, so it is worth checking out.

If you click the plus sign next to the package in tree view, icons will appear beneath it—some will look like flowcharts with green and yellow shapes and some will look like green balls (as shown in Figure 12.72). The green and yellow icons indicate features, and the balls indicate components. If you click on a feature, note that in data view the summary (assuming you are still looking at General in list view) is different. A feature can be affected by how the MSI handles it, and this summary reflects that. Here is a brief list of the check boxes and what they mean:

**Favor advertising** Advertise when possible.

**Favor source** Run program from source rather than locally.

**Favor parent** It is grayed out if there is no parent; feature inherits parent's properties.

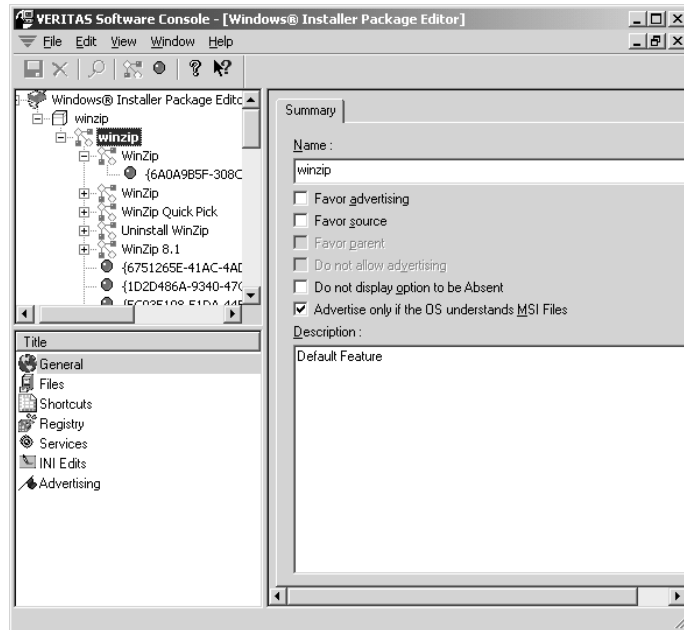

**Do not allow advertising** This one's self explanatory.

**Do not display option to be Absent** Always install the selected feature (this one could've been more intuitively named).

**Advertise only if the OS understands MSI Files** Feature will only install if the target machine has Windows Installer.

**FIGURE 12.72**

Feature data view  
summary

**NOTE** Sometimes WinINSTALL LE might get overzealous about advertising, installing itself every time it is opened. If you are having a reinstall problem, you might want to turn off advertising altogether. If the MSI cannot advertise, it has no choice but to do a full install. In doing so, however, the install will be unable to self-repair, because it will have severed ties with the MSI after installing.

There is a description field at the bottom of the summary for adding notes or explanations about the feature and its settings. If you clicked on each feature for WinZip, there would be a different description for each, but most would have the same settings.

**TIP** *The interesting thing about features in WinINSTALL LE is that during the discovery process all shortcuts are identified in the final MSI as features. Strange but true. If you click the plus sign next to one of these shortcuts/features, you will see that there is one component associated with it. If you take a look at the general summary for that component, you will find the executable for that shortcut. That comes in handy when you have to manually change each shortcut's target from feature to executable file.*

If you click on a component in tree view (see Figure 12.73), you'll see that, once again, the summary is different. You could choose to run the component from Local (which is the default and means that it will run from the installed copy), from Source (CD or network share), or Optional (run from source or local, whichever works). If you think that the component will be sharing DLLs, you can do a Reference Count: Shared DLLs to keep track. Also, you can decide whether or not that particular component will be set as Permanent (never uninstall), Never Overwrite, or Transitive (can be overwritten/upgraded).

**FIGURE 12.73**  
Component data  
view summary

You might think most of the summary information is not that important because I keep everything at its default, but it does give you an idea of some of the changes you can make to an MSI. Also, the summary information does come in handy when troubleshooting the MSI.

Speaking of behavior, it's time to use the Software Console for the task at hand: finding out if DiscoZ has recorded any unnecessary information in the MSI. Remember, the MSI should only contain things that refer to the install of the software directly (in this case, WinZip). You need to go through the different files, shortcuts, Registry entries, and such and ferret out all the unnecessary stuff. This requires a lot of guesswork, especially if it involves Registry entries. When in doubt, keep the entry. Because WinINSTALL LE does not have a Save As option on the File menu, there is no safe way to make a change and then undo it, so I usually make a copy of the MSI's folder and all of its contents. If I mess it up, I can replace it with my backup copy and go back to a cleaner version.

Keep in mind that the package represents all of its features and components, so if you have the package selected in tree view and you remove a file from the list of files added during install, it will remove it from the list of files for any feature or component that uses it. That is true overall, so it is easier to search through the different items while looking at the package and then browse all of the components and features later just to be sure.

As you can see in Figure 12.74, the files added for the WinZip MSI seem in order—license, order, readme, vendor, and whatsnew are all standard files for any software. The files that have WZ in their name are obviously the WinZip files that were added during install. You can tell this because they are under the Add tab in the data view. There are also files that can be removed (especially if this is an upgrade) during install, and fonts that can be added (although WinZip doesn't have any). At the top of each tab is an Add button, a Properties button, and a Delete button. If you find any extraneous files that were added, say `wmplayer.exe` for example, delete it because it obviously does not refer to the installation (in this example, WinZip). At this time, though, WinINSTALL LE seems to have done a good job recording the correct files to add during install.

**FIGURE 12.74**

Files to be added by the MSI package

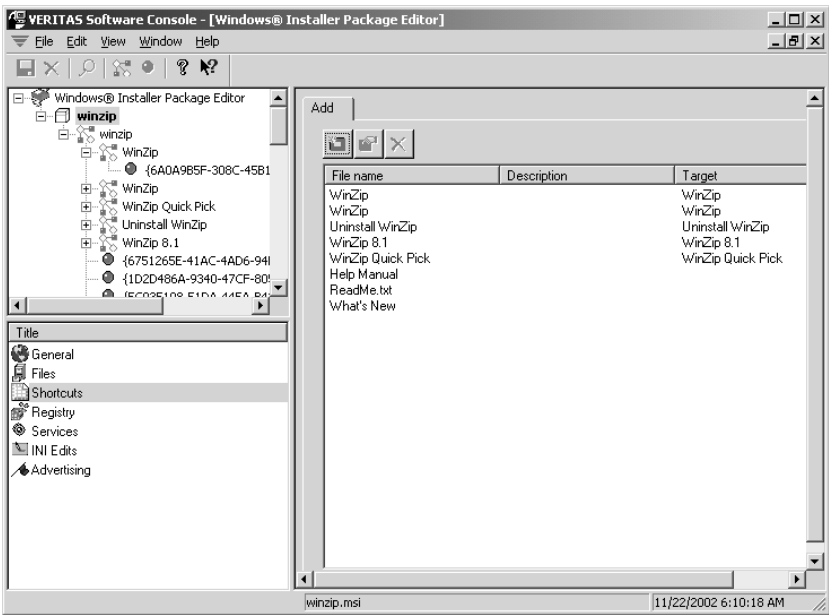

Check the executable file associated with each feature. The executable and its path can be used to redirect the feature's shortcut to point to its executable and avoid any shortcut errors upon install.

Speaking of shortcuts, let's take a closer look at them. While the package is selected in tree view, select Shortcuts from list view. Notice in data view (shown in Figure 12.75) that each shortcut for WinZip was recorded, along with its Description and Target. Note that the targets are all features; there are no actual executable files listed.

**FIGURE 12.75**

Shortcuts to be created by the MSI package

To fix that, you need to edit the properties of each misdirected shortcut. Start by selecting a shortcut (WinZip, for example) and clicking the Properties button (it's the hand holding an envelope) above the shortcut list in data view. In the Shortcut properties dialog box (see Figure 12.76), the target of the shortcut can be a feature or a file. Select the File radio button. In the field that becomes available beneath it, enter the correct executable filename and its path.

Because an MSI was meant to be installed on many different workstations, it uses the Windows variables for standard Windows objects, like the Start menu, or the System folder. For pointing at an executable, the default path would probably start in the Program Files folder. WinZip does create a folder called, appropriately enough, winzip, in the Program Files folder, and it puts its executables (and other files) there. Thus, your path in the File field would be

```
[ProgramFilesFolder]\winzip\winzip32.exe
```

**TIP** If you can't remember what the exact name and syntax is for a Windows variable (specifically, those that pertain to locations of files and shortcuts), here's a tip. Above the Target information in the shortcut's properties page is a Create In field. Just to the right of it is a little Build button (it has three dots on it). Click it, and you'll see a list of standard locations that can have a shortcut in it. Beware, though: the variable names cannot have spaces in them, they must be between square brackets, and capitalization counts. For that matter, try to be sure that the entire path that you enter in the File field exactly matches the way the real folders are capitalized.

**FIGURE 12.76**  
Pointing shortcuts  
at files instead of  
features

I just noticed the `Readme.txt` shortcut on the Start menu. That document is not generally something users need to see, so I am going to delete it. To delete a shortcut, select it in data view (see Figure 12.77) and click the Delete button (the one with the red X that's to the right of the Properties button).

**FIGURE 12.77**  
Deleting the  
`Readme.txt`  
shortcut

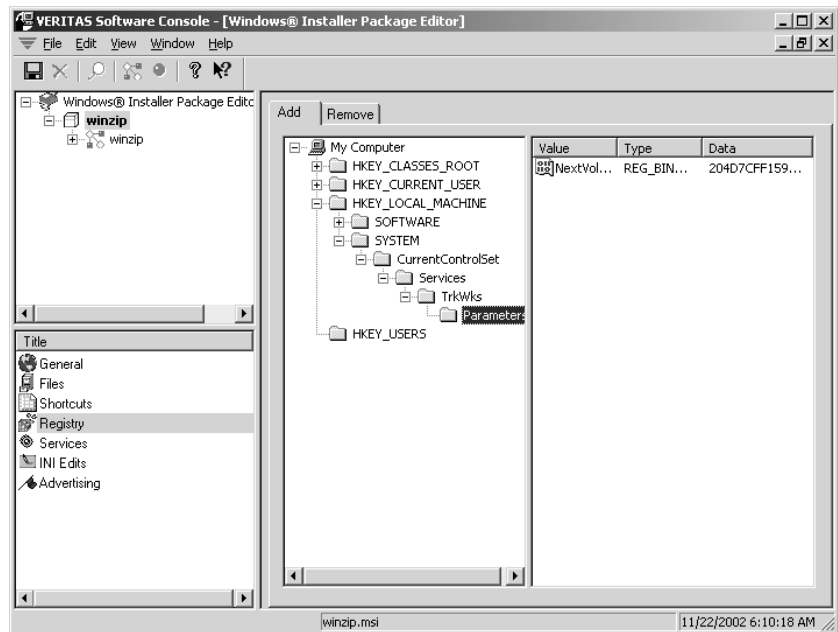

Next on the list of things to check are Registry entries. Be sure that the package is selected in tree view. Click on the Registry icon in list view.

On the right side of the window in data view, there will be two tabs, Add and Remove (see Figure 12.78). On the Add tab is an innocent-looking My Computer icon with a plus sign next to it. If you click the plus sign, you will see the HKEY folders. It's a good idea to avoid playing with the Registry. Too many programs do too many important things in it to be guessing, but you can look for obvious things, like Internet Explorer cache files or Windows cryptography settings. Such things are obviously not related to WinZip. You can also check and see if there are any machine-specific entries under the LOCAL\_MACHINE key.

**FIGURE 12.78**

Registry changes that have been recorded in the MSI package

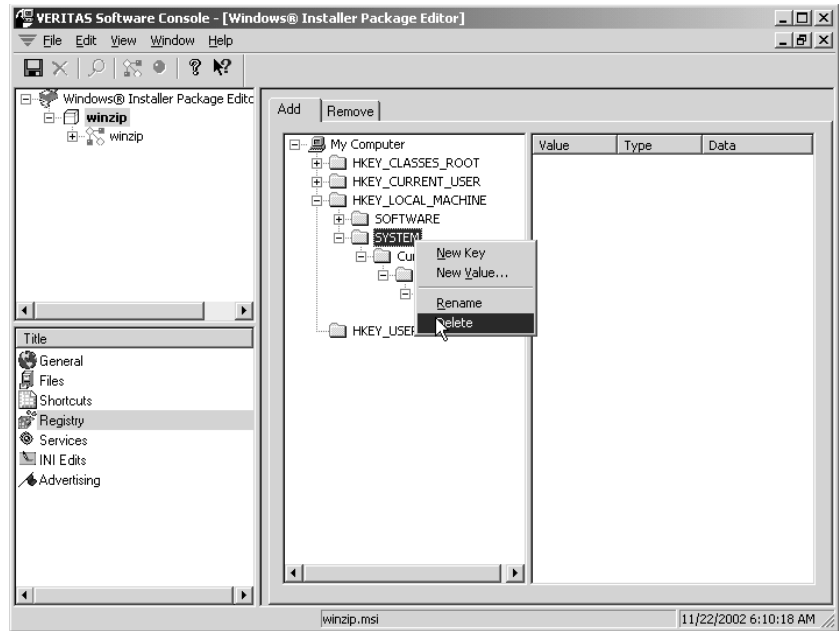

Click the plus sign next to the HKEY\_LOCAL\_MACHINE (if there is one for you; otherwise just take a look at Figure 12.78 and follow along). In this example, there is data beneath both the SOFTWARE and the SYSTEM subkeys. When I click the plus sign next to SYSTEM and follow the folders down, I discover that a service called TrkWks has been recorded. Hmm. WinZip doesn't call on any services directly, and I don't believe that it requires the distributed link-tracking client to install (that's what TrkWks is). I can safely get rid of that.

Something to remember when removing an entry, though: be sure to prune as far up the keys as possible. Don't just remove the data and then leave all those empty folders sitting there pointing at nothing. It's bad form. To delete a Registry entry, select the folder containing the bad branch (in this case, SYSTEM has nothing in it but the TrkWks entry, so I'll delete the SYSTEM subkey and all below it), right-click the folder, and choose Delete (see Figure 12.79). Now the SYSTEM folder on the client installs will not be unnecessarily modified by this MSI.

**FIGURE 12.79**

Deleting SYSTEM subkey and all its contents

Also under HKEY\_LOCAL\_MACHINE is a SOFTWARE subkey that looks interesting. If you click the plus sign next to it, you'll discover that there are two subkeys, Microsoft and Nico Mak Computing. Nico Mak, what's that? I don't really know, but it is affiliated with WinZip, so it's okay. If you look under the Microsoft folder, you'll notice that there are two folders: Cryptography and Windows. In my case, the Windows folder (as you can see in Figure 12.80) has only WinZip-related info in it (except, maybe, the BitBucket), but the Cryptography folder, alas, is irrelevant. Delete that subkey, too.

By this point, you're probably getting the hang of this Software Console thing. Just remember, everything in the MSI should relate to the software you are installing. Anything you find that definitely isn't relevant should go. When in doubt, especially in the Registry, leave it alone.

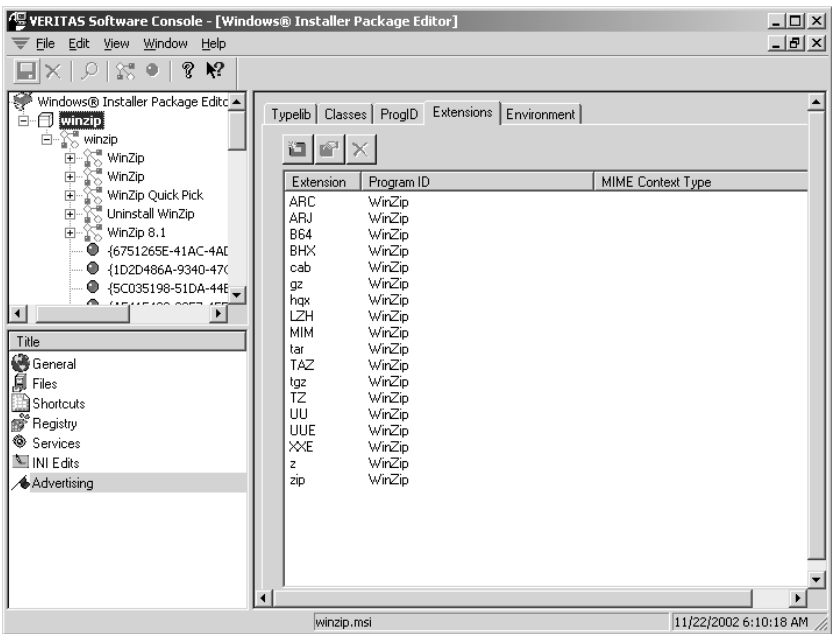

Before you finish with the Software Console and start testing your MSI, let's take a quick look at the Advertising item in list view. Since WinZip does nothing with Services and INI files, they are empty (I checked), but Advertising, well, that's a different story.

As you well know, advertising an MSI involves being able to invoke the installation of a package by activating the correct file extension(s). Thus, you should check out extensions that WinINSTALL LE thinks will invoke (in this example) WinZip. Don't get me wrong—I've never had a problem with a misplaced extension, but it is always a good idea to check. Make sure that the package is selected in tree view and that Advertising is selected in list view, then click the Extensions tab in data view. Yup, there are all of the extensions. If there were any that were missing, you could add one by clicking the Add button. Mine, however (as you can see in Figure 12.81), look fine.

**FIGURE 12.80**  
Perusing the HKEY\_LOCAL\_MACHINE subkeys in search of irrelevant entries

**FIGURE 12.81**  
Extensions associated with the MSI package

### Testing the MSI

Now it is time to take the MSI for a spin around the block. I generally do at least one test run of any MSI I build. There is always a chance that you missed something that might cause a problem later.

**TIP** Here's a trick. If you feel that there is a problem with the MSI, particularly on install, install it using **MSIEXEC** at the command line. Use the log switch and record everything the install does. With WinZip, for example, at the command prompt, use the syntax: `msiexec /i \\testsvr1.testlab.local\packages\winzip.msi /L* c:\log_file.txt`. The `/L` switch indicates that a log file should be kept, the asterisk indicates that all flags (such as errors or warnings) will be logged, and then the text file that will be created is specified. This should install the MSI on the workstation. Once it is done, open the log file in Notepad and see what happened. If there was an error, you can often see it there, even if all you actually see is a quick dialog box during install. It is also interesting to see what Registry entries get written when.

Because I do so much testing, I have an OU called “test” that has two user accounts in it to log in to my test workstations. To do a trial run on my brand new MSI, I create a Group Policy Object called `winzipMSI` for the test OU. I then edit the new GPO and, as you can see in Figure 12.82, assign the `winzip.MSI` to the users.

**FIGURE 12.82**

Doing a test run assignment of new package

Then I log in at a clean workstation with one of the test OU user accounts and see if the install works. It does, right down to the Make EXE icon on the toolbar.

Once I try out the MSI on a few more machines and am certain that it will work in production, I create a GPO for the domain and assign the new WinZip MSI to the users. That's it. The users get their WinZip and we're done with the scenario—all items on the list have been accounted for. Congratulations.

**NOTE** *I used a simple, tried and true piece of software to demonstrate creating an MSI. Because of that, I really didn't have any problems. However, it is not uncommon to do several snapshots and numerous MSI edits, a test deployment, make some more changes, and then redeploy it, before the MSI is acceptable. Don't despair, and remember that OnDemand Software does support WinINSTALL LE by both e-mail and a Knowledge Base of known issues. Bear in mind that the software you are making into an MSI might have installation problems (even WinZip can), so check the software's Web site, too.*

Software deployment has come a long way. Gone are the days when you had to spend hours watching progress bars as you installed software at the users' computers. I certainly hope that the information in this chapter will help you get started with your company's software deployment methods. To recap, let's run down a list of what we have covered:

- ◆ Publishing software
- ◆ Assigning software to users and computers
- ◆ Uninstalling software because the client fell out of the scope of management
- ◆ Removing software
- ◆ Redeploying software
- ◆ Using Software Deployment to update computer operating systems
- ◆ Creating an administrative install to deploy Office XP
- ◆ Updating administrative installs
- ◆ Upgrading software
- ◆ Resolving some possible issues concerning synchronization
- ◆ Creating and deploying ZAP files
- ◆ Creating and deploying MSI files

Hmmmmm, not bad for a day's work. Thanks for stopping by.

## Chapter 13

# Configuring and Troubleshooting Network Print Services

“PAPERLESS OFFICE,” MY SORE head. Even after years of interoffice e-mail and online documents, in many offices it’s not official until you hold the printed evidence in your hand. Printing isn’t sexy, but it’s an inescapable—and vital—part of life in the networked office.

It’s simply not practical—or necessary—to provide everyone in the office with a personal printer. Instead, you connect a printer to a print server and share the printer from there so that dozens or hundreds of people can use one printer. Of course, once dozens or hundreds of people depend on a single piece of equipment, that piece of equipment becomes pretty crucial. It needs to be up and running, dependable, and accessible to those who need it but off-limits to those who don’t.

Hence this chapter. In the following pages, I’ll talk about how to use Windows Server 2003 to complete the following tasks:

- ◆ Create a new local printer or connect to one already set up on the network or Internet.
- ◆ Secure the printer so that only those people who should be using it have access to it.
- ◆ Configure printer settings to help people find and troubleshoot print jobs.
- ◆ Speed up printing by making multiple printers look like one.
- ◆ Connect to a printer from a variety of different platforms.
- ◆ Troubleshoot the printing problems that will inevitably occur.

In the course of this chapter, I’ll use the Microsoft terminology for referring to printers and printing functions. If you’re not familiar with this vocabulary, read on before jumping in.

## Print Services Terminology

Contrary to what you might have believed, a *printer* is, in fact, not that putty-colored box that you put paper into and printed documents come out of. In the Microsoft world, a printer is a logical device that’s an intermediary between user applications and the *print device* (the thing that actually does the printing). All configuration settings apply to printers, not to print devices. The ratio of printers to

print devices is not necessarily 1:1. You can have one printer and one print device, two printers for a single print device, or one printer and several print devices. I'll talk about *why* you might want to do any of these in the course of this chapter.

When you send documents to a printer, they become part of the printer's *queue*, the group of documents waiting to be printed. Although in other operating systems, such as OS/2, the queue was important as a primary interface between the application and printing devices, in all other forms of Windows NT (including NT, Win2K, and Server 2003), the printer plays this role. Even if they're pointing to the same print device, these printers work independently, so you can set up different printing options and permissions for each one and then set up the appropriate printer for people on the network.

Most people on your network won't have their own print device on their desk. Instead, to print they'll connect to a network-accessible printer via its connection to a *print server*, the computer on which printer drivers are stored. Most of this chapter will operate under the assumption that your network's printers are connected to a print server running Windows Server 2003. A *network-interface printer* is a printer directly connected to the network via a built-in network card.

**NOTE** *Even if the rest of your network is running Server 2003 or XP, your print server doesn't have to—and vice versa. A print server can run Windows for Workgroups, Windows 9x, any version of NT Workstation or Server, LAN Manager, or even (if you installed MS-Net) Windows 3.x or DOS. The options available to you will depend on the operating system; if your print server runs an operating system other than Server 2003, then some of the information in this chapter may not apply to you.*

## GETTING ACQUAINTED WITH THE SERVER 2003 PRINTING INTERFACE

As with much of Server 2003, the first step in learning how to administer printers is to find out where all the printer management tools *are*. I won't get into the details of how to use these tools just yet, but when you're looking for the right tool for the job, this sidebar should help you find it.

To set up the printer for using forms, to configure printer ports, to add or update printer drivers, or to set spooling or error management options, you'll need to configure the printer server, not the printer or print device. Printer server properties are available from the Properties option in the File menu of the Printers and Faxes window. The Printers and Faxes window is accessible from the Control Panel, or from the Start menu.

Individual printer properties, such as the printer's description, sharing options, port used, spooling options, and device settings, are set from printer-specific properties pages. You can get to them either by right-clicking a printer's icon in the Printers and Faxes menu and choosing Properties from the context menu or by choosing Properties from the File menu of a particular printer's queue window. Because all printers are independent entities—even if pointing to the same print device—editing one printer's properties pages has no effect on any other printer.

## The Server 2003 Printing Model

The process of printing is a bit more complex than it (hopefully) looks from the outside. The NT printing model uses several components to render application data for graphical output, get the data to a printer, and then help the printer manage multiple print jobs. Some of the following information

on *how* printing works is background, but it's also helpful when it comes to troubleshooting, so wade through it if you can.

The main chunks of NT-based printing are the Graphics Device Interface (GDI), the printer driver, and the print spooler.

**NOTE** *The explanations here apply to all NT-based server operating systems: NT, Windows 2000, and Server 2003.*

## The Graphics Device Interface

The Graphics Device Interface (GDI) is the portion of the operating system that begins the process of producing visual output, whether that output is to the screen or to the printer. Without the GDI, WYSIWYG output would be impossible. To produce screen output, the GDI calls the video driver; to produce printed output, the GDI calls the printer driver, providing information about the print device needed and the type of data used.

## The Printer Driver

Printer drivers are the software that enable the operating system to communicate with a printer. They're incompatible across operating systems, so although any Win32 operating system can print to a print server without first installing a local printer driver—they'll just download it from the print server—you'll have to make sure the drivers are available for the clients that will be using the printer. That means that even though you've attached the printer to a print server, you'll need to install the Windows 98 printer drivers on that server if any network client computers are running Windows 98.

These printer drivers are composed of three subdrivers that work together as a unit:

- ◆ Printer graphics driver
- ◆ Printer interface driver
- ◆ Characterization data file

The printer graphics driver renders the GDI commands into Device Driver Interface (DDI) commands that can be sent to the printer.

You need some means of interacting with and configuring the printer. The role of the printer interface driver is to provide that means. The printer interface driver is your intermediary to the characterization data file, providing the information you see in a printer's properties pages.

The characterization data file provides information about the make and model of a specific type of print device, including what it can do: print on both sides of a piece of paper, print at various resolutions, and accept certain paper sizes.

## The Print Spooler

The print spooler (SPoolSS.DLL, in %systemroot%\system32) is a collection of dynamic link libraries (DLLs) and device drivers that receive, process, schedule, and distribute print jobs. It's implemented with the Spooler service, which is required for printing, and has the following components:

- ◆ Print router
- ◆ Local print provider
- ◆ Remote print provider

- ◆ Print processors
- ◆ Print monitor

### THE PRINT ROUTER

When a client computer connects to a print server, communication takes place in the form of remote procedure calls from the client's print router (WINSPOOL.DRV) to the server's print router (SPOOLSS.DLL). At this point, the server's print router passes the print request to the appropriate print provider: the local print provider if it's a local job, and either the Windows or NetWare print provider if sent over the network.

### THE PRINT PROVIDER

To find the right print provider, the print router polls the Windows print provider. This provider then finds the connection that recognizes the printer name and sends a remote procedure call to the print router on the print server. That local print provider then writes the contents of the print job to a spool file (which will have the extension .spl) and tracks administration information for that print job.

**TIP** By default, all spool files are stored in the %systemroot%\system32\spool\printers directory. If you like (perhaps if you've installed a faster hard drive that you'd prefer to spool from, or you're trying to avoid a fragmented hard disk), you can change that location by adjusting the value of the print server settings on the Advanced tab. To get there, open the Printers and Faxes folder and choose Server Properties from the File menu. Move to the Advanced tab, and you'll see the spooler settings, including the location of the spool file.

The print server normally deletes spool files after the print job they apply to is completed, because they only exist to keep the print job from getting lost in case of a power failure to the print server. If you want to keep track of such data as the amount of disk space required by spool files and what printer traffic is like, you can enable spooler event logging.

### THE PRINT PROCESSOR

A print processor works with the printer driver to “de-spool” spool files during playback, making any necessary changes to the spool file based on its data type.

Er—data type?

The data type for a print job tells the print spooler whether and how to modify the print job to print properly. This is necessary because methods of print job creation aren't standardized; for example, a Win2K client won't create a job the same way a Linux client does. Therefore, a variety of print server services exist to receive print jobs and prepare them for printing. Some of these print services assign no data type (in which case Server 2003 uses the default data type in the Print Processor dialog box), and some assign a data type.

The spool file can accept data from the print provider in one of two forms: Enhanced Metafile (EMF) or RAW. EMF spool files are device-independent files used to reduce the amount of time spent processing a print job; all GDI calls needed to produce the print job are included in the file. Once the EMF file is rendered, you can continue using the application from which you were printing. All the rest of the print processing will take place in the background. Unlike EMF spool files, which still require some rendering once it's determined which printer they'll be spooled to, RAW spool

files are fully rendered when created. All else being equal, EMF spool files are normally smaller than RAW spool files because they're generic instructions for rendering, not complete renderings.

WinPrint, the NT operating systems print processor, understands four versions of EMF data files (1.003–1.008), three kinds of RAW data files, and TEXT files, which have the characteristics shown in Table 13.1.

**TABLE 13.1: WHICH DATA TYPE DO I NEED?**

DATA TYPE	DESCRIPTION	SUPPORTED BY
EMF	Tells WinPrint that the job was created in Windows and is already partially rendered. WinPrint works with the GDI and printer driver to complete the rendering, then returns the job to the local print provider.	Print clients with NT-based operating systems
RAW	Tells WinPrint not to modify the print job at all, but to return it to the local print provider.	All printer clients
RAW [FF Auto]	Tells WinPrint to check for a form-feed command at the end of the print job. If one isn't there, WinPrint adds it and then returns the job to the local print provider.	All printer clients
RAW [FF Appended]	WinPrint adds a form-feed command to the print job and then returns the job to the local print provider.	All printer clients
TEXT	Tells WinPrint that the print job is ASCII text to be printed as hard copy and as is. WinPrint uses the GDI and the printer driver to produce this output, then sends the new job to the local print provider.	All printer clients

The default data type is RAW, supported by all Windows clients. To select a different data type, open a printer's properties pages and turn to the Advanced tab. Click the Print Processor button to display a list of possible print processor types. Select a different data type from the list and click OK. The new data type will be used for all print jobs that don't specify that another data type should be used.

That said, don't change the data type unless you're *sure* it's a good idea. It isn't often. If a print client can use EMF files, it will do so even if the default data type is RAW, so you're not losing anything by making RAW the default. In contrast, if you make EMF the default data type, then Windows 9x clients won't be able to print. No error messages will appear on the client that initiated the print job, and no errors will show up on the print server's console, but the print jobs they send along will disappear into the ether.

### THE PRINT MONITOR

The print monitor is the final link in the chain getting the print job from the client application to the print device. It's actually two monitors: a language monitor and a port monitor.

The *language monitor*, created when you install a printer driver if a language monitor is associated with the driver, comes into play only if the print device is bidirectional. A bidirectional print device can send meaningful messages about print job status to the computer. In this case, the language monitor sets up the communication with the printer and then passes control to the port monitor. The language monitor supplied with Server 2003 uses the Printer Job Language. If a manufacturer created a printer that spoke a different language, it would need to create another language monitor, as the computer and print device must speak the same language for the communication to work.

The *port monitor's* job is to transmit the print job either to the print device or to another server. It controls the flow of information to the I/O port to which the print device is connected (a serial, parallel, network, or SCSI port). The local port monitor supplied with Server 2003 controls parallel and serial ports; if you want to connect a print device to a SCSI port or network port, you must use a port monitor supplied by the vendor. Regardless of type, however, port monitors interface with ports, not printers, and are in fact unaware of the type of print device to which they're connected. The print job was already configured by the print processor.

By default, only the locally required print monitor is installed. To use another monitor, you'll have to create a new port in the printer configuration settings.

## The Printing Process

Those are the parts of the printing process. Here's how they fit together when printing from an NT-based client operating system:

1. The user chooses to print from an application, causing the application to call the GDI. The GDI, in its turn, calls the printer driver associated with the target print device. Using the document information from the application and the printer information from the printer driver, the GDI renders the print job.
2. The print job is next passed to the spooler. The client side of the spooler makes a remote procedure call to the server side, which then calls the print router component of the server.
3. The print router passes the job to the local print provider, which spools the job to disk.
4. The local print provider polls the print processors, passing the print job to the one that recognizes the selected printer. Based on the data type (EMF or RAW) used in the spool file, any necessary changes are made to the spool file in order to make it printable on the selected print device.
5. If desired, the separator page processor adds a separator page to the print job.
6. The print job is de-spoiled to the print monitor. If the printer device is bidirectional, then the language monitor sets up communications. If not, or once the language monitor is done, the job is passed to the port monitor, which handles the task of getting the print job to the port the print device is connected to.
7. The print job arrives at the print device and prints.

That's how print servers see printing. Good stuff to know when it comes time to troubleshoot printing problems. For the rest of the chapter, however, we'll concentrate on how *you* see printing.

## Setting Up a Printer Connection

The day hasn't yet come when you can always plug a printer into a server and expect the server to find it without you telling it that there's a printer there. Until it does, you'll need to either create the printer locally or connect to a printer on the network. You will need to set up support for a printer to use it from a computer if any of the following conditions apply:

- ◆ You're installing support for a printer connected directly to one of the parallel or USB ports of the local machine.
- ◆ You're installing support for a network-interface printer.
- ◆ You're defining a printer that sends information to a file (as opposed to a print device).
- ◆ You're making a second printer for a print device.

I'll describe first how to set up a new printer and then how to connect to a printer already installed on the network.

### Installing a Printer on a Print Server

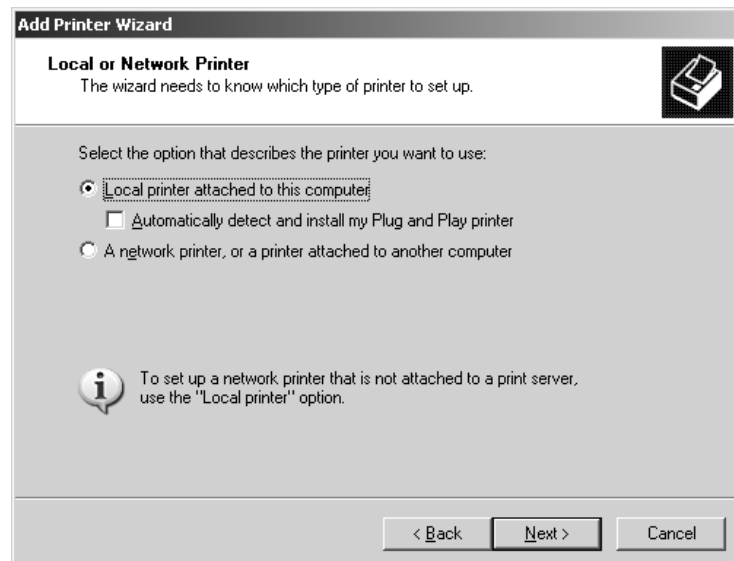

All printer management begins in the Printers and Faxes window, available either from its shortcut in the Control Panel or from the Start menu. There's an Add Printer Wizard in the Printers and Faxes folder that you must run to set up a printer on the local computer.

To create a new printer connected to the local machine, follow these steps:

1. Open the Printers menu and click the Add Printer icon you'll see there. Click Next in the opening screen of the Add Printer Wizard (the opening window isn't important; it tells you only that you're using the Add Printer Wizard in case you hadn't figured that out) to get to the screen shown in Figure 13.1. For this example, choose the default option, Local Printer, and click Next.

**FIGURE 13.1**

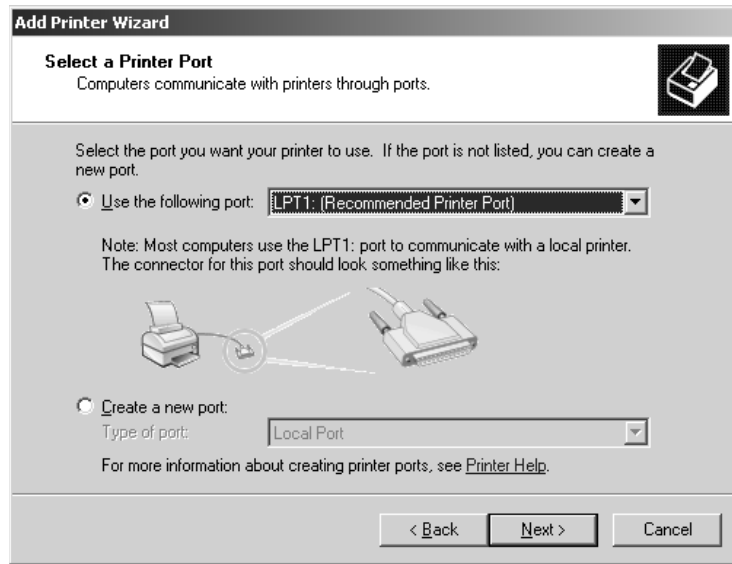

Specify first whether the printer is connected to the local computer or on the network.

2. If you're setting up a Plug-and-Play printer attached to the printer server, you can tell the server to detect it by clicking the check box visible in Figure 13.1. If not, or if you're creating a printer to send output to a file, you will have to tell the Add Printer Wizard which port the printer is connected to from the drop-down list (see Figure 13.2). When connecting to a locally attached printer, this is simple—just make sure you've selected the port the printer is plugged into. To create a printer that stores print information in a file, choose the FILE option near the bottom of the list. Click Next.

**FIGURE 13.2**

Choose the printer's port from the list.

**NOTE** Any TS ports (e.g., TS0001) near the bottom of the list represent printers connected to a computer currently connected to the server via RDP connection. There will be one port for each network or locally attached printer on the client computer. Don't connect a printer to them unless you're manually redirecting a printer to a terminal client session—something you'll rarely need to do. (See Chapter 16, "Terminal Services," to find out why.)

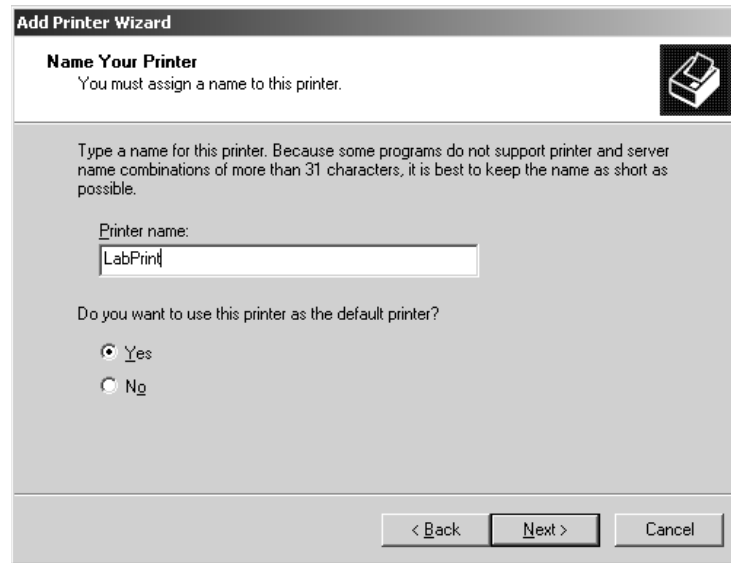

3. Next, you'll choose the driver needed for your particular printer. From the list presented, choose the printer's manufacturer from the left and the printer model from the right. By default, the server will use its own printer driver. If you've got a newer one from the manufacturer or from the manufacturer's Web site, click the Have Disk button and provide the path to the driver. If the Windows Server 2003 is connected to the Internet, you can alternatively click the Windows Update button to automatically download a newer driver from the Microsoft Web site, if one is available. Click Next.

**TIP** If the driver you need is already installed on the system—perhaps for a different printer that you already created—the Add Printer wizard will ask if you want to use the existing driver or replace it with the new one. Generally speaking, newer is better. Just make sure that you test printer drivers before putting them into production, as a buggy printer driver can cause a server to crash.

4. After you've chosen a driver to use, the Add Printer Wizard asks you to name the printer using, by default, the printer's model name (see Figure 13.3). The name cannot contain a comma, backward slash, or exclamation point, but it has few other restrictions. The name you choose can be quite long—up to 220 characters—but I don't recommend making the name any longer than is strictly necessary to be descriptive, and if you plan to do any command-line management your life will be simpler if the printer name has no spaces in it. (Names with spaces must be enclosed in quotes when you address them in batch files.) Click Next to move on.

**FIGURE 13.3**

Choose a local name for the printer.

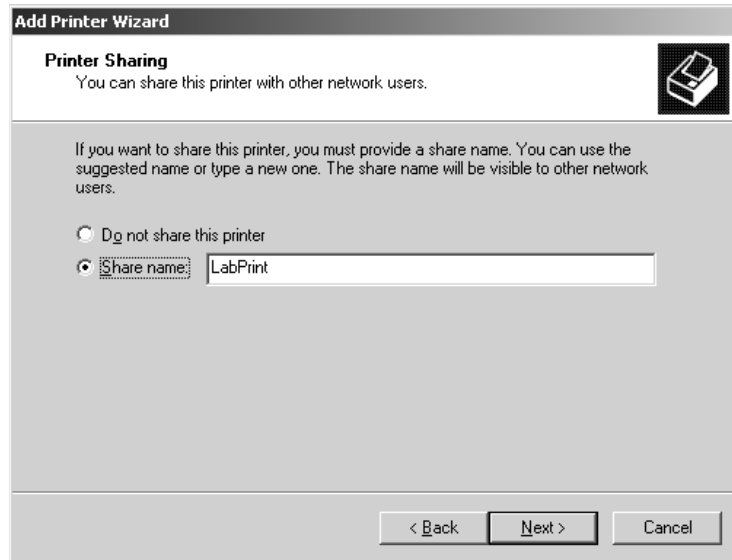

**TIP** Keep printer names short and don't put spaces in them. First, if you're ever connecting to or managing the printer from the command line, do you really want to have to type "This is the printer by the coffee machine; it's got a single paper tray and faces west" when prompted for the name of the printer? Even identifying the printer in the Printers dialog box is harder if all the printers have overly long names because the names get cut off in the display. Second, some applications can't work with a name longer than 31 characters. If you can't fully identify a printer without creating a long name, you can always add a location and printer description, as I'll describe in a moment.

5. Next, if you're sharing the printer, choose a share name for it. If the name you've given the printer has more than one word or a forward slash, the wizard will delete the spaces and combine the words until it has a single word up to eight characters long (see Figure 13.4). The reason for this is backward compatibility: DOS clients won't be able to connect to printers with names more than eight characters long or with spaces.

If you don't have DOS clients to worry about, you can make a new share name for the printer. Once again, the name may be up to 220 characters long and include spaces, but it can't contain commas, backward slashes, or exclamation points.

**FIGURE 13.4**

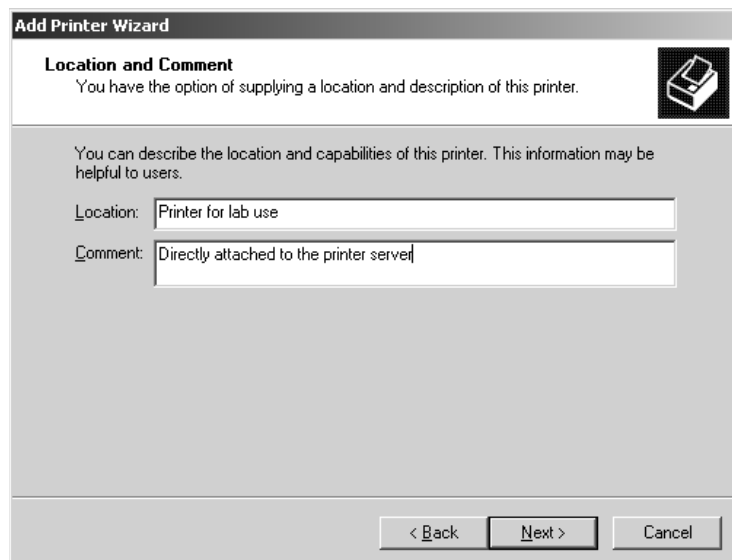

By default, the Add Printer Wizard will make a DOS-compatible name for the printer.

6. In the next stage of the installation, you'll have a chance to describe the printer and location (see Figure 13.5). The usefulness of these descriptions varies. Older clients (DOS, NT 4, Windows 9x, etc.) will display the information you enter into the Comment text box, but they won't be able to display what you enter into the Location box. Win2K and XP (and other Server 2003 servers) clients will be able to display both the Location and the Comments. Therefore, unless your network is composed entirely of Win2K or later computers, all important information should go into the Comment box. Click Next to move to the next screen.

**FIGURE 13.5**

Only Win2K and later clients will be able to see the information you enter in the Location box.

7. The next screen asks whether you'll want to print a test page when you're done. Choose the Yes or No radio button and click Next. Can't hurt—it's a good way of seeing whether you set up the printer properly *before* you try to use it.
8. The final screen in the information-gathering part of the Add Printer Wizard (see Figure 13.6) shows the options that you entered at each stage so you can go back and change options if necessary. Review your choices and click the Finish button if you want to keep the settings. The computer will copy the drivers needed and, if you told it to do so, print the test page.

**FIGURE 13.6**

Review your choices before committing yourself with the Finish button.

## Connecting to a Network-Enabled Printer

Network-enabled printers work similarly to locally attached printers, but with a couple of important differences. You'll need to be careful to set up the print device only on a single print server, and you'll need to set up a port to connect the printer to.

The reason for the first consideration may not be obvious. The thing is, that independent air the print device has as it sits off in the corner, separate from the printers on the network, is deceptive. That network-connected print device still needs a print server to spool documents to it, to manage its print queue, and so forth. It's just communicating with this print server through the network instead of through a parallel port. If a print device has two print servers pointing to it, it can get confused about which printer servers are sending which jobs to it, which can lead to garbled output as it tries to read two spooled files at once. (The busier the print device is, the more likely it is to get confused.) So don't confuse it. Although any server—or even workstation—could set up a printer for that print device locally, only give it one printer server.

The good news is that you're not likely to be overrun with people setting up rogue print servers. First, to set up a locally attached printer, you need Administrator or Account Operator privileges for the computer. Second, you'll need to create a special TCP/IP port for that printer's use. Since

anyone doing so will need to know the name of the port and have the permission to create it on their computer, that should limit the number of people setting up rogue print servers.

Setting up a printer for a networked print device is much like setting up a printer for a locally attached printer, with a few exceptions. First, there's the matter of telling the Add Printer Wizard where the printer is. *Do* tell it that the printer is local. *Don't* check the box telling the wizard to automatically detect Plug-and-Play printers. It won't find it and you'll waste time searching for it.

Second, if you're creating the first printer for this network print device on the print server, you'll need to create the port for the printer to connect to. In the page prompting you to select a printer port, select Create a New Port and choose Standard TCP/IP port from the drop-down list. Click Next to begin the Add Standard TCP/IP Printer Port Wizard, and click Next to move through its opening screen.

1. Type the name of the port that the new print device uses. You can't make up a name here but must supply the name unique to this print device on the network, as shown in Figure 13.7. The port name must also be unique on the print server—you can't create the same port twice.

**NOTE** *If a printer for the networked print device is already set up somewhere on the network, you can find the port name by opening the printer's properties.*

**FIGURE 13.7**

Type the print device's port name.

2. The wizard will look for a device using that name on the network. When it finds it, it may ask you for more information about the printer device's type, as in Figure 13.8. This isn't a fatal error—just find the printer in the drop-down list (in this example, HP Jet Direct) and click Next.

**FIGURE 13.8**

You may need to provide more information about the type of print device.

3. If the wizard can't find the print device at *all*, make sure that you've entered the port name correctly, that the print device is on, and that the network is set up correctly. Don't try to continue if the wizard simply cannot find the device (it's okay if it's unsure that the device is configured correctly), as doing so will just set up a useless port. When you've told the wizard about the kind of device it's looking for (or when it's found it on its own), click Next to review your choices in the box shown in Figure 13.9.

**FIGURE 13.9**

Review the port settings and click Finish to continue setting up the printer.

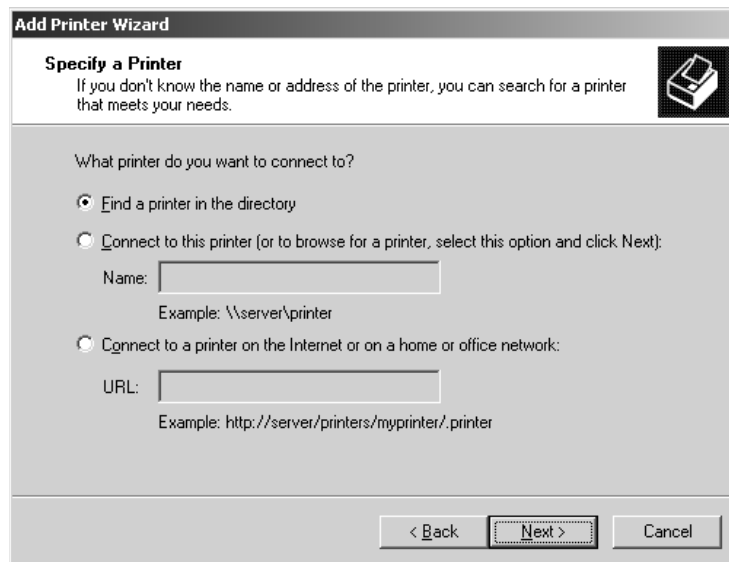

That's it. You've now created a TCP/IP port, and the Add Printer Wizard will continue as it did for creating a locally attached printer.

## Connecting to a Shared Printer

Some servers—such as the terminal servers discussed in Chapter 16—may need to connect to printers already set up on other print servers. To do so, start the Add Printer Wizard in Printers and Faxes and click the Add a Printer button on the left side of the folder. Click Next to move past the opening page. On the Local or Network page, choose A Network Printer, or a Printer Attached to Another Computer. (This option is terribly misleading, since the *only* printer you can connect to here is one previously set up on another computer, but we'll let that go for now.) Click Next to move to the Specify a Printer page in Figure 13.10.

**FIGURE 13.10**

You have several options for specifying a printer path.

What you do from here depends how you're connecting to the printer:

- ◆ If you know the name of the share name of the printer, type it in the space provided. (Of course, if you know the printer's share name, you might as well type **net use \\servername\printername/persistent:yes** from the command line and save yourself the trouble of running the wizard.)
- ◆ If you need to browse for the printer, choose the second option and click Next.

**NOTE** If you're still using an NT 4 domain controller, the first option in the list will be Browse for Printer, not Find a Printer in the Directory, and browsing using the first two options will show the same dialog boxes.

- ◆ If someone's configured the print server to share its printers through a browser window, type the URL for the printer and click Next.

### BROWSING FOR PRINTERS

Since I'll cover Internet printing a little later in this chapter, for now let's assume that you're browsing for the printer. When you choose this option and click Next, you'll see a dialog box like the one in Figure 13.11, prompting you to pick a domain, look for a server, then find the appropriate printer.

**FIGURE 13.11**

Browsing for a shared printer

That's it. The next screen will show you the printer you chose. When you click Finish, the computer you're configuring will be set up to use that printer.

If you provided a path to the printer, it's even easier. When you click Next you'll see the Finish screen showing the name of the printer you connected to. Frankly, it's not worth running the wizard if you know the server and printer name—just use `net use` to connect from the command line.

### FINDING A PRINTER IN THE DIRECTORY

Browsing is fine for a small network, but if you don't know which server a printer is connected to or even what domain it's in, it's easier to search the Active Directory for a printer matching the features that you need, or that's in a particular location. To do so, choose the first option in the Specify a Printer page and click Next to open the dialog box in Figure 13.12.

You can search for a printer based on just about any characteristic—or combination of characteristics—that you like. Searching for a printer by name doesn't seem very likely, since if you knew that much you'd probably know its domain and its server as well. And you almost certainly

don't know the model precisely enough to type it exactly, not with printer model names having a length reminiscent of the names of minor royalty. However, you might know the printer's location, so you can enter that in the appropriate box.

**FIGURE 13.12**

Searching the Active Directory for a printer

**TIP** Since people may be using a printer's location to search the Active Directory for that printer, keep printer locations short and consistent (e.g., "Lab" or "Reception").

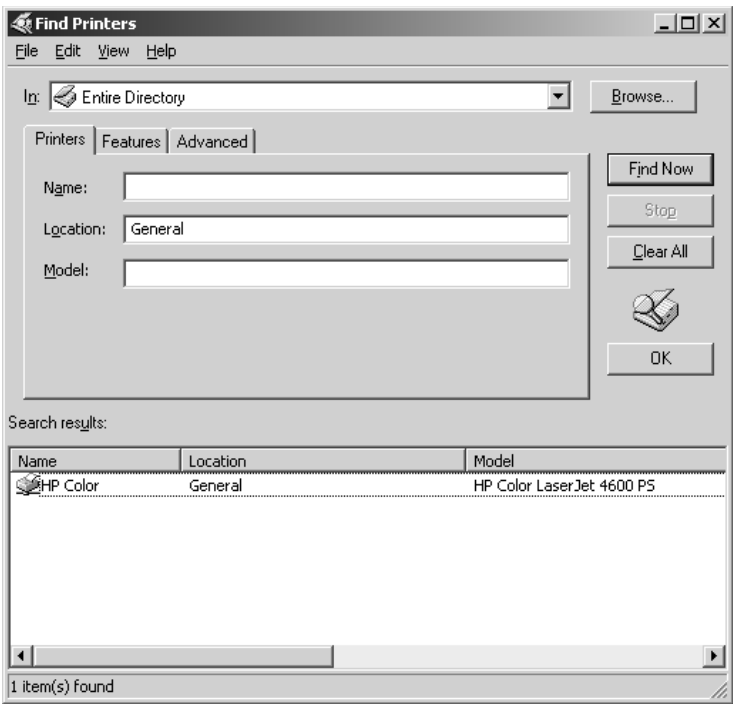

In addition to knowing where the printer you want is, you probably know enough to know that you're looking for a color printer, or one that can staple. Therefore, in addition to the location on the Printers tab you can turn to the Features tab and check the box for the appropriate feature. When you click Find Now, the wizard will query the Active Directory, looking for a match for all the criteria you specified, and return the results as shown in Figure 13.13. I've listed the standard search criteria in Table 13.2.

The contents of the Advanced tab will be most suited to people who *really* know their printers, since the search criteria there get more granular than most people will need. Whereas the first two tabs allow you to describe a printer in terms of where it is, what it's called, and/or what you want it to be able to do, the Advanced tab allows you to describe the printer exactly. When you click the Field button, you can choose from any of the characteristics visible in Figure 13.14.

Performing a search using these advanced criteria works like the search you performed already. Choose the features you want to search for and click the Find Now button. The screen will display the results as it does in Figure 13.13.

Once you've found the printer you want, the rest is easy. Choose the printer you want and click OK. If this is not the first printer installed for the computer, the wizard will ask if you want this to be the default printer. After you've chosen, you'll see the familiar dialog box prompting you to review your choices and click Finish to set up the printer connection.

**FIGURE 13.13**  
Results of searching  
for a printer by  
feature and location

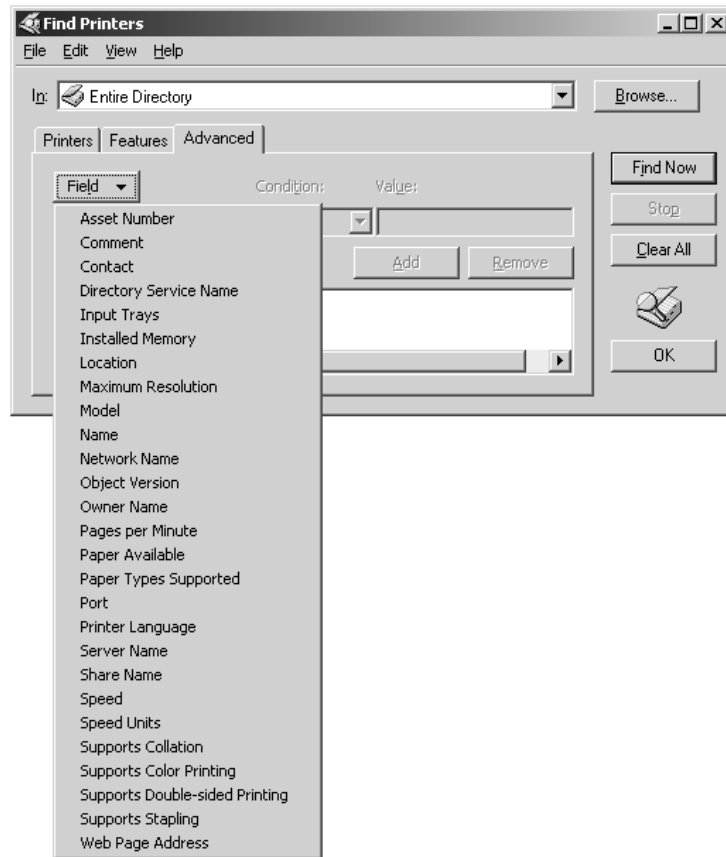

**TABLE 13.2: STANDARD SEARCH CRITERIA FOR FINDING PRINTERS IN THE ACTIVE DIRECTORY**

PRINTER CHARACTERISTIC	LOCATION
Color support	Features
Double-sided printing support	Features
Location	Printers
Minimum resolution	Features
Minimum speed	Features
Model	Printers
Name	Printers
Paper size	Features
Stapling support	Features

**FIGURE 13.14**

Advanced search criteria for finding printers in the Active Directory

### Creating a Second Printer for One Print Device

At this point, you have one printer for one print device. If you'd like to create a second printer—perhaps to configure a different set of permissions for it—you can do so in the same way you created the first printer. Follow the procedure to create a local printer, making sure you do two things:

- ◆ Give the new printer a different local name and share name.
- ◆ Choose the exact same settings (port, printer manufacturer and model, and so on) you chose for the first printer.

Sending documents to the new printer will cause them to print on the same print device. The only difference will lie in the configuration options you set for the new printer.

**NOTE** Not all options set in a printer's properties pages are printer specific. Port time-outs, for example, apply to any parallel port on the print server. One printer's time-outs will apply to all printers for that print device.

## Deleting a Printer

Sometimes, you'll need to delete a printer from a print server. Most of the time, this process is extremely simple: you open the Printers and Faxes section of the Control Panel, right-click the printer about to be sent to that big network in the sky, and choose Delete from the context menu. The printer should disappear immediately. If the printer you deleted was the default, another printer on that computer will become the new default.

If the printer you deleted *doesn't* disappear immediately, make sure that it's not in the middle of trying to print a document. Even if a printer never worked—for example, you were trying to set up a network-attached printer and specified the wrong port name—it can still have waiting print jobs. (Actually, this is *especially* likely if the printer never worked but you insisted on setting it up, damn the errors and full speed ahead.) Check the print queue of the printer you're trying to delete. If it has waiting print jobs, choose Cancel All Print Jobs from the Printer menu and then try to delete the printer again. Rebooting the print server will not clear the list of spooled print jobs—you must explicitly cancel them.

## Preparing for Web Printing

Web-based printing allows users to print or manage documents from their Web browsers with very minimal setup. It takes a little more prep work than sharing a printer with the local network, but it's easier for inexperienced users to set up their own computers. As you saw earlier, to connect to a networked printer, you need to know something about that printer so you can either name it explicitly, browse for it, or find it in the Active Directory. With Web printing, you just have to click the right link—or the only link, if a particular person only has access to one printer—and the printer installs itself.

### WHAT CAN (AND CAN'T) WEB PRINTING ACCOMPLISH?

Your first thought might be that Web printing will be a good way to add remote printer access so that people who don't work in your office can send print jobs to your printers. For example, I recently had to FedEx 50 pages of a presentation to another office, which meant that I had to print out the presentation, put it in an envelope, fill out the slip, and call FedEx to pick up the package. If the recipient had set up their printer for Internet printing, then I could have just sent the print job to their printer directly and skipped the FedExing part, right?

Well, maybe not. First, the flow of information in Web-based printing is no different from that of an ordinary print job, except that you've added a Web server into the mix. Print jobs are *big*, bigger than the files they're printing, because formatting a print job requires extra information. If you try to send a big print job across a slow link, it may take a while to get there.

What about printing shorter documents? It would be possible to use Internet printing just as you would a fax. So long as you only used the printer like you would a fax—you don't often fax 50-page PowerPoint presentations, do you?—then you'd be okay. But doing that requires setting up a printer explicitly for this purpose, and it opens up a security hole because you're allowing people to log in to the domain from the Internet. If I were doing this, I'd set up a network printer just for anonymous users to connect to, and explicitly deny those anonymous users from doing anything else on the network. I'd also set up the print server for this printer outside the network's DMZ, so that access to the printer server didn't give people access to other network computers.

Frankly, the best use I've seen for Web printing is that it really streamlines the printer setup process for the client. As you'll see in the "Internet Printing" section (on setting up client access to the printer via the Web), this process is much simpler than using the Add Printer Wizard: You tell the user to run Internet Explorer 4 or later, connect to the print server by typing `http://printservername/printers` in the Address section of the browser, then click the printer they see there—since you will have used security permissions to make sure that they can only see the printer they're supposed to connect to. The user clicks the link for that server, then clicks the Connect link to automatically download the driver to their computer. That's it—the printer is installed and available to any application.

### SETTING UP A WEB PRINT SERVER

The protocol used in Web printing depends on whether the printer is available on the LAN or on a WAN. Web printing uses the Internet Printing Protocol (IPP), encapsulated within the HyperText Transfer Protocol (HTTP) used for browsing the Web. Printers on the local LAN will use the faster remote procedure calls (RPCs) to send jobs to the printer, just as they do for traditional print jobs. Because an Internet print server must be able to accept incoming HTTP traffic to communicate with print clients not on the LAN, the print server must also be a Web server. This means that you'll need to install the Internet Information Services (IIS) on the print server and run the service. You can install IIS from the Add/Remove Windows Components tool in the Add/Remove Programs applet in the Control Panel—it's one of the components of the Web Application Server service.

If you look at IIS's details, you'll notice that Internet Printing is one of its components and selected for installation by default. This means that Internet printing is enabled, right? Well—not exactly. For security reasons, Internet Printing is prohibited *even if you install it along with IIS*. To enable it, open Internet Information Services from Administrative Tools after you've installed the core service. One folder there is labeled "Web Services Extensions." Open this folder, and you'll see a list of services and three buttons: Allow, Prohibit, and Properties. Select Internet Printing and click the Allow button.

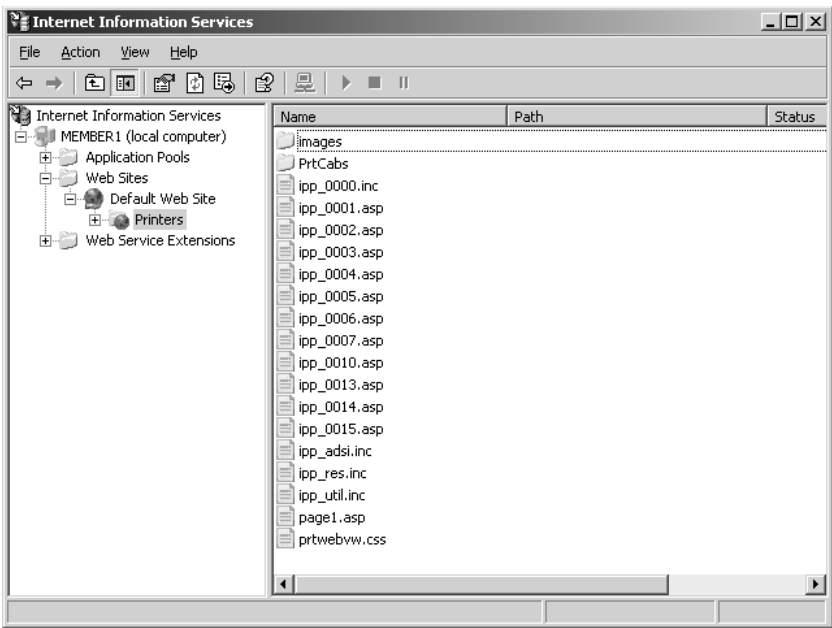

### SECURING A WEB PRINT SERVER

Once you've got IIS installed and have allowed the Internet Printing Web extension, the print server can accept clients connecting to it by typing its URL into IE. However, as it stands, the printer is open to everyone who can type its URL, and you do *not* want just anyone connecting to network computers—or even just anyone printing large print jobs. You should do some security tweaking before making this printer available. Open the Internet Information Services tool in the Administrative Tools program group. (If it's not there, make sure that you installed IIS. Unlike in Windows 2000, in Server 2003 IIS is not installed by default.) All the Web servers in the domain will be listed below the Internet Information Services folder. Find the Web print server in this list. Within its Default Web Site folder, look for the Printers folder. At this point, your management console should look something like the one in Figure 13.15.

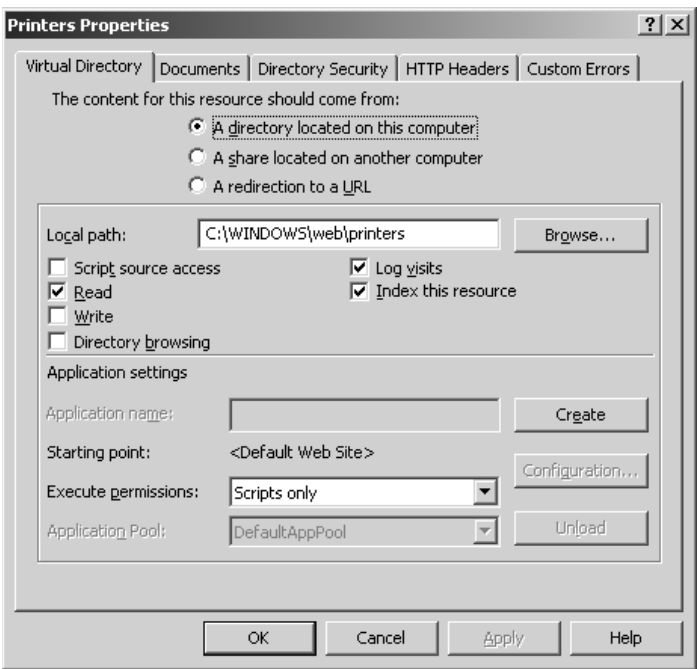

Now, right-click the Printers folder and choose Properties from the context menu that appears. You'll see a tabbed properties page like the one in Figure 13.16.

On the Virtual Directory tab shown here, make sure the entry points to the right information for printing. If you're setting up Internet printing on the print server, this should be the selected option—a directory on this computer. To configure Internet printing for another computer, provide the network path to that print server. If you do provide a connection to another print server here, the printer will only be available so long as the printer is online and has a live connection to the Web server.

**FIGURE 13.15**  
Find the Printers folder for your Web printer.

**FIGURE 13.16**  
The properties page for the Printers folder

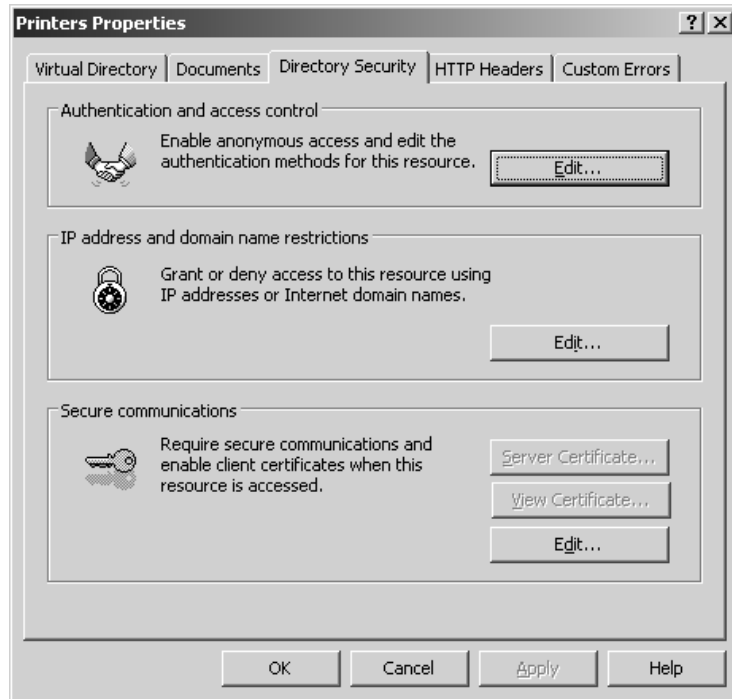

**TIP** If creating a connection to a shared printer on another computer, you have the option of either letting people use their own credentials to access that computer or supplying other credentials, if people accessing the Web page would not normally have access to the remote print server. Click the *Connect As* button (visible when you choose to connect to a remote resource) to provide the alternate credentials.

Secure access to the printer from the Directory Security tab (see Figure 13.17).

**FIGURE 13.17**

Printer security settings

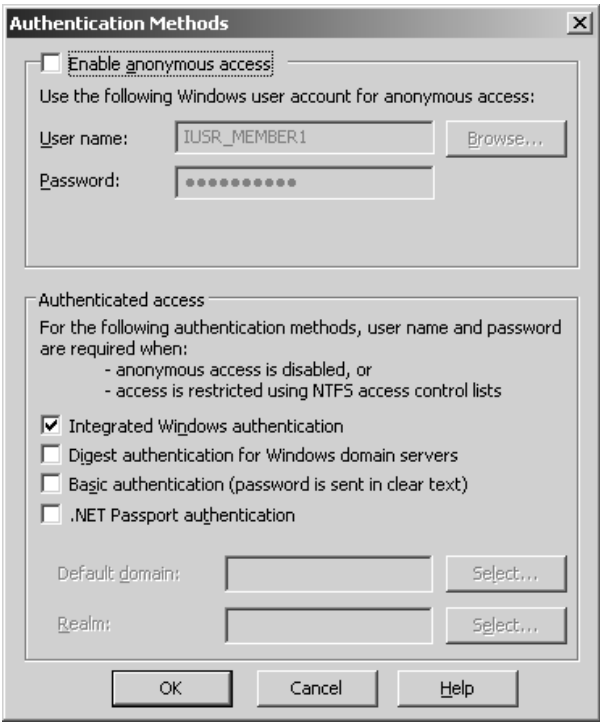

User authentication is set from the Authentication Methods dialog box (see Figure 13.18), accessible from the Directory Security tab when you click the Edit button for Authentication and Access Control. You can enable anonymous access with the privileges assigned to IUSR\_MEMBER1, or you can choose another account for people to use for anonymous access—even creating a Printer User account so you can track what people using the printer are doing. Edit the authentication settings by clicking the Edit button (see Figure 13.19).

Alternatively, you can require that anyone connecting to the printer via the Web get authenticated on the network first. Set up the Printers virtual folder for basic authentication if you want people to be able to manage printers from any browser. IIS will fuss at you for choosing this option because it sends passwords in clear (unencrypted) text, but if you choose Kerberos (Integrated Windows authentication) or challenge/response (Digest authentication) for greater security, you'll limit yourself to managing printers from Internet Explorer 4 or later. Server 2003 Passport authentication is (obviously) limited to those with a Server 2003 Passport account. By default, authentication will

be based on the domain that the Web printer is part of; to choose a different domain, click the Edit button and browse for the domain you want to use. If the box in the Browse dialog box is blank, the local domain will be used for authentication.

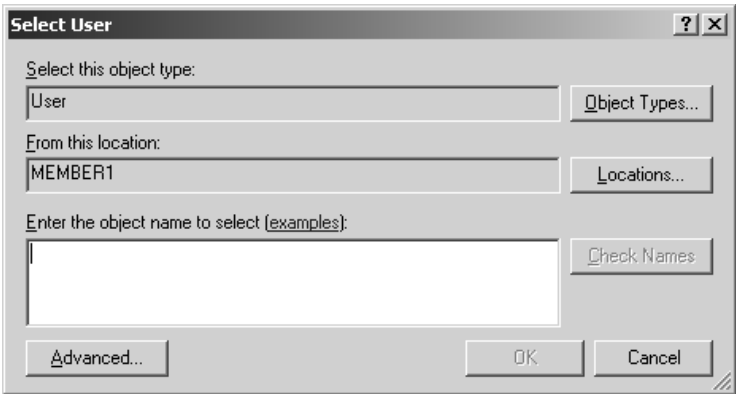

**FIGURE 13.18**

Choose an authentication method for Web print management.

**FIGURE 13.19**

You can edit the authentication settings for people accessing the Printers folder.

Another method you can use to restrict access to a Web printer is to permit only members of a particular domain or only those with a specific IP address. To do so, go back to the Directory Security tab and click the Edit button for IP Address and Domain Name Restrictions. You'll see a dialog box like the one in Figure 13.20.

When you first open this dialog box, no one will be specifically denied or granted access. (Note that you can use this dialog box to either explicitly permit or deny access.) To add an entry to the list, first click the appropriate radio button to indicate whether you're adding a "denied" entry (the Denied Access radio button) or a "permitted" entry (the Granted Access radio button). When you've made your choice, click the Add button to open the dialog box in Figure 13.21. You must *deny* some-one print access to keep them off the printer. Even if you delete the Everyone group and remove the explicitly given permission, people will still be able to print unless denied print access.

**FIGURE 13.20**

A list of permitted or forbidden domains and networks

**FIGURE 13.21**

Choose the domain name, IP address, or network to which you want to permit or deny access to the Web printer.

**TIP** Be sure to pick the right radio button (Granted Access or Denied Access) before you define the IP address/domain/group of computers to which you're permitting or denying access. Otherwise, you'll have to re-create the entry.

To permit or deny a single IP address, use the Single Computer option. Of course, if that single computer is getting its IP address from a Dynamic Host Configuration Protocol (DHCP) server, this option won't always apply to the same computer. A more effective method of restricting printer access is to define access for a group of computers, using the network IP address and the subnet mask (when you click each option, the boxes to fill in change accordingly). You *can* also permit or deny access to the computer based on domain membership, but this is an expensive operation. If you identify a domain by name, the name must be resolved on both ends of the connection before the Web server can identify the domain, and this will slow down print jobs considerably.

Once you've identified the computer(s) for which you want to permit or deny access to the Web printers folder, they'll appear in the list in the IP Address and Domain Name Restrictions dialog box. Permitted addresses will have a key icon; denied addresses will have a lock icon. The print server is now ready to accept print requests from clients.

**TIP** *Performance will be better if you grant/deny access based on IP address rather than domain name. If you choose to make domain name the criterion, every time the server needs to authenticate someone it will need to look up the domain—a time-consuming operation.*

## Getting the Printer to the Clients

The method you use to connect a client workstation to a networked printer depends on the operating system the client is using. DOS clients must connect from the command line and need locally installed drivers, 16-bit Windows clients can connect from the graphical interface and need their own drivers, and 32-bit Windows clients connect from Network Neighborhood or My Network Places and don't even need locally installed printer drivers—they can grab them from the server, so long as you made sure that the appropriate drivers were installed there. (We'll talk about how to install other drivers a little later in this chapter.)

**NOTE** *As you may recall, 16-bit Windows is not an operating system, it's a graphical operating environment for DOS. All DOS workstations must have locally installed printer drivers. You may need to install the driver more than once or install it to application directories to make sure the applications see the printer. You'll also need to manually update drivers should new versions become available (unlikely as that is).*

## CONNECTING FROM DOS

To set up LPT1 from DOS, type **net use lpt1: \\server\printername** at the command prompt, where *server* is the name of the print server and *printername* is the name of the printer. If you want to reconnect to this printer every time you log in to the network, add the **/persistent:yes** switch to the end of the command. Just typing **/persistent** won't do anything, but if you leave off the switch altogether, the connection will default to the persistency settings previously defined.

**TIP** *Not sure of the name of the print server or the printer? Type **net view** at the command prompt to see a list of all servers. Type **net view \\servername** to see a list of all resources shared from that server.*

For example, suppose you're setting up network printer support for a DOS workstation that does not have a locally connected printer. Some older DOS applications don't give you a chance to select

an output port—it's their way or the highway. Therefore, you'd like to automatically redirect *any* output sent to LPT1 to be intercepted by the network-accessible printer HP5 attached to the print server BIGSERVER. You want to remake this connection every time you log in to the network so that you don't have to worry about printer support.

The command to fulfill this set of conditions would look like this:

```
net use lpt1: \\bigserver\hp5 /persistent:yes
```

This command will work not only from DOS, but from the command line for any Windows operating system.

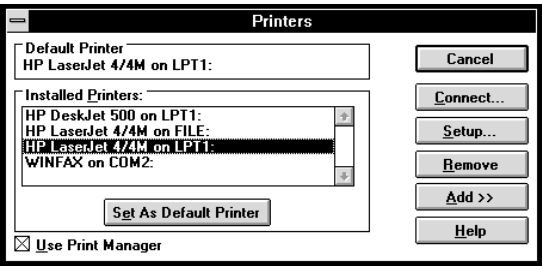

**CONNECTING FROM WINDOWS 3.X OR WINDOWS FOR WORKGROUPS**

To connect to a shared printer from network-enabled Windows or from Windows for Workgroups, select the Printers icon in the Control Panel. You should see a dialog box that shows the printer connections you already have, like the one in Figure 13.22.

What you do from here depends on whether you're just reconnecting to a previously established network connection, creating a new network connection to a printer you can support, or starting at the beginning by installing local support for the printer.

**FIGURE 13.22**

A list of installed printers for Windows for Workgroups

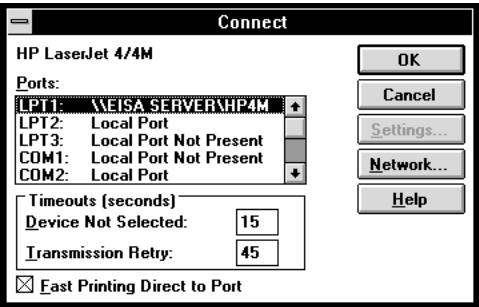

**Connecting to an Available Printer**

To connect to any of these previously connected printers, you just click the Connect button to open the dialog box shown in Figure 13.23. Click OK, and you're done.

**FIGURE 13.23**

Connecting a Windows for Workgroups client to a previously installed network printer

### Creating a New Network Connection

If you're connecting to a new printer, then instead of clicking Connect, choose the Network button to open the dialog box shown in Figure 13.24. Find the print server and printer you want and click OK.

**FIGURE 13.24**  
Creating a new connection to a networked printer

### Installing a Printer Driver for Win16 Operating Systems

If you haven't already installed support for the printer, you've got a couple steps ahead of you. Rather than clicking the Connect or Network button, click Add to see a list of installed printers and available printer types (see Figure 13.25).

**FIGURE 13.25**  
A list of available printer types

Find the printer you want from the list and click the Install button. The system will prompt you for the location of the printer drivers. Browse for the drivers or insert the requested disk.

Once you've installed the correct driver, you can create the network connection to the printer and connect to it.

### CONNECTING FROM WINDOWS 95 OR NT CLIENTS

The first time I connected to an NT printer from an NT Workstation back in 1993 (NTW predated Windows 95, you may recall), I thought that I must have missed a step—it was too easy. You don't have to install local driver support at all; just connect to the printer. 32-bit Windows clients don't use locally stored drivers but instead reference the ones you've installed on the server to support them. This not only saves you a step in the process of installing printer support, it makes it much easier to update printer drivers. When there's a new driver out, you don't have to run around to each client with a floppy disk or set up some kind of remote installation script—you just install it to the server, and when the clients connect, they'll use it automatically.

To install a printer from Windows 9x or Windows NT, open the **Printers** folder, accessible as a shortcut from the Control Panel, and start the Add Printer Wizard. Click the **Next** button to open the dialog box shown in Figure 13.26.

**FIGURE 13.26**

Specify that the printer is connected remotely, not locally.

Be sure to say that the printer will be managed by a printer server, not locally. Click **Next** and choose the printer you want from the list, as shown in Figure 13.27. Click **Finish** and the printer is locally available.

**TIP** *If you want to connect to multiple printers, you must do so one printer at a time.*

You can also connect to network-accessible printers from the NT and Windows 9x **Network Neighborhood**. Open **Network Neighborhood** and double-click the appropriate print server. As shown in Figure 13.28, **Network Neighborhood** will then display all resources shared from that server, including printers.

From here, you can right-click the appropriate printer and either capture the printer port (redirecting all output sent to, say, LPT1 to the network printer) or install support for the printer to make it accessible with UNC nomenclature.

**FIGURE 13.27**

Choose a printer from the list of servers and printers.

**FIGURE 13.28**

Installing printer support from Network Neighborhood

### CONNECTING FROM WINDOWS 2000 AND WINDOWS XP

The Add Printer Wizard in Win2K and Windows XP looks a little different from the one in Windows NT or Windows 9x, but the basic effect is much the same for all three operating systems:

1. Start the Add Printer Wizard and click through the obligatory Welcome to the Add Printer Wizard opening screen. When asked whether you want to create a local or network connection to a printer, choose the network option, as shown in Figure 13.29.
2. Next, indicate the printer's location. What happens here depends on whether your network is using NT 4 domains or the Active Directory.

If you're connecting from a Win2K/XP computer that's part of an NT 4 domain, then, as you can see in Figure 13.30, Win2K supports connecting to printers either in terms of the printer's name or by an intranet/Internet address, like this:

`http://printservername/printers/printername/.printer`

where *printservername* and *printername* are what they sound like: the print server and its share name. If you aren't sure of the printer's name, you can leave that space blank and browse for the print server. The browse function doesn't work for printers with their own name or URL; you must enter a valid name for the printer if you choose that option.

**FIGURE 13.29**

When connecting to a network printer, be sure to specify the network connection.

**FIGURE 13.30**

Type the name of the printer's server or its URL.

**TIP** Frankly, if you're connecting with a URL, it's a lot easier to do it from a browser so you can click links to printers rather than having to know their share names. One mistyped letter in that URL and you get an error message telling you that the printer setup utility could not connect to the printer. If you're using a browser, all you need to know is the name of the print server.

3. If you choose to browse for a printer, you'll see a browse list like the one in Figure 13.31, showing the printers on the network and the servers they're connected to. As you can see, any location information or comments attached to a printer will show up when you select a printer, so you can easily find the one you want.

**FIGURE 13.31**

Scan the list of available printers and choose the one you want to connect to.

If you're connecting from a computer with an account in the Active Directory, you have another option: searching the Active Directory for the printer you want. Check the box that says Find a Printer in the Directory and click Next, and instead of browsing as described previously, open a dialog box from which you can browse for printers by a collection of different criteria and in different parts of the Active Directory (users, computers, domain controllers, and so forth). You can also search for printers based on their name or on other criteria, such as what features they support. I've explained these settings in detail in "Connecting to a Network-Enabled Printer," earlier in this chapter. Although that section discussed connection from the perspective of a Server 2003 computer, the details are identical.

4. Once you've chosen the printer, the wizard will ask if you want to set up the printer as the preassigned printer for all applications (Figure 13.32). If you've already got a preassigned printer, the default option is No; if this is the first printer connection you're setting up, the printer is set up as the default without any prompting from you.

**NOTE** The default printer will have a check mark on its icon in the **Printers** folder.

5. Finally, the Add Printer Wizard will show you the options you've chosen so far, letting you click either Finish to install support or Back to change an option. If you've already got the drivers installed, that's it—you can use the new printer immediately. Otherwise, you'll have to copy the new drivers from the CD or your installation directory.

**FIGURE 13.32**

Specify whether the new printer should be the one all applications choose to print to.

The printer should appear in the Printers dialog box. Its icon will look like that of a locally connected printer, with the addition of a network connection attached to it.

### INTERNET PRINTING

If your network clients are running Internet Explorer 4 or later and you're having users connect to their own printers, forget the Add Printer Wizards: There's now a better way. If your print server is running IIS, people can connect to any shared printers from a browser and it's *really easy*.

**NOTE** *Although the documentation implies that this procedure might work with Netscape, I haven't been able to make it work. I'd stick with Internet Explorer.*

You have a couple of options when it comes to connecting to a printer via a Web browser. If you know the print server's name but not the name of the printer you want to connect to, then in the Address box in IE type **http://servername/printers** to open a browser page like the one in Figure 13.33. In this example, the name of the print server is CLONE300 (original, yes). You do need to know the print server's name. There's no "browse the network for printers" option built into this.

**NOTE** *If you're one of the people who avoids the pesky **http://** prefix by typing **www** instead (I do it so I don't have to squint at the screen to see that I typed both the colon and the two forward slashes), you should know that the **www** prefix won't work here. If connecting locally, you can just skip the **http://** prefix altogether, though, like this: **//printservername/printers**.*

To connect to a particular printer, click its link in the list to open the screen in Figure 13.34. You're not connected yet, you just have the option of connecting.

**FIGURE 13.33**

List of all available printers on a print server

**FIGURE 13.34**

You must explicitly connect to a printer to use it.

To connect to the printer, click **Connect** in the list of printer actions. A small status bar will display the progression as the print server sends you the drivers you need, and you'll be connected just as you would had you connected from the Add Printer Wizard. The only difference is that because the installation process is so simplified—you connect to a printer and you click **Connect**—you never get the option of setting the new printer as the default. If you want to make the new printer the default over an existing printer, you'll need to open the Printers folder, right-click the printer in question, and choose **Make Default** from the context menu.

**TIP** If you know the name of the printer, you can link to it directly like this: `http://servername/printername`. If you have permission to access the printer, then that puts you directly into the printer's information screen, from which you can connect to the printer.

As I said earlier, Internet printing represents an excellent way of simplifying client-side printer setup. If you have a corporate home page, you could put a link on the home page, something along the lines of “click **HERE** to connect to a printer.” The user clicks **THERE**, they go to the page where the printers are listed (and, by tweaking security settings, you can make sure that they only see the printer they’re supposed to connect to), they click the printer, and then click to connect. This works for any client that can run IE4 or later. If you’re connecting across the Internet, a dialog box appears asking for the domain name, username, and password; if you’re connecting locally, this dialog box does not appear.

### Using Client-Side Printers in a Terminal Server Environment

When the Terminal Services Edition of Windows NT was first released, the display protocol—the protocol downloading application output to the client machines and uploading keystrokes and mouse clicks to the server—had some holes in it. Remote and local sessions didn’t share a Clipboard, so you couldn’t cut and paste between applications running on the client and those running on the server. Remote control of sessions wasn’t supported. Session clients couldn’t use their locally connected printers without sharing them from the network and then connecting to them from the terminal server session.

Beginning with Win2K, terminal sessions could get local access to client-side ports. Using the new desktop client, clients can access their local printer from a terminal server session without sharing the printer with the network. The only catch is that it’s not quite as simple as that for all clients.

Win32 desktop client print requests sent to local printers will be automatically redirected to the local printer so long as you’ve previously installed the driver needed for the printer on the terminal server (and are using RDP 5 or later, since this feature requires the printer mapping virtual channel to be enabled). You’ll have to manually configure Windows terminals and Win16 clients to use locally attached printers.

#### AUTOMATICALLY REDIRECTING PRINTERS

Other than making sure the driver is installed on the terminal server, you don’t have to do anything to set up an automatically redirected printer. When a person with a client-side printer—locally attached or set up on the network—logs onto a terminal server and initiates a session, a fake print job owned by the Administrator is sent to the printer. This isn’t a real print job, just a notice to the printer that it’s being redirected for use with the terminal server session—you’ll probably never notice it if you don’t deliberately look at the status box for the printer during the second or two required for the redirection to take place. Behind the scenes, what’s happening is that the terminal server checks the name of the printer driver on the client and looks for the same printer driver on the terminal server’s `NTPRINT.INF` file. If the terminal server doesn’t find that driver name, then the Event Viewer will log error messages and the redirection won’t work.

Assuming the redirection does work, if you look in the **Printers** folder for the terminal server session, you’ll see the redirected printer there identified by its name, the name of the computer it’s connected to, and the number of the terminal server session. For example, the printer **HP Laser** that’s connected to the computer **MONSTER**, using Session ID4, will be identified in the **Printers** folder as **HP Laser\MONSTER\Session 4**.

For automatic printer mapping to work, all of the following must be true:

- ◆ The name of the printer driver on the client and the server must be identical. It's not enough that they be the drivers for the same printer—the names have to match.
- ◆ The client session must have printer redirection enabled.

If the printer *doesn't* automatically redirect, check the System event log in the terminal server to find out why.

### MANUALLY REDIRECTING PRINTERS

Win16 clients and those using Windows-based terminals (WBTs) will need to manually redirect printers. This may not always be possible with a WBT because the RDP client for older WBTs may not have been updated to version 5 (version 4 does not support redirection of client-side printers). However, new WBTs generally have the RDP5 or later client, and you should be able to get an updated client for older terminals that don't already include it.

To manually redirect a printer for a terminal services client, follow these steps:

1. Get the name or IP address of the client device. (If your Window's terminals don't use names—not all do—you'll need to use the terminal's IP address.) Start a terminal session from that client machine.
2. Start the process of manually adding a locally connected printer to the terminal server.
3. In the part of the wizard where you're choosing the port the printer is connected to, scroll down in the list until you see the name or IP address of the client computer with the printer attached, like this:  
Ts002 CLIENTPC LPT1
4. Choose that port to attach the printer to, and install the printer normally.

When a client disconnects or logs off a session, the printer queue is deleted and any incomplete or waiting print jobs are deleted. Once you have manually redirected a printer for a terminal session, that redirection will take place automatically thereafter, and the print queue will be automatically created from the information stored on the client.

### PREVENTING PRINTERS FROM BEING REDIRECTED

But what if you don't want clients to use their local printers during terminal server sessions? You may not, especially if the client is connecting to a printer across a dial-up connection. Sending a print job from terminal server to client-side printer may be acceptable at LAN speeds but unwise over a 56Kbps modem connection since sending the print job back to the client for printing can make the connection slow to a crawl. Or you may want people to use a networked printer for their terminal server sessions for auditing purposes. Whatever the reason, you may want to disable printer redirection.

To prevent printer redirection on a per-user basis, open the user account's properties pages and turn to the Environment tab. On that tab is a section called Client Devices, underneath which are three check boxes that control whether that person has access to client-side drives and client-side printers and whether that client should automatically print to the client-side default printer. By default, all three boxes are checked, enabling all client-side printers and drivers. To keep the client's printer

from being redirected to the terminal session, uncheck the box that says **Connect Client Printers at Logon**. To permit the user to redirect client-side printers but to keep the default printer from changing to the client-side default, uncheck the box that says **Default to Main Client Printer**. Alternatively, turn off printer redirection from the Remote Desktop Connection client on their computer. Turn to the Local Resources tab and make sure that the Printers box is unchecked. (To avoid duplicating effort, you can save settings and distribute them to users.)

If you don't want *anyone* connecting to the terminal server via a given display protocol to use their local printers, you can do this as well. Open the Terminal Services Configuration tool that's in the Administrative Tools section of the terminal server. Click the **Connections** folder in the left pane so that the installed display protocols (only RDP, unless you have MetaFrame installed) appear in the right. Open the properties pages for RDP and turn to the Client Settings tab.

There are two sections on this tab. The Connection section on the top is a duplicate of the Client Devices section of the per-user Environment properties just discussed. By default, the per-user settings control, but if you want to apply the settings discussed previously not just to individual users but to everyone using the display protocol, you can deselect the option that says **Use Connection Settings from User Settings** and edit the entries accordingly. The section at the bottom of the Client Devices tab controls which client-side resources are disabled. Disable client-side printing as follows:

- ◆ To prevent users from redirecting any client-side printers, deselect **Windows printer mapping**.
- ◆ To prevent terminal users from redirecting client-side printers attached to parallel ports, disable **LPT port mapping**.
- ◆ To prevent terminal users from redirecting client-side printers attached to serial ports, disable **COM port mapping**.

## Automatically Installing Printers

You've seen now how to get printers to people by walking through the installation wizards. However, this method requires you either to permit users to create their own printers—which is prone to error—or to install them yourself on each computer. In the interests of saving a little time, let's take a look at some methods of simplified printer deployment.

### INTERNET PRINTING

As I mentioned earlier, the best use of Internet printing is not, in fact, allowing people to send print jobs over the Internet—it's a security hole and will require an awful lot of bandwidth. Instead, consider using Internet printing to automatically set up printers. When a person connects to the printer via the Web page (which you have locked down as described earlier so that only their approved printers show), the driver is automatically downloaded to the client computer if it's not already there.

### PROGRAMMATICALLY INSTALLING PRINTERS

If you don't mind doing a little scripting, then you can also automatically install printers on the basis of user or computer identity when the user logs on—and then unmap the printer connection when a particular user logs off. As is true of scripting in general, this takes some work up front. However, for any task you'll be repeating on a regular basis, scripting it will save you an awful lot of time and trouble. This will only fully work on NT-based operating systems such as NT, Windows 2000,

Windows XP, and Windows Server 2003, but if you preinstall drivers onto Windows 9x computers it will work there as well.

**NOTE** A Resource Kit tool called *PrintAdmin* enables you to programmatically install and manage printers on the local computer or remote computers running NT operating systems. To use it, you'll need to know how to use VBScript, and, to be perfectly frank, I think the method I'm describing here is easier and completely adequate if installing is your main goal.

I don't have space for a complete treatise on scripting Windows 2000 here, but the basic idea is this: Win32 operating systems support a scripting environment called Windows Scripting Host (WSH) that enables you to run VBScript and JScript scripts to perform tasks that you'd normally have to perform by hand. In scripting, real objects such as printers are represented by scripting objects, which you manipulate by addressing the *properties* (characteristics) of those objects and exploiting their *methods* (things they can do). Objects are nouns, properties are adjectives, and methods are verbs. WSH is supported on all Win32 operating systems. WSH abstracts the interface to a number of Win32 objects. One of these is `WshNetwork`, a collection of network resources—shared drives and printers. It can also “see” the name of the computer the script is running on and the name of the person currently logged on; the computer name (`.ComputerName`), username (`.UserName`), and computer domain (`.UserDomain`) are all properties of the `WshNetwork` object.

**TIP** For those who've never touched scripting before, create scripts in a text editor such as Notepad and save them with a `.vbs` extension. Windows cannot interpret VBScript—this isn't a command-line language like the `net` commands.

For our purposes, we care about only `WshNetwork`'s printing-related methods. To map a printer explicitly to a port as you would with `net use`, use the `.AddPrinterConnection` method. To create a Windows printer connection (and automatically install the driver on NT-based operating systems) use the `.AddWindowsPrinterConnection` method—this is the method I'll use here. To set the default printer for a computer, use the `.SetDefaultPrinter` method.

### Creating a Generic Printer Connection

Good so far? Let's take a look at the simplest way of accomplishing this with VBScript:

```
Option Explicit
Dim oNetwork, sPrintPath
Set oNetwork = CreateObject("WScript.Network")
sPrintPath = "\\sandworm\printer"
oNetwork.AddWindowsPrinterConnection sPrintPath
oNetwork.SetDefaultPrinter sPrintPath
Set oNetwork = vbEmpty
Set sPrintPath = vbEmpty
```

In this example, I've defined the variables the script will use (so that if I mistype a variable name then I'll get an error message instead of a new variable), created a connection to the `WshNetwork` object (which we must do to call on its properties and methods), assigned the UNC path to the shared printer path to the `sPrintPath` variable to make the path information easier to deal with, and then called on the appropriate methods to create the printer and make it the default, supplying the variable

representing the printer path as an argument. Finally, I've been a good little coder and set the variables I used equal to `vbEmpty` now that I'm done with them so that the memory required to support those variables may be released. So long as I assign a valid path in line 4, then this script will work on any NT-based computer. To make this script work for yourself, just replace the highlighted path in line 4 with a valid shared printer UNC path.

Incidentally, there's nothing stopping you from using this script to install support for more than one printer but making one of those printers the default. You'll need one variable for each separate UNC path to the printers for which you want to install support.

### **Creating a Computer- or User-Specific Printer Connection**

Thing is, you probably don't want to install the same printer on every computer in the network. Rather, you'd prefer to establish a connection based on user identity or computer name—particularly the latter because it's often more important that the printer you use be close to where you're sitting than that it be assigned to you personally. That script could look something like this:

```
Option Explicit
Dim oNetwork, sPrintPath
Set oNetwork = CreateObject("WScript.Network")
Select Case oNetwork.ComputerName
    Case "Gamma"
        sPrintPath = "\\sandworm\printer1"
    Case "Geektoy"
        sPrintPath = "\\sandworm\printer2"
    Case Else
        sPrintPath = "\\sandworm\printer3"
End Select
oNetwork.AddWindowsPrinterConnection sPrintPath
oNetwork.SetDefaultPrinter sPrintPath
Set oNetwork = vbEmpty
Set sPrintPath = vbEmpty
```

As you can see, this script starts out just like the other one: I've defined the variables I'm using and established a connection to the `WshNetwork` object. By including the `Select Case` statement, however, I've allowed the script to read the local computer name and make a decision about what printer to install based on that information. I've included two valid options, but just so I don't have to create options for *every* computer on the network I've also included a `Case Else` option that says in effect, "If you can't do anything else, do this." The value of the computer name determines the value for `sPrintPath`, which then gets plugged into the `.AddWindowsPrinterConnection` and `.SetDefaultPrinter` methods as in the previous example. Again, replace my computer names and printer paths with yours.

I could have done exactly the same thing using the name of the user logged in as the argument for `Select Case`. Taking only the `Select Case` snippet, that could have looked like this:

```
Select Case oNetwork.UserName
    Case "Christa"
        sPrintPath = "\\sandworm\printer1"
```

```

Case "Mark"
    sPrintPath = "\\sandworm\printer2"
Case Else
    sPrintPath = "\\sandworm\printer3"
End Select

```

The rest of the script looks just like the previous example. User-specific mappings are not persistent, incidentally. If Christa logs on and gets her printer mapped, then logs off, when Mark logs on and gets his printers mapped he will not see both Christa's printers and his printers—just his. If you want to disable a computer-specific mapping or a mapping not replaced by another mapping, however, you'll need to manually remove the printer or use the `.RemovePrinterConnection` method to `WshNetwork`, supplying the printer path as an argument as you did to add the printer. For example, you could create a script to include in the logoff script for Windows 2000 computers.

### ***Creating a Location-Specific Printer Connection***

The previous example allows us to create a default printer based on which computer the script runs on. As you can see, though, you'll need to either create options for each computer on the network, or make up more than one version of the script to distribute according to computer location. In a large network, either option could get cumbersome. There is a third way: you could ask the user to tell you where they are in broad terms (e.g., "library" or "second floor") and then install the appropriate printer based on that information. For example:

```

Option Explicit
Dim oNetwork, sPrintPath, sLocate
Set oNetwork = CreateObject("WScript.Network")
sLocate = _
    InputBox("Where are you? Type 'Lab', 'Library', or 'Reception'.")
Select Case sLocate
Case "Lab"
    sPrintPath = "\\sandworm\printer1"
Case "Library"
    sPrintPath = "\\sandworm\printer2"
Case "Reception"
    sPrintPath = "\\sandworm\printer3"
Case Else
    Wscript.Echo "That is not a valid choice." :Wscript.Quit
End Select
oNetwork.AddWindowsPrinterConnection sPrintPath
oNetwork.SetDefaultPrinter sPrintPath
Set oNetwork = vbEmpty
Set sPrintPath = vbEmpty

```

What I've done here is create an input box prompting the person running the script to tell me where they are. Based on that input, the script will assign a printer to their computer. If they type an invalid choice, then the script nags at them and ends—that's what the `Wscript.Quit` method does. Alternatively, you could assign a generic printer if the person running the script didn't choose one of

the three valid options. This script does require user input, but so long as you trust your user base to know what part of the building they're in, it should work.

**TIP** Use the location-specific printer installation script as a template for creating default printers based on user location. If you use group policies to disable the Add Printers applet in the Control Panel and hide shared printers by ending their names in a dollar sign (\$), then people will be able to connect to only the printers programmatically assigned to their username, computer name, or location—and you can set the default. This will keep the people in Lab A from mistakenly sending their print jobs to Lab Z, three buildings away.

WshNetwork methods are not the only ways to manage printers through VBScript, but without getting into Windows Management Instrumentation (WMI) and the Active Directory Services Interface (ADSI), they are the simplest. For much more information about scripting Windows 2000 administration, check out *Windows 2000 Automated Deployment and Remote Management* (Sybex, 2001), a guide to using VBScript for Windows 2000 management for anyone who's used to working from the GUI. I've also written several "Scripting Solutions" columns for Windows and .NET Magazine, available from [www.winnetmag.com](http://www.winnetmag.com), which go into some more detailed scripted printer installations using WMI and ADSI to work with computer IP addresses and group memberships.

## Securing Printers

Just because you've networked a printer doesn't mean you want everyone with a domain account to be able to use it. Maybe you'd like to reserve the color printer for people who need to use the more expensive ink, or you want to keep people from printing their résumés after hours. Perhaps it's something as simple as wanting to make sure people connect to the right printer so you're not plagued with people complaining that their job didn't print when they've actually sent five copies to the wrong printer. In this section, let's talk about what you can do to make printers available only to the people you say at the times you say.

**TIP** Printer security doesn't always give you the degree of granularity you need to give everyone the permissions they need and no more. Consider setting up multiple printers for each print device, setting different permissions for each, and only giving people access to the printer tuned for their needs.

## Tuning Printer Permissions

You can make printers available all the time to everybody, or you can pick and choose the times and circumstances under which the printer will be available. Here's how.

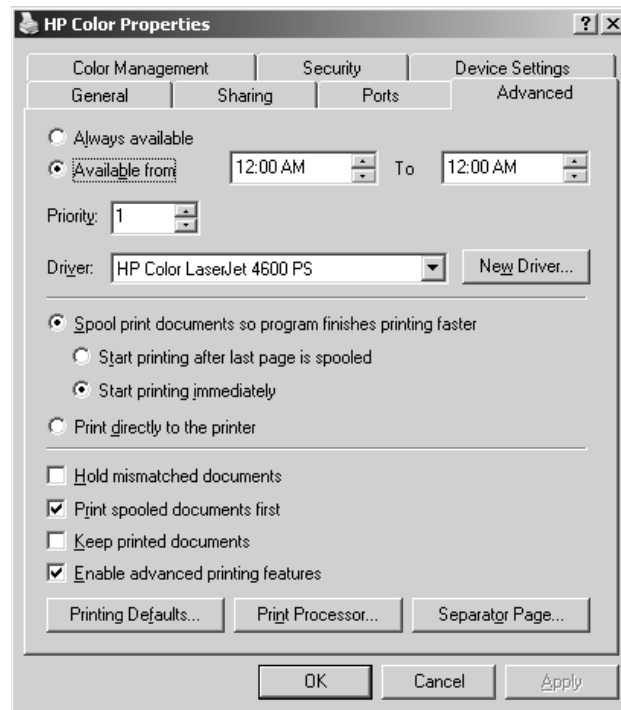

### SETTING AVAILABLE HOURS

By default, a printer will always accept print jobs. You can determine the hours during which a printer will send jobs to the print device. If a print job is sent to a printer after hours, the job will be queued but not printed until the printer is again available.

To edit a printer's hours of availability, turn to the Advanced tab of its properties pages (see Figure 13.35) and set new times. This tells the print server to hold print jobs in the spooler until the printer is again available. The new settings won't affect any jobs that have already been sent to the printer.

**FIGURE 13.35**

Define times for the printer to be available.

If you want a print device to be always available to some users and only available during certain hours to others, you'll need to create multiple printers for the single print device, as explained earlier in this chapter. Once you've done so, you can configure the printing hours separately for each printer.

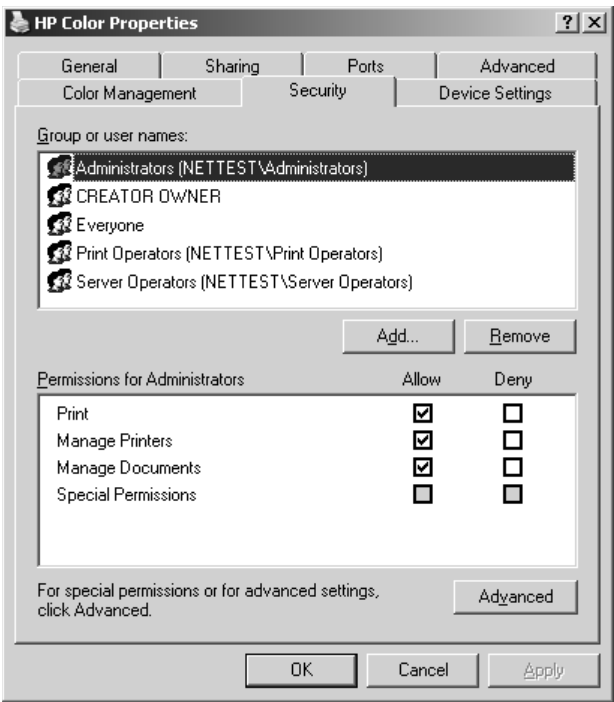

### SETTING PRINTER PERMISSIONS

Those familiar with the NT/Win2K argot will remember that you secure an NT-based network by defining user rights for what people can *do* on the network and setting permissions for the resources that people can *use*. Printer security is controlled with permissions on a per-group or per-user basis. Permissions generally stack—that is, the most permissive set of permissions available to you applies—unless you're talking about denied access. Denied access overrides permissions.

To set or edit the permissions assigned to a printer, log in with an account that has Administrator permissions, open the printer's properties pages, and turn to the Security tab. You'll see a dialog box like the one in Figure 13.36.

**TIP** If you turn to a printer's Security tab and see a list of Security IDs (SIDs) instead of user or group names, and the cursor changes to an hourglass when over the dialog box, don't panic. The print server is retrieving the names from the domain controller and will show the user and group names after a few seconds. If this doesn't happen—if the SIDs never resolve to user and group names—then there's something wrong with either the domain controller or the connection between the two servers.

**FIGURE 13.36**  
Default printer permissions

From here, you can edit the basic permission sets of the groups for whom some kind of printer access has been defined, denying or granting explicit access in three areas: printing (the ability to send print jobs to the printer), managing print jobs (the ability to control whether a print job is printed or the order in which it's printed relative to other jobs), or managing the printer (controlling *all* printing activity on a printer).

**NOTE** Table 13.3 includes a complete list of all permissions and how they apply to printers.

Not sure how to interpret the check boxes? If a permission is checked, then it's either explicitly enabled or disabled, depending on which box is checked. If a permission is clear on both sides, then it's implicitly enabled. Shaded permission boxes imply that a permission is granted or denied through inheritance. You can explicitly enable or disable the permission by checking the appropriate box.

**Fine-Tuning Printer Access**

The Security page only shows the default groups and the basic permissions they've been assigned. For more control over the permission process, click the Advanced button to open the dialog box seen in Figure 13.37.

From here, you can see the state of the defined permissions and whether they're allowed or disallowed. To begin with, all defined permissions are allowed. The comment below the list of users and groups notes whether the highlighted permission applies to the basic membership of that group only or also to subgroups within that group. You can adjust these permissions either by adding new

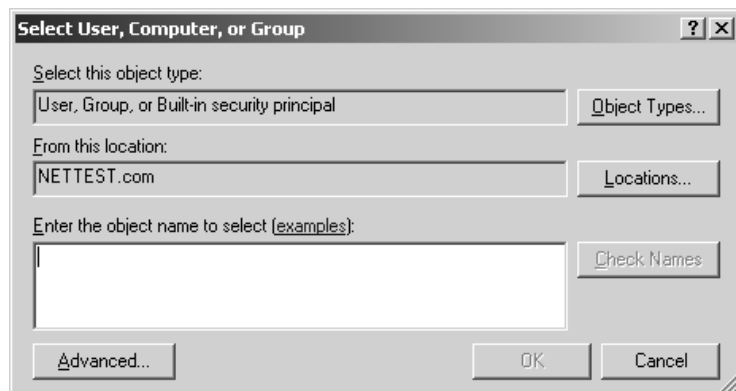

users or groups to the list (getting them from the domain controller) or by editing the permissions of the groups already there.

**FIGURE 13.37**  
Setting advanced  
printer permissions

To define permissions for a new user or group, click the Add button to open the dialog box in Figure 13.38. If you know the name of the user or group account you want to set printer permissions for, then you can type it here, clicking the Check Names button to confirm that the user or group account exists. If a user or group account beginning with the string you typed exists, then the name will be underlined in the text box in this dialog box.

**FIGURE 13.38**  
Choosing a user or  
group account for  
which to configure  
printer permissions

If there's more than one match (for example, I have one account that I use for administrative purposes and another that I use in Ordinary User mode, but both have my name in them), then a dialog box like the one in Figure 13.39 will prompt you to choose the one you mean. If there are *no* matches for the string you typed, then clicking Check Names will display a message box telling you so and nagging you to try again.

**FIGURE 13.39**

There may be more than one match for the string you're checking

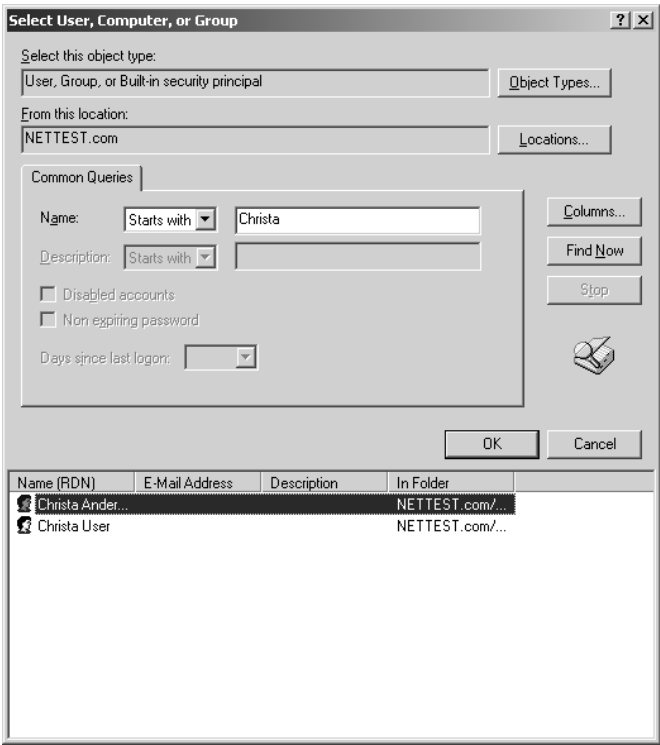

Theoretically, if you're not sure of the name, you can search for it by clicking the Advanced button to open the dialog box in Figure 13.40. You can even edit the columns setting to include more information in the results of the query, to make sure that you've got the right person. However, if you click the Name drop-down list, you'll see that you can search for either the exact name or the name that the account you need begins with. In other words, you can perform the exact same search that you can perform from the standard search tool shown in Figure 13.38. The moral of the story is that you need to know at least the beginning—at least the beginning *letter*—of any account for which you want to configure printer permissions.

Anyway, let's get back to configuring printer permissions for the account we've found. Once you've clicked OK in the dialog box in Figure 13.38, you'll open a dialog box like the one in Figure 13.41. The permissions listed here have the characteristics outlined in Table 13.3.

**TIP** If the user or group you want isn't displayed in the list, type it into the Name box. If you've already created an account for this user or group, you'll be able to edit its permissions.

You can customize user permissions by explicitly permitting some actions and denying others. For example, permission to manage printers normally implies permission to change permissions for that printer. However, you can get around this by allowing printer management while denying the ability to change permissions. This doesn't always work—you can't permit people to print yet deny them the ability to read permissions—but it's worth experimenting to see whether you can get the degree of granularity you want in access permissions.

**FIGURE 13.40**  
Performing an  
advanced search for  
an account name

**FIGURE 13.41**  
Defining the  
permissions of a  
new user

**TABLE 13.3: PRINTER PERMISSIONS AND THEIR IMPLICATIONS**

ACCESS TYPE	EFFECT	TIED TO
Print	User can send jobs to the printer.	Read permissions
Manage Printers	User can change printer properties and permissions.	Print, read permissions, change permissions, and take ownership of the printer
Manage Documents	User can control document-specific settings and pause, resume, restart, and delete spooled print jobs.	Read permissions, change permissions, and take ownership of the printer
Read Permissions	User can see the permissions all users and groups have for that printer.	N/A
Change Permissions	User can change the permissions all users and groups have for that printer.	Read permissions (although this won't be checked)
Take Ownership	User can take ownership of the printer.	Any permissions assigned to the creator/owner of the printer

**NOTE** *Printer permissions can apply to the printer only, to documents only, or to both the printer and the documents printed on it.*

Changing permissions for an existing user or group works in much the same way: Select a name, click the View/Edit button, and you'll see the same set of options to explicitly grant or deny permissions.

Since a user account may belong to more than one group, and those groups may have different permissions, it can sometimes be hard to sort out what permissions an individual has. The Effective Permissions tab in Server 2003 should theoretically make it easier to sort this out, but doesn't do a very good job of it, since edited permissions are checked but look identical whether they're allowed or denied (see Figure 13.42).

**Auditing Printer Access**

Curious to know who's doing what to the printers under your care? Turn to the Auditing tab shown in Figure 13.43 (accessible from the Advanced button of the Security section of a printer's properties) to set up auditing to list events in the event log. Unlike Windows 2000, in Server 2003 you don't need to turn on auditing—it's on by default.

Although Server 2003 has security auditing enabled, it's not set up for printer auditing. By default, the print server doesn't log printer use or security events, so the list on the Auditing tab of a printer's properties pages will be empty when you originally turn to it. To add events to audit, click the Add button to move to a dialog box like the one you used to edit printer permissions (see Figure 13.44). Again, you can enter either the exact name of the user or group account to audit, or you can enter the beginning of the account name. Just make sure that you check the names for validity before continuing, or your audit won't do much good—monitoring a nonexistent account and all.

**FIGURE 13.42**

Sadly, the Effective Permissions tab doesn't tell you much.

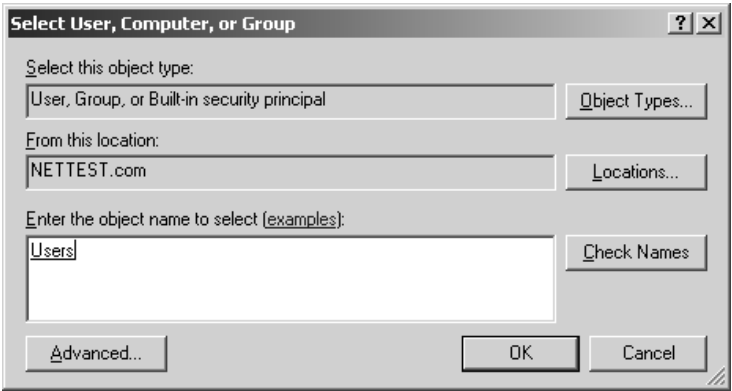

**FIGURE 13.43**

Print servers don't initially audit any events.

**FIGURE 13.44**

Choose a group or user to audit.

As when setting printer permissions, you'll first choose a group or user to audit from the list, then you'll choose events to audit. After you've chosen a group or user to audit and clicked OK, you'll move to a dialog box like the one in Figure 13.45.

**FIGURE 13.45**

Choose the events to audit.

The dependencies shown here work the same way as the ones described in Table 13.3. The main difference is that here you're monitoring the attempts to *do* these things, not granting or denying permission to do them. Also, the Successful and Failed columns aren't mutually exclusive like the Allow and Deny ones are—you can monitor both failed and successful attempts to take ownership of a printer, for example. When you've finished tweaking the auditing options, click OK to return to the main Auditing tab, which will now look something like the one shown in Figure 13.46. Entries for these audits will now appear in the Security portion of the Event log.

**FIGURE 13.46**

A list of users and events to audit

### ***Assigning an Owner to a Printer***

Even if a printer's owner is a user (and thus has minimal control over a printer), that owner has permission to manage documents—a permission ordinary users do not normally have. Administrators can give the printer to a new owner from the Owner tab of the Access Control Settings dialog box accessible from the advanced security options. The options are the person who made the printer in the first place and an administrator of the domain, as you can see from Figure 13.47.

To make a new owner, just double-click the appropriate entry. You'll open the by-now familiar dialog box from which you can choose user accounts. Find the person you want to be an owner of that computer, and click OK. That person's name will be listed alongside the other printer owners.

**FIGURE 13.47**

A list of possible owners for the printer

## Group Policy Settings for Printers

Server 2003 has some group policies that you can edit to configure how much control users have over adding and removing printers and over how those printers appear in the Active Directory.

### PRINTER-SPECIFIC GROUP POLICY SETTINGS

The Group Policy settings in the Microsoft Management Console include some policies you can tweak to configure how the printer appears in the Active Directory or in the domain (see Figure 13.48). To get to these settings, open the Group Policy snap-in and move to the Administrative Templates section of the Computer Configuration settings. As you can see from Table 13.4, some of these settings apply only to Active Directory–aware clients, but others apply to any client because they’re actually settings to the print server or the way the printer is published in Active Directory.

When you first install the operating system, none of these settings will be configured. To enable or disable a policy, right-click that policy and choose Properties from the pop-up list that appears. You’ll see a dialog box that looks like the one in Figure 13.49.

Click appropriate radio buttons to enable or disable the policy, and enter a value as needed. If you need more information about what a policy actually does if enabled, turn to the Explain tab, but this information also appears in the left margin of the policy pane when you’ve selected a policy, as shown in Figure 13.49. Once you’ve chosen to actively clear or check a box, the policy’s entry will change from Not Configured to Enabled or Disabled.

**FIGURE 13.48**  
Group policies  
controlling printer  
publishing

**TABLE 13.4: PRINTER PUBLICATION POLICIES**

POLICY	DEFAULT VALUE (WHEN UNCONFIGURED)	DESCRIPTION
Allow Printers to be Published	On (permits publishing)	Toggles to allow printers to be published. If a printer isn't published, clients can't find it in the Active Directory using the procedure described earlier. When configured, overrides Automatically Publish New Printers in Active Directory policy.
Allow Pruning of Published Printers	On (will prune)	Controls whether the pruning service may remove printers that it can't find when browsing for them. If you enable this option, you can tune it with the pruning interval, retry, and priority policies.
Automatically Publish New Printers in Active Directory	On (will publish)	Controls whether newly shared printers are added to the Active Directory. Allow Printers to be Published overrides this policy, so if that policy is disabled, printers will not be published even if this policy is enabled.
Check Published State	Only at startup	Verifies that published printers are indeed in the Active Directory. You can set this value to Never (the default) or at varying intervals ranging from 30 minutes to 1 day.

*Continued on next page*

**TABLE 13.4:** PRINTER PUBLICATION POLICIES (*continued*)

POLICY	DEFAULT VALUE (WHEN UNCONFIGURED)	DESCRIPTION
Computer Location	None	Identifies the location of the printer server. Use this setting in combination with Prepopulate Printer Search Location Text to make people choose a particular location for their printer, avoiding the possibility of choosing the wrong printer and sending print jobs three states away.
Custom Support URL in the Printer Window's Left Pane	Off	Ordinarily, the left window of the Printers folder displays the Microsoft URL and (if available) the URL for the printer's maker. If you enable this policy and type in a URL, you can point people to a different location—perhaps a customized troubleshooting guide on the company Web site.
Directory Pruning Interval	8 hours	Determines the interval at which printers that haven't announced themselves recently are removed from the directory of published printers. The pruner reads this value every hour, so changes will not take effect immediately. This policy applies only to domain controllers.
Directory Pruning Priority	Normal	Tunes the priority of the pruning thread, responsible for deleting outdated printer entries in the Active Directory. The higher the priority of the pruner thread (or any thread), the more often it will get CPU cycles and thus the more often the Active Directory will be updated—but the fewer CPU cycles the other threads will get. You can set this value to Lowest, Below Normal, Normal, Above Normal, or Highest. This policy applies only to domain controllers.
Directory Pruning Retry	2 tries	Determines how many times the pruning thread will attempt to contact a print server before giving up and deleting that printer's entry from the Active Directory. This policy applies only to domain controllers.
Prepopulate Printer Search Location Text	On	Enables location tracking (based on the subnet of the printer server and the client) and a browse feature. Use this feature to point people to a certain location for their printers.
Printer Browsing	Off in domains using the Active Directory; on in NT 4 domains dependent on browsing to publish resources	Controls whether the print subsystem can add printers to the browse list. In a domain that uses the Active Directory, the print subsystem does not announce printers to the master browsers in the domain. If you disable printer browsing, you prevent the print subsystem from announcing the printers even in an NT 4 domain.

*Continued on next page*

**TABLE 13.4:** PRINTER PUBLICATION POLICIES (*continued*)

POLICY	DEFAULT VALUE (WHEN UNCONFIGURED)	DESCRIPTION
Prune Printers That Are Not Automatically Republished	Never	Controls the circumstances under which a printer connected to a computer running an operating system not using the Active Directory or a printer published outside its own domain—and thus not controlled by the domain-level pruning rules earlier in this table—may be pruned. Choosing Never means that the printer will never be pruned. Choosing Only When the Print Server Is Found means that the printer will be pruned if the print server is found but the printer isn’t available. Choosing Only When the Printer Isn’t Found prunes printers that are not automatically republished. This setting applies only to printers published from Active Directory Users and Computers, not from the Printers section of the Control Panel.
Allow Print Spooler to Accept Client Connections	No, until a client shares a printer with the network or views the print queue on a shared printer	Server 2003 only
Web-Based Printing	Web-based printing allowed	When disabled, won’t accept print requests sent via HTTP, or publish printers to the Web. You’ll still need to enable the Internet Printing Web extension, though.

**FIGURE 13.49**  
Configuring print server policies

***TIP** You can run through the list of policies with the Previous Setting and Next Setting buttons without exiting and reentering the policy properties box. The only catch is that if you click Cancel, you'll cancel every policy change you made while the window was open.*

**USER-SPECIFIC PRINTER SETTINGS**

To edit user settings for adding and removing printers, click Start/Programs/Administrative Tools/Active Directory Users and Computers. Click the Active Directory container of the domain you want to manage (an organizational unit or a domain). Right-click that container, and then click Properties. On the Group Policy tab, click New to create a new group policy, then Edit to open the Group Policy Editor. The settings you're looking for are in User Configuration/Administrative Templates/Control Panel/Printers and are described in Table 13.5.

***WARNING** These settings generally apply to the Add Printer Wizard. If someone uses the Add Hardware tool to add a printer, for example, then they can circumvent Disable Addition of Printers.*

**TABLE 13.5:** GROUP POLICIES FOR USER CONTROL OVER PRINTERS

POLICY	DESCRIPTION
Browse a Common Web Site to Find Printers	Adds the path to an Internet or intranet Web page to the Add Printer Wizard. You can use this policy to direct users to a Web page from which they can install printers, making it easy for users to find the printers you want them to add. Without this policy, users must know the exact URL of the print server configured for Internet printing. When users click Browse, Windows opens an Internet browser and navigates to the specified address to display the available printers.
Browse the Network to Find Printers	Permits users to browse the network for shared printers from the Add Printer Wizard. If you disable this policy, users will need to know the exact name of a printer to connect to it from the Add Printer Wizard.
Default Active Directory Path When Searching for Printers	Specifies the Active Directory location in which searches for printers begin. If you enable this policy, these searches begin at the location you specify in the Default Active Directory Path box. Otherwise, searches begin at the root of Active Directory. However, this policy does not restrict searches to that point.
Point and Print Restrictions	When enabled, restricts users either to the printers named here (identified by fully qualified domain names) or to the printers in their forest, depending on which setting you pick. (XP SP1 and Server 2003 only)
Prevent Addition of Printers	Removes the Add Printer Wizard from the Start menu and from the Printers folder in Control Panel. This policy does not prevent users from accessing Add/Remove Hardware or running a program (such as an administrative script) to add a printer. Nor does it delete printers already added—it just prevents them from using the Add Printer Wizard to add more of them.

*Continued on next page*

**TABLE 13.5:** GROUP POLICIES FOR USER CONTROL OVER PRINTERS *(continued)*

POLICY	DESCRIPTION
Prevent Deletion of Printers	Prevents users from deleting local and network printers. If a user tries to delete a printer, such as by using the Delete command in the Printers tool in the Control Panel, Windows displays a message explaining that the action is prevented by a policy. This policy does not prevent users from running programs to delete a printer.

## Configuring Printer Settings

Sharing a printer with the network and securing it isn't generally the end of the story. You haven't yet added support for separator pages used to help dozens of printer users avoid picking up each other's documents, and you haven't configured messaging so the right people get printer messages. And what about setting up printer priorities so that the print server will print user documents on the right printer, without user intervention?

**NOTE** *The options described in this section apply to both network and locally connected printers.*

To configure a printer's settings, right-click its icon in the printer's properties pages and choose Properties from the pop-up menu that appears (see Figure 13.50).

**FIGURE 13.50**  
Use this dialog box to fine-tune a printer's settings.

Most of the basic configuration options, such as name changes and sharing, are pretty self-explanatory once you look at the screen. I'll go over the more complex options, but if you're trying to figure out where an option is configured, refer to Table 13.6 for a quick guide to what's where.

**TABLE 13.6:** PRINTER OPTIONS AND LOCATIONS IN THE PROPERTIES PAGE

OPTION TO CHANGE	LOCATION	REASON TO EDIT
Add more client drivers	Additional Drivers dialog box, available from the Sharing tab	Load drivers for printer clients so they can be automatically downloaded to the client (available for 32-bit Windows and Itanium only).
Add more ports	Ports tab	Restore ports that you've deleted or add support for direct network connections to the printer.
Change port time-outs	Ports tab when you click the Configure Port button	Increase port time-out settings to make ports wait longer to receive printer data. Helps if the print job isn't getting to the printer quickly enough.
Edit printer configuration settings	Device Settings tab	Edit the printer settings, including the amount of memory installed, fonts installed on the printer, page protection, and the like.
Edit user or group permissions to the printer	Security tab	Edit the list of users or groups with access to the printer or change the permissions they have.
Set the hours printer will accept print jobs	Advanced tab	Edit to shut off a printer after certain hours, perhaps when the workday is over.
Change local printer name	General tab	Use for local printer identification.
Change network printer name	Sharing tab	Use for printer identification on the network.
Set the page order	Layout tab of Printing Preferences dialog box, available from the Printing Preferences button on the General tab or the Printing Defaults button on the Advanced tab	Toggle between printing pages in normal or reverse order.
Set paper orientation	Layout tab of Printing Preferences dialog box, available from the Printing Preferences button on the General tab or the Printing Defaults button on the Advanced tab	Toggle between portrait and landscape orientation of printer output.

*Continued on next page*

**TABLE 13.6:** PRINTER OPTIONS AND LOCATIONS IN THE PROPERTIES PAGE *(continued)*

OPTION TO CHANGE	LOCATION	REASON TO EDIT
Identify the paper source	Paper/Quality tab of Printing Preferences dialog box, available from the Printing Preferences button on the General tab or the Printing Defaults button on the Advanced tab	Choose a different paper tray to print from, perhaps for higher-quality paper or printing from transparencies.
Set the print processor	Print Processor button on the Advanced tab	Toggle between default print formats (EMF, TEXT, or RAW).
Set the printer spooling	Advanced tab	Toggle between using printer spooling and sending documents directly to the printer.
Edit separator pages	Separator button on the Advanced tab	Specify a new separator page for print jobs.
Enable printer pooling	Ports tab	Use to connect two or more print devices to a single printer.

### Defining Port Settings

Port settings control how the print server sends print jobs to its ports. You can't do too much to configure ports other than define which port a printer sends print jobs to and, in the case of parallel ports, how long the printer is willing to wait for an expected print job before reporting an error condition. Unless I say otherwise, you'll be controlling most port settings from the Ports tab (see Figure 13.51).

#### ASSIGNING A PRINTER TO A NEW PORT

If you move a print device from one port to another, you'll need to edit the device's port settings. Open the printer properties pages, turn to the Ports tab, and check the box next to the correct port. Notice that you can select multiple ports only if printer pooling is enabled.

Not sure what all those ports are? TS ports are printer ports of terminal server sessions. LPT ports are parallel (8-bit) ports. COM ports are serial (1-bit) ports. Finally, any port prefaced with a server name indicates a network connection. The terminal server session ports show the ports attached to currently connected terminal server clients and can be used to manually redirect ports, as described in "Manually Redirecting Printers." Any TCP/IP ports you've installed for network-connected printers will also appear in this list.

#### CREATING A PRINTER POOL

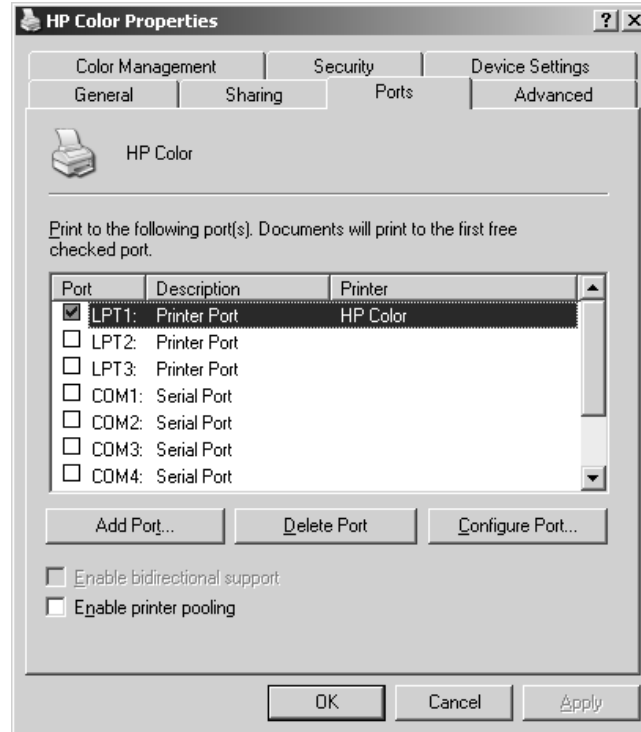

As I mentioned in the beginning of this chapter, the ratio of printers to print devices isn't always 1:1. You've already seen how you can create multiple printers for a single print device. I'm talking here about how to make a single printer support multiple print devices.

Why would you want to do this? It's mostly a matter of efficiency. Even with the fast print devices available today, busy offices may have more print jobs coming through than one printer can handle.

To keep things running smoother and reduce delays, you can distribute print jobs among multiple printers. Print clients will all send their print jobs to the same printer, but the jobs will go to the printer that's least busy at any given time. This is called *printer pooling*.

**FIGURE 13.51**

The Ports tab for a printer

To set up a printer pool, turn to the Ports tab for the printer. Make sure the box enabling printer pooling is checked, then select all the ports to which printers in the printer pool are attached. These ports can be local ports, ports connected to terminal server clients, or network ports.

There are a couple catches to printer pooling. First, the printers in the pool must be identical to each other—same make, model, and amount of installed memory. Second, I highly recommend putting the pooled printers in the same physical location. It's not going to endear you to your user base if they have to wander from place to place looking for their print jobs.

**TIP** Consider using separator pages with usernames in printer pools since users will not necessarily know which printer their job went to.

### SENDING DOCUMENTS DIRECTLY TO THE PRINTER

As I explained in the description of the printing model at the beginning of this chapter, the print server normally creates a spool file that's sent to the printer for printing rather than sending documents directly to the printer port. Spooling documents means the application you're printing from is only tied up for the time it takes to create the spool file, not to print the entire document. This is called *printing in the background*.

If you can't use print spooling for some reason—perhaps if the print server's hard disk is so full that it can't create the spool file—then you can send documents directly to the printer port, without creating a spool file or using print server resources. Turn to the Advanced tab of the printer's properties pages and select **Print Directly to the Printer**, as shown in Figure 13.52.

**FIGURE 13.52**

Disabling print spooling

*This is not something you'll often want to do. Spool files allow you to print large and complex documents without running out of printer memory. They also allow users to regain control of their applications quicker. Only disable print spooling if you can't print otherwise—it's something to mess around with if images aren't coming out properly.*

## Using Separator Pages

When a lot of people are using the same printer, keeping print jobs organized can get complicated. To help you minimize the number of people who wander off with each other's print jobs, the operating system supports separator pages. These extra pages are printed at the beginning of documents to identify the person doing the printing, the time, the job number, or whatever other information is defined in the page. (I'll explain how you can tell what information a page will print, and how you can create your own custom separator pages, in a minute.)

**TIP** Like other printer options, separator pages are assigned to printers, not to print devices, so you can use a different separator page for each printer.

CHOOSING A SEPARATOR PAGE

By default, printers don't use separator pages. To use one of the default separator pages provided with Server 2003, move to the Advanced tab of a printer's properties pages and click the Separator Page button. You'll see a dialog box like the one in Figure 13.53.

FIGURE 13.53

Choose a separator page.

Type the name of the separator page or click the Browse button to open the %systemroot%\system32 folder (where the pages are stored) and find the one you want. Table 13.7 describes the four built-in separator pages.

TABLE 13.7: DEFAULT SEPARATOR PAGES		
PAGE NAME	DESCRIPTION	COMPATIBILITY
SYSPRINT . SEP	Prints a blank page before print jobs	PostScript
PCL . SEP	Switches a dual-language printer to PCL mode	PCL
PSSCRIPT . SEP	Switches a dual-language printer to PostScript mode	PostScript
SYSPRTJ . SEP	Prints a blank page before print jobs sent to a PostScript printer	PostScript

There's one catch to choosing a separator page: The page must be available locally. Although you can choose an SEP file stored in a network-accessible folder, a separator page that's in a networked location will not print. The system won't fuss at you either when you choose the SEP file or when you send a print job to a printer, but print jobs will have no separator page.

CREATING A NEW SEPARATOR PAGE

Given that the built-in separator pages are mostly necessary in specific instances, you'll probably want to create your own separator pages if you use them at all. Separator page files are just text files, so you can create the file in Notepad.

On the first line of the new file, type a single character—any character will do—and press Enter. This character will now be the *escape character* that alerts the print server that you're performing a function, not entering text, so make it one that you won't need for anything else. Dollar signs (\$) and pound signs (#) are both good escape characters, but the only rule is that you can't use the character as text.

Once you’ve picked an escape code, customize the separator page with any of the variables shown in Table 13.8. Be sure to include the escape character before each function, as I’ve shown in this table with a dollar sign.

TABLE 13.8: SEPARATOR PAGE FUNCTIONS	
VARIABLE	FUNCTION
\$B\$\$	Prints text in block characters created with pound signs (#) until you insert a \$U. Be warned—printing text like this takes up a lot of room. You probably don’t want to use this option.
\$D	Prints the date the job was printed, using the format defined on the Date tab of the Regional Options applet in the Control Panel.
\$E	Equivalent to the Page Break function in Word; all further functions will be executed on a new page. If you get an extra blank separator page when you print, remove this function from the SEP file.
\$Fpathname\filename	Prints the contents of the specified file to the separator page, starting on a blank line. As separator pages are strictly text-only, only the text will be printed—no formatting.
\$Hnn	Sets a printer-specific control sequence, where nn is a hex ASCII code that goes directly to the printer. Look in your printer manual for any codes that you might set this way and for instructions on how and when to use them.
\$I	Prints the job number. Each print job has a job number associated with it.
\$Lxxx	Prints all the characters following (represented here with xxx) until it comes to another escape code. Use this function to print any customized text you like.
\$N	Prints the login name of the person who submitted the print job.
\$n	Skips n lines (where n is a number from 0 to 9). Skipping 0 lines just moves printing to the next line, so you could use that function to define where line breaks should occur.
\$T	Prints the time the job was printed, using the format defined on the Time tab of the Regional Options applet in the Control Panel.
\$U	Turns off block character printing.
\$Wnn	Sets the line width, where nn is a number of characters. Any characters in excess of this line width are truncated. The default (which you don’t have to define) is 80 characters.

For example, the following SEP file

```
$
$N
$0
$D
```

```
$L This is a separator page. Only use these pages to organize
$L print jobs because they're otherwise a waste of paper.
$1
$T
```

produces this output:

Christa

10/31/02 This is a separator page. Only use these pages to organize print jobs because they're otherwise a waste of paper.

3:49:11 P.M.

Notice that there are only line breaks if you specifically include them. Without the `$n` codes, all output will be on a single line.

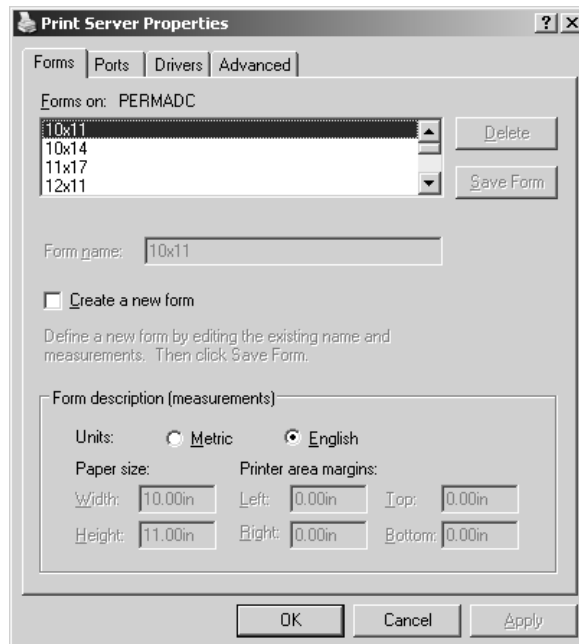

When you're done, save the separator page file with an `.sep` extension to the `%systemroot%\system32` folder if you want to store it with other separator pages. Otherwise, you can store the page anywhere on the print server. To use the new page, just load it as you would one of the defaults.

## Adjusting Print Server Settings

To edit server-wide printer settings, open the **Printers** folder, make sure that no installed printers are highlighted, and choose **File/Server Properties**. You'll see a tabbed dialog box like the one in Figure 13.54.

**FIGURE 13.54**

Edit server properties to change settings that apply to all printers.

**TIP** To make sure you're editing server-wide settings, highlight the *Add Printer* icon in the **Printers** folder before choosing *Server Properties* from the **File** menu.

## Choosing Form Settings

A Server 2003 arranges its print jobs on the paper based on forms, which define a template for where text should appear. Print servers come with a long list of predefined forms you can choose from, but they also allows you to define your own form settings for customized needs such as printing to company letterhead.

Print servers are set up to print on blank 8.5 × 11 paper (the standard size). To choose a new form, find it in the list. To create a new form, edit the settings in the dialog box, choose a new name for the form, and then click the **Save Form** button.

**NOTE** You must choose a new name for the form. You can't overwrite or delete the built-in forms on the print server.

## Configuring Server Port Settings

Although you can configure the following settings from any printer's properties pages, I think it's less confusing to edit them in the server properties. That way, you're reminded that the settings you make here apply not just to a single printer but to all affected printers.

### ADDING AND DELETING PORTS

We've already discussed how to create a TCP/IP port for a network-connected printer. Most people won't need to add or delete other kinds of ports, but here's how you do it if you need to:

1. Open the print server's properties pages and turn to the **Ports** tab. You'll see a list of the currently installed ports.
2. Click the **Add Port** button to open the **Printer Ports** dialog box.
3. Click the **New Port** button and provide a name for the port in the text box that appears, then click **OK**.
4. Back in the **Printer Ports** box, click **Close** to return to the **Ports** tab.

The new port should appear in the list of installed ports.

**NOTE** Add COM ports if you have a multiport serial adapter and will support more than four serial printing connections. Add network ports if you're supporting a printer connected directly to the network.

This will add a new port listing to `HKLM\Software\Microsoft\Windows NT\CurrentVersion\Ports`—no reboot required.

To delete a port, just select it in the list and click the **Delete Port** button. You'll be prompted to confirm that you really want to delete the port. When you do so, the port listing will immediately disappear from the Registry.

### OOOPS! I DELETED A PORT I WAS USING!

It is easy to replace accidentally deleted parallel ports. Click the Add Port button and choose to add a local port. Give the port the appropriate name (such as LPT1) and you're done.

It is *not* so easy to replace an accidentally deleted serial port. In that case, you'll need to add the port, then edit the Registry to define it as a serial port. Add the port as described earlier, then open REGEDT32 and move to HKLM\Software\Microsoft\Windows NT\Current Version\Ports. Find the value for the port you deleted, then double-click it to edit its value to 9600,n,8,1. Unless you deleted every COM port, you'll have other COM port values there for reference.

Parallel, file, terminal client, and network connections have no values in the Registry—just entries.

### EDITING PORT TIME-OUTS

A print device connected to a parallel port (identified as LPTx) will wait a certain interval from the time it expects to receive a print job to the time it gets it. If the print device doesn't get the job within that time, it will notify the person sending the print job that there's an error. Technically speaking, it's not the printer that's complaining, but the parallel port.

You can adjust the interval of time that a parallel port will wait before complaining that it hasn't yet received an expected print job. Turn to any printer's Ports tab, select a port, and click the Configure Port button. You'll see a dialog box like the one in Figure 13.55.

**FIGURE 13.55**

Edit the value to increase or decrease the transmission time-out.

The normal time-out period is 90 seconds. Raise or lower this value by typing in a new number. The lower the value, the more sensitive the port will be to delays. Higher values may make the printer more forgiving of transmission delays, but if you do have a real problem printing, it will take longer for you to discover this. As noted earlier, port settings apply to all printers using that port.

### Adding or Updating the Printer Driver on a Print Server

One of the cool things about using Win32 clients for network printing is that you don't have to install local driver support anymore. This really speeds up the client installation process and makes it easier to update drivers since you no longer have to run from workstation to workstation with the new driver media.

For this to work, however, you *do* need to install support for those clients on the server end so that the client can access them as necessary. Drivers are added on a server-wide basis—if you have more than one printer of the same type connected to your print server, you'll update all drivers at once, not just the ones that printer is using.

To add a driver:

1. Turn to the Drivers tab of the printer server's properties pages. You should see a list of installed drivers that looks like the one in Figure 13.56.

**FIGURE 13.56**

Drivers previously installed on the server

2. Click the Add button on this screen to start the Add Printer Driver Wizard. Click through the opening screen to the point where you can choose the manufacturer and printer model for which you're adding support.

**TIP** The list of available printer drivers includes only those that come on the installation CD. If you've got an updated driver, click the Have Disk button and provide the path to the driver file.

3. From the list that appears, choose all the Win32 clients that will be connecting to this printer from the network. Server 2003 supports drivers for all Win32 platforms on Intel and Server 2003 and XP on Itanium.

**NOTE** Remember, the fact that DOS and Windows 3.x drivers aren't listed doesn't mean that you can't print from those clients. It just means that those drivers are not included with the operating system, and you'll need to install them on the clients.

4. When you click Next, you'll see the wizard's final screen, telling you what driver support you have added.

Updating a driver is simpler:

1. From the Drivers tab of the server's properties pages, highlight the driver you want to update and click the Update button. The print server will ask you whether you're sure you want to update the driver.
2. You'll be prompted for the location of the driver files—either the installation CD or a floppy or network connection.

That's it—the driver's updated.

**TIP** Not sure where to get driver updates? Forget any floppy disks that came with your hardware—those drivers are apt to be very out of date. Instead, go to the printer manufacturer's Web site and look for a Downloads section. The most recent drivers should be available there.

## Keeping Track of Your Printing

Server 2003 offers some messaging and logging capabilities that you can use to monitor the printing process or refer to for troubleshooting when something's not going right. To configure these capabilities, turn to the Advanced tab of the server's properties pages (see Figure 13.57).

**FIGURE 13.57**

Set logging and messaging options for your print server.

Most of these options are fairly self-explanatory. The spooler error, warning, and information events go into the logs visible from the Event Viewer. They don't record every print job sent to the printer (thank goodness, or you'd end up with a huge event log), only spool events.

Messaging is configured from the same tab. By default, the person originating a print job gets a message when the print job is completed or if there's a problem with it. You can disable messaging here, send the error message to the *computer* originating the job, or set up the print server to beep when there's a printing error. Most of the time, the default options will work fine.

## Managing Print Jobs

Managing print jobs is pretty straightforward whether you're doing it from the **Printers** folder or from the Web.

### Managing Printers and Documents from the **Printers** Folder

If you double-click a printer's entry in the **Printers** folder, you'll see a list of all print jobs currently waiting to be printed and the following information:

- ◆ The filename of the document being printed
- ◆ The job's status (printing, spooling, or paused)
- ◆ Who sent the job to the printer
- ◆ How many pages are in the job and how many remain to be printed
- ◆ The file size of the print job
- ◆ The time and date the user submitted the job

When you select a job in the list, you can use the tools in the Document menu to pause a job, resume a paused job, restart a print job from the beginning, or delete a print job. The only catch is that you have to do all this while the job is still spooling to the print device. You can't control the parts of the job that have already spooled to the physical printer's memory from this console.

If you pause a print job, you can edit its priority or printing times in the middle of printing. From the Document menu, choose Properties to open the dialog box in Figure 13.58.

From here, you can view many properties inherited from the printer and passed to the job, and you can raise or lower the job's priority. The higher a job's priority, the higher its place in line, so you can use this feature to manipulate the order in which jobs print even if one job got to the printer before another did. This can be very useful on those occasions when the person printing the 200-page manual sends their job to the printer before the person creating a cover sheet for the FedEx package that has to be ready by 3:30.

**FIGURE 13.58**

Properties of a  
print job

## Managing Printers and Documents from a Browser

You can't completely manage a printer from a browser—you can't adjust printer settings, paper sizes, and the like—but you can do Basic Printer and Document Management Stuff.

You can pause, resume, or cancel all print jobs for a particular printer. From the printer's page, click the link naming what you want to do to the printer.

You can pause, resume, or cancel individual print jobs from the Web browser. When print jobs are active, they're displayed on the printer's Documents page, visible when you click the Documents link under Printer Actions. Each print job has a radio button next to it; to select a print job, click it so that it's highlighted. When you've selected the print job, you can pause, resume, or delete it using the links provided there.

## Troubleshooting Printer Problems

Printing under Server 2003 is usually pretty trouble-free—in the software, at any rate—but every once in a while you may run into problems. The remainder of this chapter describes some of the more common printing problems and tells you how to solve them.

### Basic Troubleshooting: Identifying the Situation

First, try to figure out *where* the problem lies. Is it the printer? The application? The network? If you can tell where the problem lies, you'll simplify the troubleshooting process.

**TIP** *The printing problem that frustrates me most is paper jams. Getting that last shred of jammed paper out of the printer can drive you to madness. To minimize paper jams, store paper somewhere with low humidity (curled paper jams easier), don't overfill the paper tray, and keep paper neat before it goes in the tray.*

Printer troubles can happen due to any combination of three different causes:

- ◆ Hardware errors
- ◆ Software errors
- ◆ User errors

**TIP** *One basic part of printer troubleshooting is to make sure the person is connected to the right printer and knows which print device is associated with that printer. Some troubleshooting jobs end with the task of finding the printer with five unclaimed print jobs on top of it.*

### **NO ONE CAN PRINT**

If no one can print, check the print device and network connection. Check the easy stuff first: Is the printer on and online? Does the cartridge have ink? Is the printer server up and running? Did the printer *ever* work, or is this its maiden voyage? If it never worked, make sure you've got the right driver installed, or try downloading a newer one from the manufacturer's Web site.

From the console, check the port settings. Is the printer sending data to the port the print device is connected to? Make sure to set up the TCP/IP port for a network-connected printer properly.

Also, see if you can print from the print server's console. There could be a network problem preventing people from reaching the print server.

Make sure there's enough space on the print server's hard disk to store spool files. If the print server can't create spool files, it can't print from a spool.

Make sure the printer is set up to use the proper print processor.

If using Internet Printing, make sure that this service is enabled.

### **SOME PEOPLE CAN'T PRINT**

What do those people have in common? Are they all in a single subnet? In the same user group? Using the same application? Printing to the same printer? Find the element they have in common, and that's probably the element that's causing the printing problem. For example, if everyone who's printing from NT clients can print and everyone printing from Windows 9x clients can't, then check the data type (on the Advanced tab of a printer's properties—click the Print Processor button to see what the currently selected default data type is). Unless the data type is RAW, then print jobs that people create from Windows 9x clients will disappear—you won't see any error messages, they just won't print.

### **ONE PERSON CAN'T PRINT**

If only one person can't print, try to narrow down the source of the problem. Can the person print from another application? Can the person print from another computer? If this person can't print at all, see if someone else can print from their computer. If so, check the permissions attached to the person who can't print. They may be denied access to the printer altogether.

**TIP** *If only one person is having printing problems, try rebooting the computer and retrying the print job. Some applications (such as Netscape Navigator 4.51) have a problem if they crash in the middle of creating a print file—they won't accept another one because they think the previous job is still being created. Sometimes, this problem will prevent any application from printing from that computer. In such a case, the only thing to do is reboot and try again. Logging out and in again won't do it.*

## Using Online Resources

If you get completely stuck, try the links included in the left pane of the **Printers** folder. (Note that these links will be visible only if you've got Web content enabled. If you disabled Web content to clean up the desktop, you can reenable it for this folder only by opening Tools/Folder Options and, on the General tab of the Folder Options dialog box, choosing Enable Web Content on My Desktop.)

The More Info link leads to a printer page on the Microsoft Web site at [www.microsoft.com](http://www.microsoft.com), the manufacturer's link leads to their printing page (if they have one), and the Microsoft Support link leads to the printing home page in the Microsoft support area of its Web site. (I'd provide the link, but given how often Microsoft rearranges its Web site, by the time you read this it wouldn't be accurate.) If your print server has an Internet connection, you can connect directly from the **Printers** folder, but if not, you can still plug the URLs into a browser to see if the online resources can help you with your question.

**TIP** *Considering how often Microsoft reorganizes its Web site, you might be better off using the URL policy I described earlier to link to a custom home page with a troubleshooting guide and perhaps the latest drivers. Nothing is more frustrating than being desperate enough to try the Web tool but then discovering the link is dead.*

Unglamorous as printing is, it's an essential service for just about any organization. In the previous pages I've talked about how to set up printers for local use or for your network, how to get those printers to the people who need them, how to automatically deploy printers through Internet printing and simple administrative scripts, and how to keep those printers from those who haven't any reason to be using them. After reading this chapter, you should feel ready to do your part to help keep those recycling bins full.

## Chapter 14

# Connecting Microsoft Clients to the Server

YOU'VE BUILT YOUR SERVER, created users, and shared network resources. Now you need to configure your client systems to use those resources. In this chapter, I'll show you how to set up various client systems with networking components, how to log on to the network, how to find and connect to shared resources, how to manage your passwords, and, when applicable, how to find and connect to the Active Directory.

Throughout this chapter, I'll connect to the same server, on the same domain, and with the same user account.

- ◆ My username is phewson.
- ◆ My domain name is REDHILLTOWN.COM.
- ◆ The domain controller is ZOOROPA.
- ◆ Other servers on the network are OCTOBER and SALOME.

## What You Should Know Before Setting Up Network Clients

Before you jump into configuring workstations, there are a few things you should know about clients and the network environment. If you are new to Microsoft networks and have just picked up this book and opened it to this page, you might want to look over some of the previous chapters before attempting to configure clients:

- ◆ Chapter 2 covers the basics of networking software and security.
- ◆ Chapters 6 and 7 deal with TCP/IP protocol and infrastructure; TCP/IP is likely to be the only protocol used on your network these days.
- ◆ Chapter 9 shows you how to set up user accounts and computer accounts, for systems that can participate in domain-level security.

If you've read these chapters, or are generally familiar with the concepts, you can safely skip to the section on configuring your type of workstation. Otherwise, I'd like to point out some general issues that form the background for this chapter. If you need more detail than I can provide in an overview, please review the chapters just listed.

## Client Software

For each client you configure, you'll be loading three basic software components: a *driver* for the network interface card (NIC), a *network protocol*, and a *network client*.

The NIC driver is vendor and hardware specific. Before loading any network protocol or client software, the operating system must recognize the network card and load the appropriate driver. Fortunately, due to the advancement of Plug and Play, most of the client systems in this chapter can automatically detect the NIC and load a driver included with the OS. If the driver is not included with the OS, or if your client system fails to detect the network card, you must use the driver and installation instructions for your operating system that are provided by the manufacturer. However, I recommend that you always use the vendor-supplied driver if it is more recent than the one supplied with the OS. The network card's OEM disk or CD usually includes release notes, installation instructions, and any available diagnostic software. If it's feasible, use the same type of network card throughout your network; you will become familiar with any idiosyncrasies of the hardware, and you can use the same installation procedures, drivers, and diagnostic software on all of your workstations.

The network protocol software is usually included with the operating system and sets message packaging and routing standards for network communications. Client and server systems must use a common protocol to communicate. For the vast majority of Microsoft networks these days, TCP/IP is the standard. Windows Server 2003 Enterprise Edition and Active Directory require TCP/IP to function properly. This server release also includes NWLink, an IPX/SPX-compatible protocol for connectivity to Netware servers, and AppleTalk for Macintosh clients, but the legacy (and nonroutable) protocol NetBEUI is no longer an option. If you have worked with several different releases of Microsoft operating systems, you'll have noticed that the default protocols and client components have changed with every release. To keep things simple, and to reflect current networking practices, all of the network clients in this chapter will use TCP/IP to communicate with the server. For convenience (mine and yours), the clients in the examples will obtain a unique IP address and other necessary protocol configuration information from a DHCP server on the network. Why? In the real world, you will have a static IP address for 99 percent of your servers 99 percent of the time. For workstations, however, it is much more convenient to assign addresses dynamically. A DHCP server not only assigns IP addresses to clients, it can also supply all of the other values required in your particular TCP/IP environment. DHCP also keeps track of IP assignments and updates clients dynamically when you want to make configuration changes. Refer to Chapter 6 for more information on TCP/IP addressing and Chapter 7 for more details on DHCP.

The network client is the software component that locates network resources and connects to them. On older client systems, the network client may also need to conceal the network from legacy applications, making network resources appear to be local when an application is not network-aware. For any given flavor of file-mounting, printer-sharing software that runs on a server, there is a client counterpart. To connect to Netware servers, for example, clients need a Netware-compatible client. The Microsoft network client component is usually called the Client for Microsoft Networks. On NT 3.x and 4, however, it is called the Workstation Service.

## Domains, Workgroups, and Active Directory

The client systems discussed in this chapter may participate in workgroups and/or domains (I purposely use the term "and/or" because membership in these isn't mutually exclusive). Additionally,

some clients can access directory services to locate network resources. To optimize your client configurations, you'll need to understand these three levels of association.

Workgroups are simply logical groups of clients and servers. They populate the browse list you see in Network Neighborhood or My Network Places. Workgroups make it easier for clients to find and attach to network resources. Servers that belong only to workgroups, however, lack centralized security. Each server maintains separate security information.

Domains provide centralized security, along with the resource grouping function of workgroups. Domain user accounts exist to permit people to use a single login name to log on to any workstation and access resources on any server that belongs to the domain. Only systems based on the NT operating system, however, can be domain members. NT-based systems include NT 4, Windows 2000 Server and Professional, Windows XP, and Windows Server 2003. Domain member systems have a computer account in the security database; this account is very similar to a user account. If a Windows 2000 Professional system, for example, is only in a workgroup, domain users cannot log on to the workstation with a domain account. If you want your users to log on to one of the systems just listed and access resources on a domain, you must join the workstation to the domain.

Systems not based on NT (this includes Windows 9x, Windows for Workgroups, and DOS clients) cannot be domain members. These systems can only participate in workgroups. No real security database exists on the workstation; users can log on without a domain account, or even a local account. To enable users access to domain servers and resources, however, the network client software on these systems can be configured to log users on to a domain.

Active Directory (AD) adds a layer of functionality to the workgroup and domain model; the AD is a database of domains, user and computer accounts, resources and services, and even trust relationships. AD does use domain security, but it has been designed to manage bigger and more complex networks than domains and workgroups can handle. For a full rundown of Active Directory, check out Chapter 8. The thing to remember here is that only Windows 2000 and XP include fully functional AD client software. However, Active Directory client extension packages are available for Windows 9x and NT 4. The AD Client extensions for 9x and NT 4 include support for newer authentication methods and directory searches.

**NOTE** The Active Directory Client Extension (commonly called DS Client) for Windows 95 and Windows 98 is included on the Windows 2000 CD-ROM in \CLIENTS\WIN9X\DSCLIENT.EXE. The client for NT 4 is available for download from Microsoft at: <http://www.microsoft.com/windows2000/server/evaluation/news/bulletins/adextension.asp>.

Table 14.1 summarizes the network association capabilities of the clients you'll be configuring in this chapter:

**TABLE 14.1: NETWORK CAPABILITIES OF CLIENT OPERATING SYSTEMS**

CLIENT OPERATING SYSTEM	WORKGROUP MEMBER	DOMAIN MEMBER	ACTIVE DIRECTORY CLIENT
Windows XP Professional	✓	✓	✓
Windows 2000 Professional	✓	✓	✓

*Continued on next page*

**TABLE 14.1:** NETWORK CAPABILITIES OF CLIENT OPERATING SYSTEMS (*continued*)

CLIENT OPERATING SYSTEM	WORKGROUP MEMBER	DOMAIN MEMBER	ACTIVE DIRECTORY CLIENT
Windows NT 4	✓	✓	Add-on
Windows 98	✓		Add-on
Windows 95	✓		Add-on
Windows for Workgroups	✓		
DOS	✓		

A final word: systems based on the NT operating system maintain local security databases. The configuration changes you are about to perform require administrative privileges. When configuring Windows NT, Windows 2000, or Windows XP clients, you must first log on as Administrator or use an equivalent account.

Now you are ready to begin connecting client systems to the Windows Server 2003 network.

## Connecting Windows XP Professional Workstations

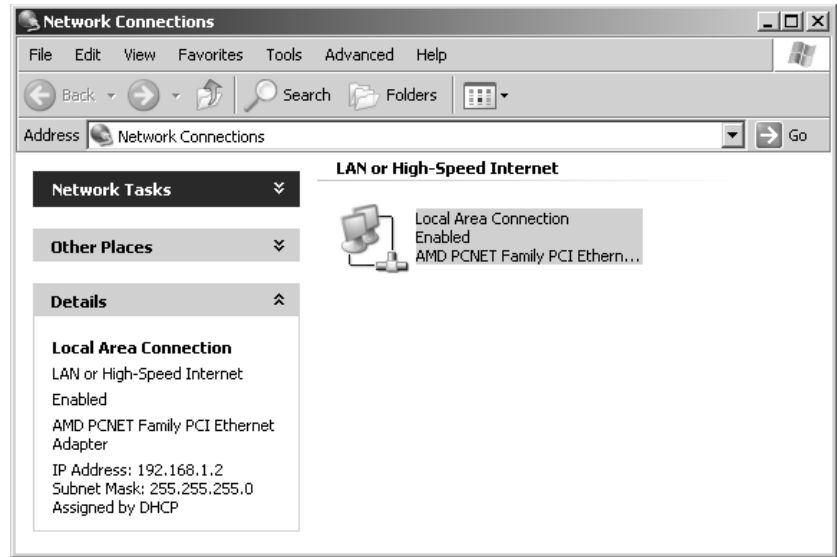

Windows XP Professional is the ideal client for Windows Server 2003. The client and server operating system and user interface are the same, and XP supports all of the great Server 2003 features, including remote administration, remote installation services, and group policies. Universal Plug and Play makes installation of your supported network card driver virtually automatic. If your network card is present and detected when the OS is being installed, XP automatically loads the driver. If you accept the typical network settings during the installation of XP, setup will go ahead and install TCP/IP Protocol and the Client for Microsoft Networks. If you install the NIC later, XP automatically detects the new hardware and loads a driver, or prompts the user for the location of the correct driver. Either way, once the driver for the NIC is loaded, you're home free. If you only need the TCP/IP protocol and the Client for Microsoft Networks, there's not much for the admin to do except join a domain or specify a workgroup.

### Verify Your Network Configuration

First, log on to the system as a user with administrative rights. Before trying to join the domain, you should at least take a look at the Network Connections applet in the Control Panel to ensure that the network card was detected and the appropriate software has been loaded. As shown in Figure 14.1, if the network software has loaded properly, you will see an icon named Local Area Connection (if you have more than one NIC installed, you will see more than one Local Area Connection icon). You should see that the connection is enabled, and if you highlight the connection and expand the details (as in Figure 14.1), you should also see the IP address that was assigned by DHCP. If you do not see a Local Area Connection icon, your NIC may not have been properly detected. Use the Device Manager to isolate the problem, or try to add the network adapter manually using the Add New Hardware Wizard in the Control Panel and your OEM-provided disk or CD-ROM.

**FIGURE 14.1**

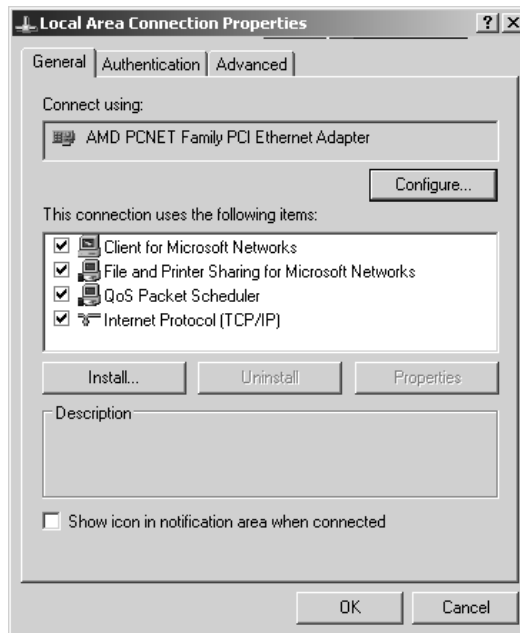

The Local Area Connection Icon in Network Connections

If everything looks rosy, right-click the Local Area Connection icon and click Properties to view your network configuration information. The properties page, shown in Figure 14.2, lists installed components: network card type, protocol, and the client software. TCP/IP is automatically configured to use DHCP; to statically assign IP information, select TCP/IP and click Properties. Figure 14.3 shows the Internet Protocol (TCP/IP) properties page.

**FIGURE 14.2**

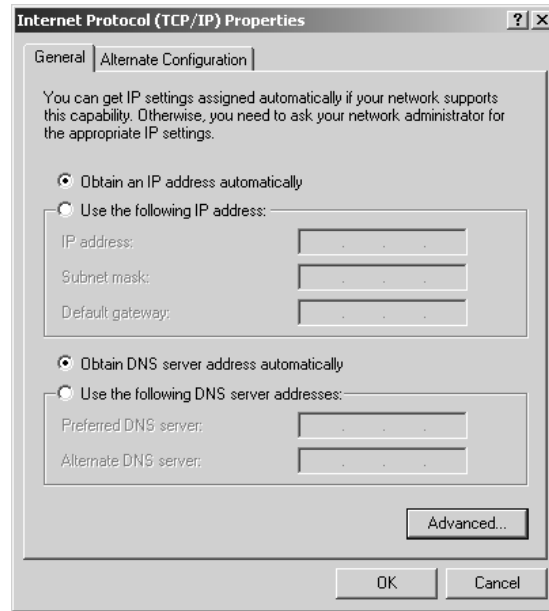

Local Area Connection properties page

**FIGURE 14.3**

Internet Protocol properties page

**NOTE** To be absolutely certain that your network card and TCP/IP are working properly, open a command prompt, use *IPCONFIG* to verify your DHCP addressing, and then use *Ping* to test network connectivity. Ping your IP address, the IP of the router, and the IP of the server or another node on your network. While you are at it, ping a couple of systems by name to test your DNS resolution. See Chapter 6 for more information on troubleshooting network problems with TCP/IP. This applies to all of the workstations you'll configure in this chapter, although the syntax and supported arguments of *IPCONFIG* and *Ping* will change with the operating system.

## Joining a Domain

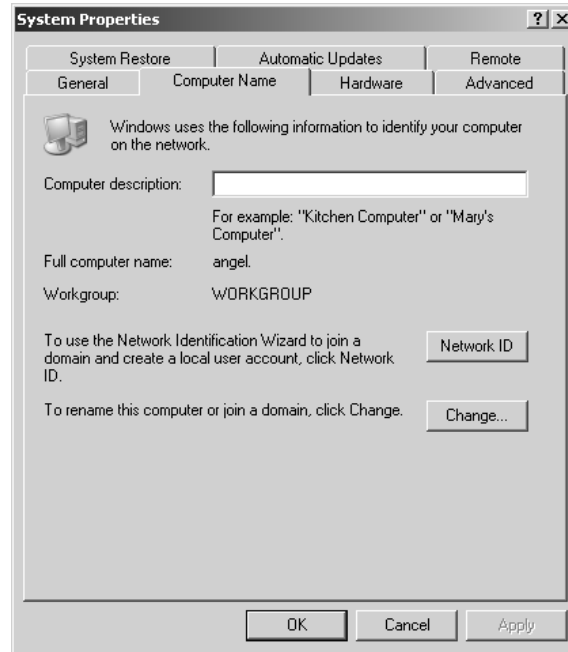

Now that you know your network card is working properly and you have successfully obtained configuration information from DHCP, it's time to join the domain. If your Windows XP Professional client will exist in an Active Directory environment, you need to create a machine account for it in the target domain. Members of the Administrators and Account Operators group on the domain can use the Active Directory Users and Computers tool to do this beforehand, and that is the recommended course of action. However, you can also create a machine account from the workstation during the network part of the setup program, or you can use the System Control Panel, if you know the username and password of an account with the ability to create machine accounts in the domain. Since this chapter deals with client-side configuration, I'll give you the steps to create the machine account from the workstation as you join the machine to the domain.

To join a domain, open the System applet. The System applet is in the Control Panel, or you right-click My Computer from the Start menu and click Properties. I prefer this to wrangling with the XP Control Panel's Category View. Navigate to the Computer Name tab (see Figure 14.4). The XP Professional System, ANGEL, currently belongs to a workgroup named WORKGROUP. Click Change to join a domain. As shown in Figure 14.5, change the radio selection to Domain and type in your domain name, **REDHILLTOWN.COM** in this case. Notice that you use the full Active

Directory domain name here, not the NetBIOS name REDHILLTOWN. Click OK. If an account for the system does not already exist on the domain, XP prompts you to supply a domain username and password with permission to create the account (see Figure 14.6). If all goes well, you'll see a message welcoming you to the domain.

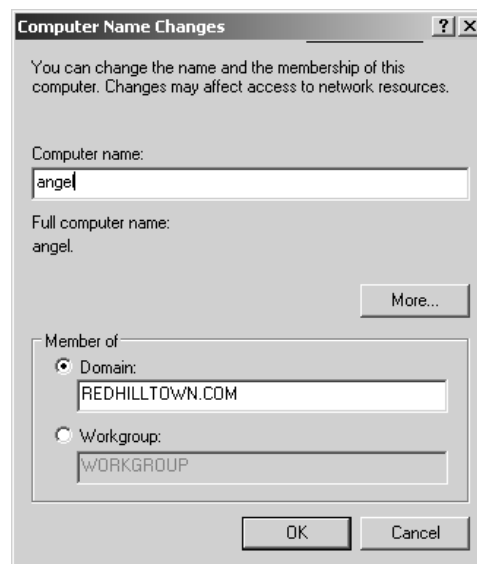

**FIGURE 14.4**

Computer Name tab in System Properties

**FIGURE 14.5**

The Computer Name Changes dialog box

**FIGURE 14.6**

Supply a username and password to join the domain.

Restart the system for the changes to take effect. When the system restarts, you'll have the option to log on using a local account or using a domain user account. To access resources on the domain, users need to log on with a domain user account. Activate the drop-down list for Log On To and choose your domain name. From now on, the default choice will be to log on to the domain, not the local machine. When XP is finished logging you on and loading your personal settings, it's time to connect to network resources.

**NOTE** *How is it possible to join the workstation to the domain and then log on using a domain account? How does the workstation identify you and assign you rights and permissions? Actually, when the workstation joins the domain, the domain's Domain Users group is added to the workstation's local Users group membership. In addition, the Domain Admins group is added to the Administrators group on the local workstation. By default, then, if a domain controller authenticates you as a member of the Domain Users group, the workstation will accept you as a local user. And if the domain controller recognizes you as a Domain Admin, the workstation will grant you local admin rights as well. This is the default behavior for all NT-based client operating systems: Windows XP, Windows 2000, and Windows NT.*

## Connecting to Network Resources

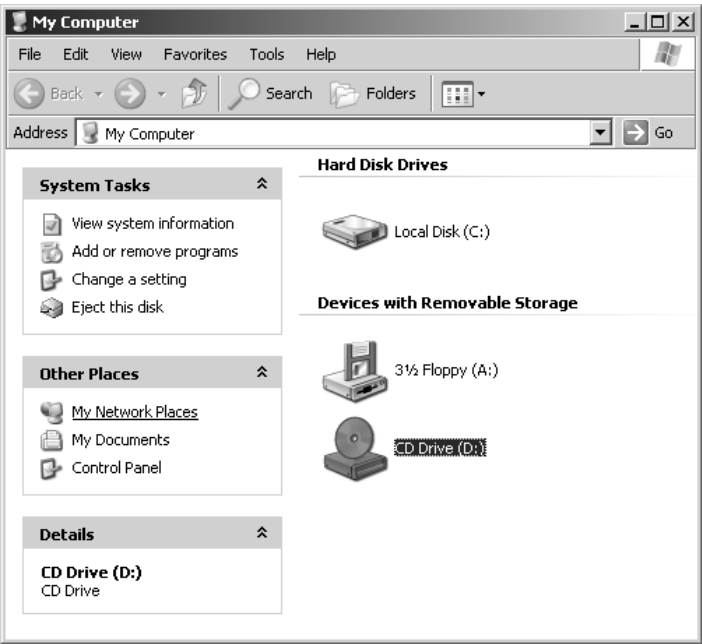

In Windows XP, My Network Places is not shown on the Desktop by default; the easiest way to open it is from My Computer. Open My Computer from the Start menu and choose My Network Places from the list of Other Places (see Figure 14.7).

As you can see in Figure 14.8, My Network Places offers three different options for finding and connecting to network resources:

- ◆ Use the Add Network Place Wizard to create a shortcut to a network resource. The wizard can locate the resource using a UNC name (`\\SERVER\SHARE`), which you provide, or you can open a browse list from within the wizard.
- ◆ Use Search Active Directory for shared folders or printers. This only works for shares and printers that have actually been published in the Active Directory, though.
- ◆ Browse the network by choosing Entire Network from Other Places. This is the Network Neighborhood–style browse list that you've been familiar with since Windows 95.

**FIGURE 14.7**

Open My Network Places from My Computer.

**FIGURE 14.8**

Finding resources from My Network Places

The Add Network Place Wizard is fairly straightforward, so let's skip to the Search Active Directory option. Select it from the list of Network Tasks with a single click (remember, it's a link), and a dialog box called Find Users, Contacts, and Groups will open (see Figure 14.9). This powerful little applet gives you access to a searchable directory of computers, shared folders, and printers, as well as users, groups, and contacts. From the Find drop-down list, choose Shared Folders. If there are multiple domains on the network, you can make the search more specific by choosing your domain name from the In drop-down list. If the list of shared folders is likely to be long, you can search by name or keyword or use the Advanced tab to search by other properties. Once you've set your search criteria, click Find Now to locate the shared folders. Figure 14.10 shows the results of a search for shares on the REDHILLTOWN domain.

**FIGURE 14.9**  
The Find Users,  
Contacts, and  
Groups dialog box

**FIGURE 14.10**  
Active Directory  
search results

To connect to a shared folder found by the Active Directory search engine, double-click your selection in the results window to open the folder in Explorer, or right-click the folder and choose Map Network Drive. As shown in Figure 14.11, the Map Network Drive dialog box will automatically fill in the server and share information. Mapped drives will be persistent unless you deselect the check box labeled Reconnect at Logon. By default, the current username and password will be used; click Connect Using a Different Username to specify a different account to use for the connection. If you want to create a shortcut to this resource instead of mapping a drive letter to it, the link named Sign Up for Online Storage or Connect to a Network Server invokes the Add Network Place Wizard.

**FIGURE 14.11**

Mapping a network drive to a shared resource

If you prefer browsing the network to searching the Active Directory, use the Entire Network link in My Network Places. This is the same type of browse list found in Windows 2000, NT 4, and Windows 9x. One advantage to using the browse list is that all shares and printers will be listed, not just AD-published resources. If administrators forget, or don't bother, to publish share and printer information to the directory, shared resources will still appear on the browse list.

Once you've located and selected the resource on the browse list, double-click to open it, or right-click to see a list of options. As you see in Figure 14.12, right-click options include Map Network Drive and Create Shortcut. If you choose the latter, Windows will offer to put the shortcut on your Desktop. Although you cannot choose a different location for the shortcut, it's a simple matter to copy or move the shortcut after creating it.

**FIGURE 14.12**

Options for connecting to a shared folder

## Changing Domain Passwords

It's good security practice for a new user to change their password the first time they log on to the network. It's also a default parameter set when the admin first creates a new user account. So if a user is logging on to the network for the first time, they will see a message informing them that they must change their password. The Change Password dialog box then opens and the user types the old password and the new one (twice for confirmation). If the old password is correct and the new password meets the password criteria (these are discussed in Chapter 9) and both entries match each other, the user sees a confirmation of the password change and the logon process continues.

After the initial logon and password change, administrators can use Active Directory Users and Computers to reset a user's password or to expire a password so that the user must change it the next time they log on. See Chapter 9 for the procedures to reset and expire domain account passwords. Users can change their own domain passwords after logging on by using Ctrl+Alt+Del and the Change Password button. The Ctrl+Alt+Del sequence is the same one used to lock the computer or shut it down, so it's important that users know about it.

## Connecting Windows 2000 Professional Workstations

Windows 2000 Professional and Windows XP share many of the same features, so the steps to configure Windows 2000 Professional are virtually the same as the ones for Windows XP Professional. Sure, some of the names for things have changed, or the applets have been moved around, but don't

let that throw you. In case you skipped right to this section, I'll go through the steps again. Before proceeding, log on to the workstation as a user with administrative rights.

## Verify Your Network Configuration

To verify your network configuration, open Network and Dialup Connections (Start/Settings/Network and Dialup Connections). Check to make sure that the Local Area Connection is enabled. Double-click the icon to see the status of the connection. If you do not see a Local Area Connection icon, the card may not have been detected. In that case, try to use the Device Manager or the Add New Hardware Wizard (both of these are found in the Hardware tab of the System Applet in the Control Panel) and your OEM-provided disk or CD-ROM to install the driver. If the icon is present but grayed out, the connection may be disabled for some reason. Right-click the icon and choose Enable if you see the choice. If there is a red X on the icon, the NIC is not receiving a signal from the cable. It may be unplugged or defective. If the icon has no red X and is not grayed out, verify that the network software components have loaded properly. Right-click the Local Area Connection icon and choose Properties, or click the Properties button from the Status dialog box. Open the TCP/IP properties page and verify that DHCP is enabled. If you are still not convinced, open a command prompt (Start/Run/cmd.exe) and type **ipconfig /all** to see the dynamic IP configuration, then try pinging some other nodes on the network. When you are satisfied that everything is working, close your open windows and join the workstation to the domain.

## Joining a Domain

To join your Windows 2000 Professional system to the domain, open the System applet (right-click My Computer on the Desktop and choose Properties, or open Start/Settings/Control Panel/System). Go to the Network Identification tab (it's called Computer Name in Windows XP). Click the Properties button to open the same dialog box you encountered back in Figure 14.5. Click the Member of Domain radio button information and type in the domain name. Click OK. If you have not already created the machine account on the domain, the system will prompt you for the username and password of an account authorized to create the machine account in the domain. Type in the username and password and click OK. If all goes well, you'll see a dialog box welcoming you to the domain.

When prompted, restart the system for the changes to take effect. When the system restarts, you'll have the option to log on using a local account or using a domain user account. To access resources on the domain, you need to log on using a domain user account. Activate the drop-down list for Log On To and select your domain name. From now on, the default choice will be to log on to the domain, not the local machine.

## Connecting to Network Resources

To connect to network resources from a Windows 2000 Professional workstation, open My Network Places on the Desktop (see Figure 14.13) and you'll see two choices: Add Network Place or Entire Network.

Choose Add Network Place if you want to create a shortcut to a network resource. Figure 14.14 shows the Add Network Place Wizard. Type the name of the resource or select a share from a list using the Browse button. Click OK. Provide a user-friendly name for the connection in the next

window and click Finish. The wizard will automatically open the folder for viewing, and a shortcut will appear in the list of My Network Places. This shortcut can be moved or copied to a different location, such as the user's Desktop.

**FIGURE 14.13**  
My Network Places

**FIGURE 14.14**  
The Add Network  
Place Wizard

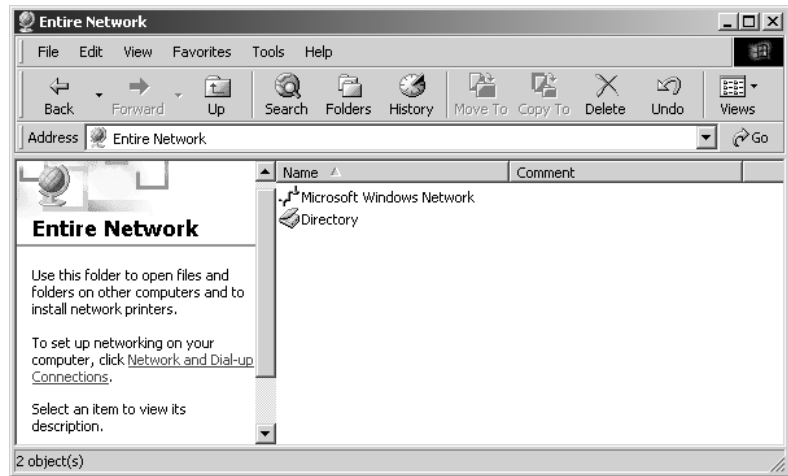

To access resources using a browse list or by searching the Active Directory, choose the Entire Network option in My Network Places. You'll see a list of links to search for different types of objects and a link to view the entire contents of the network. Click the link to view the entire contents of the network and you'll have two more choices (see Figure 14.15). Choose Microsoft Windows Network, not Active Directory (you will not find a list of shares by opening Active Directory). Finally, a list of domains and workgroups appears. Click your domain name and select a server from the list to see its shared folders. Figure 14.16 shows a list of shares on the server ZOOROPA. Double-click to open the shared folder, or right-click to see a list of options as shown in Figure 14.16.

Available options include Map Network Drive or Create Shortcut. The latter choice will create a shortcut on your Desktop.

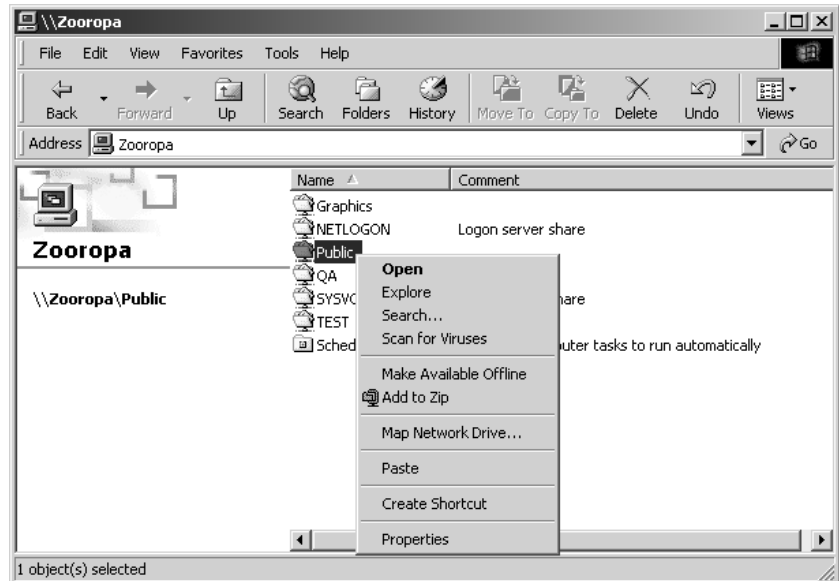

**FIGURE 14.15**

Browsing the entire network

**FIGURE 14.16**

Connecting to a shared folder from the browse list

**NOTE** You cannot search for a list of shared folders using the Search for Files and Folders link found in My Network Places/Entire Network, but you can search for computers. Once a list of computers is found, double-clicking a computer on the list will present a list of shares. However, this process is not as intuitive as the Active Directory search function you saw back in Windows XP.

## Changing Domain Passwords

The steps for changing a user's password on the domain are the same in Windows 2000 Professional as they are in Windows XP Professional. After logging on successfully, press Ctrl+Alt+Del on the keyboard and click the Change Password button to change your domain password.

## Connecting Windows NT Workstations

Because it is still so frequently used on corporate networks, Windows NT 4 is next on our list of clients. Microsoft designed NT and its descendants to be more secure (and therefore more suitable for corporate networks) than Windows 9x or Me. Like Windows 2000 and XP, Windows NT can participate in domain security. Businesses with security concerns are more likely to use NT systems on their corporate offices; Windows 9x/Me is often used only for laptops with special hardware requirements.

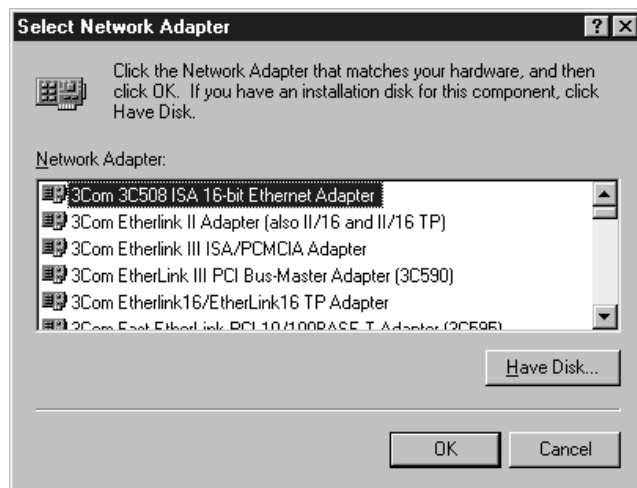

If you've installed Windows NT 4 on your system already, chances are you've already installed all of the required networking components. However, NT doesn't have the broad hardware support and the advanced Plug-and-Play features of Windows 2000 and XP. So, to be on the safe side, I'll walk you through all of the configuration steps. This section, like previous ones, assumes that you already have a fully functioning operating system.

## Configuring the Workstation

Windows NT will detect your network card during setup and install most or all of your required networking components by default. However, unlike Windows XP and 2000, if you install a network card after the operating system is configured, you may have to manually install the driver because NT does not support Plug and Play. In any case, you will probably want to verify your configuration to make sure you are set up for your particular network. To do this, log on to the system as Administrator, or use a local account that is a member of the local Administrators group. Now fire up the Network Control Panel and select the Adapters tab. If you need to install a network card, click Add to see a list of supported network cards (shown in Figure 14.17).

**FIGURE 14.17**

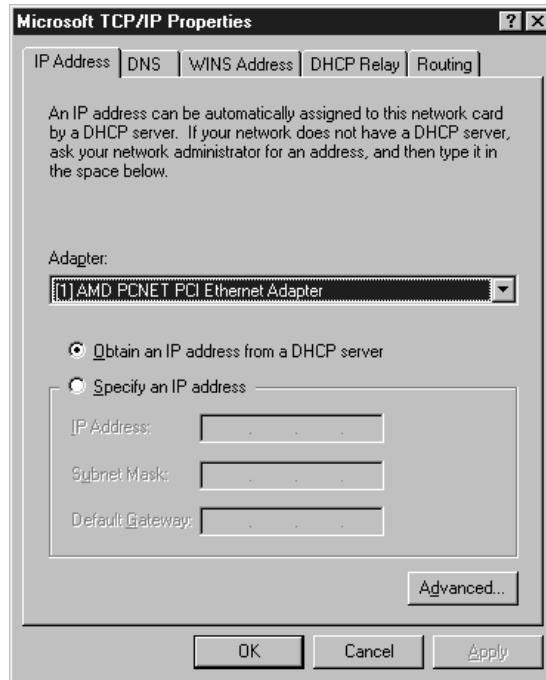

Selecting a network adapter

Scroll down the list to find your network adapter, or click Have Disk to install an unlisted—but supported—network adapter. The system will prompt you for the location of the driver files. If you want setup to get the driver from the NT CD-ROM, most of them are in the \i386 directory. However, additional network card drivers are located on the CD-ROM under \drvlib\netcard\X86. Type in the path for the files and click Continue to load the adapter.

Now you need to select a network protocol. Move to the Protocols tab. Default protocols are TCP/IP, NWLink IPX/SPX Compatible Transport, and NWLink NetBIOS. If you don't need the NWLink components, remove them now. If the protocol you need is not listed, click Add to see a list of supported protocols. Select your protocol from the list and click OK. If you select the TCP/IP protocol, setup will offer to use DHCP protocol to dynamically provide an IP address. Choose Yes if you want the workstation to use DHCP. Now setup will ask for the location of the protocol files. Type in the path, or if the default path in the dialog box is correct, click Continue to copy files from the \i386 directory on the NT CD-ROM. To configure a static address or other TCP/IP parameter, highlight the protocol and click Properties. The TCP/IP properties page is shown in Figure 14.18.

**FIGURE 14.18**  
TCP/IP properties

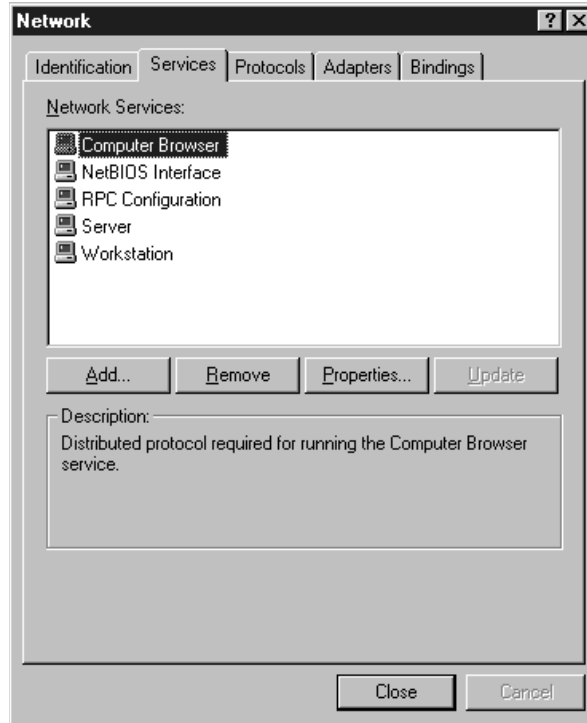

**NOTE** If you enable DHCP but configure any other parameters in the TCP/IP properties pages, the parameters you supply—such as DNS servers, WINS servers, default gateways, or domain names—will override any setting that the DHCP server gives the client. This is true for all clients discussed in this chapter.

Now let's look at the Services tab in the Network Control Panel (shown in Figure 14.19). You may already be familiar with the terms *Client for Microsoft Networks* and *File and printer sharing for*

*Microsoft Networks.* These names for Microsoft networking components are replaced by the terms *Workstation* and *Server* in Windows NT. The Workstation service, called Client for Microsoft Networks in every Windows OS except NT, is the network client component. The Server service (usually called File and printer sharing for Microsoft Networks) allows resource sharing to the network. These components require little or no configuration to operate effectively as a network client.

**FIGURE 14.19**  
Network services

If you've added an adapter or modified a protocol in the Network Control Panel, click Close, and NT will ask you to restart the system. After rebooting, note whether there are any errors at startup and check the Event log for more information if necessary. It's not a bad idea to verify your network connectivity at this point by opening a command prompt. `IPCONFIG` will verify that your PC has acquired an IP address from a DHCP server. `IPCONFIG /ALL` will show you more details. Use the `Ping` command to test connectivity to other nodes on the network. When you are satisfied that everything is working properly, it's time to join the domain.

## Joining a Domain

Open the Network Control Panel again and select the Identification tab. You will see your computer name and domain or workgroup membership configuration. Like Windows XP and 2000, a Windows NT system needs a computer account in the domain. If the account has not already been created, you'll need to use an account with Account Operator or Administrator privileges to join the domain. You do not need to hold any special domain privileges to assign the system to a workgroup, however.

To join a domain, click the Change button from the Identification tab. You will see your current domain and workgroup membership, along with your current computer name. In the Identification Changes dialog box, change the selection from Workgroup to Domain and type your domain name in the text box (shown in Figure 14.20). If a computer account has already been created for this system, click OK. Otherwise, check the check box labeled Create a Computer Account in the Domain and type in a username and password to create the computer account. This username and password must have either Account Operator or Administrator rights on the domain you are joining. To be on the safe side, enter the full domain name in the Username text box. Instead of typing **Administrator**, for example, type **REDHILLTOWN\Administrator**. This ensures that you use the Administrator account from the REDHILLTOWN domain. Click OK and wait for the pop-up dialog box welcoming you to the domain.

**FIGURE 14.20**

Changing the domain name

After completing the domain membership change, you are prompted to reboot the server for the changes to take effect. When the logon dialog box appears after rebooting, pull down the Domain list and select your domain name. This also changes the default domain for future logons. Type a valid domain user account and password in the space provided. Click OK to log on with your domain user account. From now on, the default choice in the logon dialog box will be to log on to that domain instead of the local machine.

**TIP** By the way, if there are multiple domains on your network, you can choose one of the trusted domains from the list in the logon dialog box. It depends on the security configuration of your network, but domain member workstations can accept logons for users from their domain and from trusted domains. This makes it much easier for staff visiting from other offices to use local workstations.

## Connecting to Network Resources

To connect to a network resource with a Windows NT client, open Network Neighborhood to see a list of systems with shared resources in your local domain or workgroup. To view resources in other domains and workgroups, click Entire Network, and then choose Microsoft Windows network. Once you've found the server and shared folder you are looking for, select it in the window and double-click to open the folder, or right-click and choose from a list of options. Like your previous clients, the options include Map Network Drive and Create Shortcut.

**NOTE** You may have noticed that you have to choose Microsoft Windows Network to access the browse list. Clicking Microsoft Windows Network tells your software that you want to use the Client for Microsoft Networks, instead of some other installed client, to find servers. For instance, if the Netware client were installed, you would select Netware Network from the browse list to search for Netware servers. If a Unix client were present (there are a number of these on the market), an option that probably includes the term NFS would show up on the list. You would select it to look for servers running the NFS file server software.

If you want to map one or more logical drives to network resources, try a more direct approach than the Entire Network/Microsoft Windows Network browse list. Simply right-click Network Neighborhood and choose Map Network Drive. A dialog box similar to the one shown in Figure 14.21 will appear.

**FIGURE 14.21**

Mapping a network drive

Drill down the list to your target server and share, and change the default drive assignment if necessary. If you know the server name and share name, however, you don't need to browse for it. Just type it in to the Path text box. Notice the option Connect As. If you don't specify another user account, Windows NT will use the credentials of the logged-in user to establish the network connection. The Connect As option allows you to connect to a network share with a different set of

credentials. To do so, type the username in the Connect As box or, as shown in Figure 14.21, type in the full **DOMAINNAME\username** to designate a domain account to use. If you want to specify a local account on the target server, use the **MACHINENAME\username** convention. If prompted, supply the password for the account you are using to connect and click OK. Keep in mind when using this option that Windows NT can only map to a given server with one set of credentials. If I have already connected to a server, I can't specify a different username for a new connection, even if I'm connecting to a different share.

There are times, though, that you may get an error message saying that your credentials conflict, indicating that you are already connected under a different username. This can occur even if you don't have any drive connections to that server. If this happens, open a command prompt (open Start/Run and type **cmd** in the Run box) and type **net use** to see your open connections. You will probably see a connection to that machine's IPC\$ share without a drive letter specified. This happens when you do things like open an administrative tool and point it to another machine. You don't realize that you have connected to that server already, but you have. First, make sure all programs using that connection are closed, then drop the connection by typing **net use \\server\share /d**. For example, if I had previously connected to ZOOROPA with the Event Viewer and saw a connection to \\ZOOROPA\IPC\$, I would type **net use \\ZOOROPA\ipc\$ /d**. Now go back to the Map Network Drive dialog box and give it another try.

## Changing Domain Passwords

The steps for changing a password on the domain are the same in Windows NT as they are in Windows XP and Windows 2000. After logging on successfully, press Ctrl+Alt+Del on the keyboard and click the Change Password button to change your domain password.

## Accessing the Active Directory

The DS Client for NT 4 is available for download from Microsoft's Web site—just open the Windows 2000 Server home page and search for “Active Directory Client Extensions”. The client requires Service Pack 6a and Internet Explorer 4.01 or higher. **DSCLIENT.EXE** is a self-extracting executable with a straightforward wizard installation. It also supports quiet mode with the **/q** switch for deploying to multiple workstations. The client replaces many DLL files for changes “under the hood.” Some of these files will not be removed if the DS Client is uninstalled. From the user's point of view, the DS Client adds the capability to search for people and printers published in Active Directory and replaces the Windows Address Book with an updated, AD-aware version.

**NOTE** Files that cannot be removed by uninstalling the DS Client are: **Netlogon.dll**, **Netapi32.dll**, **Mup.sys**, **Wkssvc.dll**, and **Wldap32.dll**. These files upgrade NT 4's basic logon and networking behavior for compatibility with Active Directory networks.

## Connecting Windows 9x and Windows Me Workstations

Connecting a Windows 9x or Windows Me workstation to the network is almost as simple as connecting Windows XP and Windows 2000. You have Plug and Play on your side, which usually takes the guesswork out of installing the network card. Once the card is installed, a default set of network

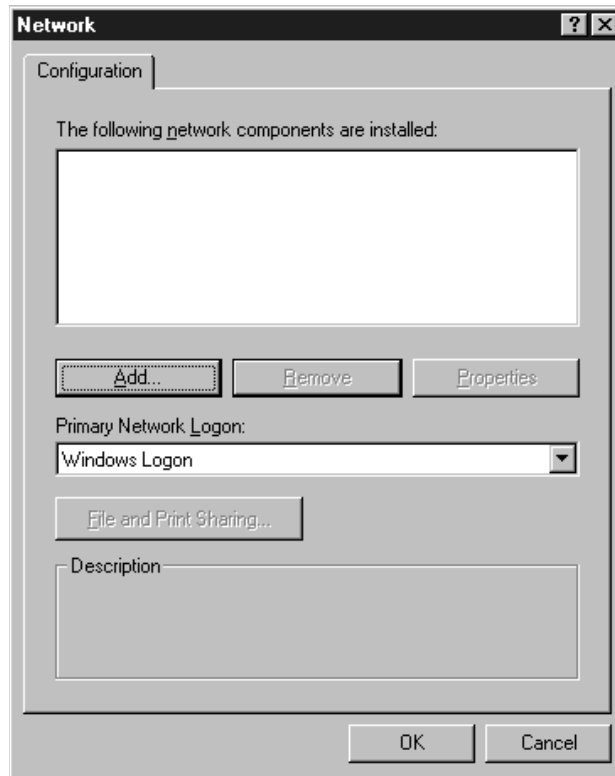

components loads automatically. Unlike Windows XP, 2000, and NT 4, Windows 9x cannot join the domain and does not require a machine account. You'll still need to tell the workstation about the user's logon domain, however.

## Configuring the Workstation

Let's assume that your workstation is up and running with Windows 9x and has no networking components installed. Open the Network Control Panel (select Start/Settings/Control Panel, then open up the Network applet). You should see an empty network configuration dialog box like the one shown in Figure 14.22.

**FIGURE 14.22**

The Configuration tab of the Network Control Panel for Windows 9x

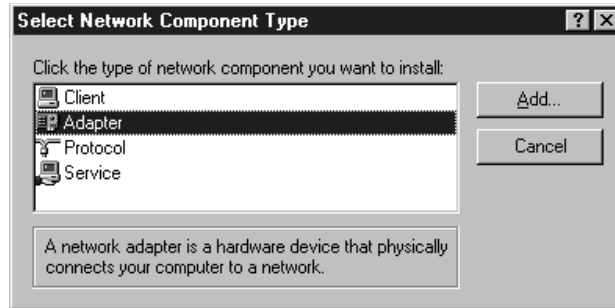

You need to install a network adapter, at least one protocol, and at least one type of networking *client*. Additionally, you can add a *service*, such as file and print sharing. I am assuming that your system has none of these, so click the Add button. As shown in Figure 14.23, you are asked which type of networking component to add.

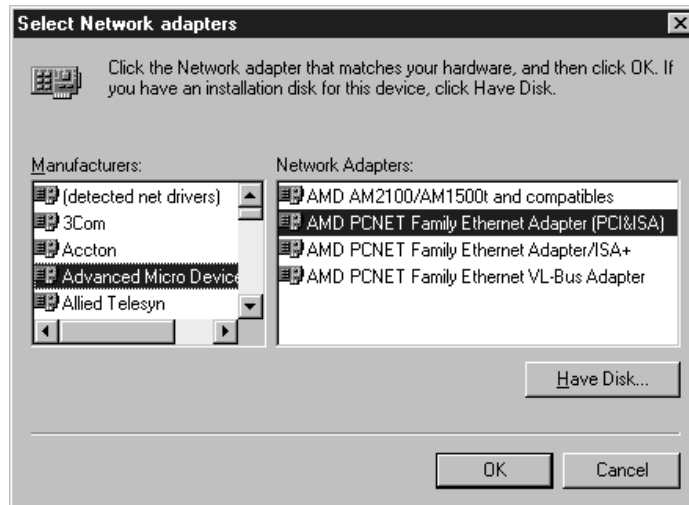

As always, you'll start off by adding an adapter. From the list of component types, select Adapter and then click Add once again to open up the dialog box shown in Figure 14.24.

**FIGURE 14.23**

The Select Network Component Type dialog box

**FIGURE 14.24**

The Select Network Adapters dialog box

In the Select Network Adapters dialog box, you'll see a list of adapter manufacturers on the left and corresponding adapters on the right. Choose your adapter from the list, or if your adapter is not on the list and you have the OEM disk, click Have Disk and then click OK. Setup will try to copy the files needed from the Windows CD-ROM or the manufacturer's disk.

Once the adapter is installed, an interesting thing happens. Windows knows that adapters need protocols and network clients, so it installs a set of default components to make your life easier. In Windows 95, IPX/SPX and NetBEUI are the default protocols. Two clients are loaded as well: the Client for Microsoft Networks and the Client for Netware Networks. In Windows 98, as you can see in Figure 14.25, only the Client for Microsoft Networks and TCP/IP are installed by default. If your system is Windows 95, you may need to add TCP/IP Protocol and then remove the Netware Components and NetBEUI protocol. If you add TCP/IP, Windows will need to copy files from the CD-ROM. For convenience, TCP/IP is already configured to use DHCP automatically. To statically assign an IP address or other configuration information, highlight TCP/IP and click Properties.

**FIGURE 14.25**

A full complement of networking components is installed by default.

After adding the adapter and configuring the other network components, but before designating a workgroup and logon domain, I suggest that you close the Network Control Panel, let Windows copy the files it needs from the CD-ROM, and restart when prompted. Look for any errors at startup. If you don't see any, log on and use WINIPCFG.EXE and the command prompt to verify TCP/IP connectivity.

### Designating a Workgroup and a Logon Domain

Unlike a Windows NT or Windows 2000 machine, and more like a Windows for Workgroups machine, a Windows 9x machine cannot be a domain member. However, it does not have to *belong* to a specific domain in order for a user to log on to that domain.

Before you configure Windows to log users on to a domain, you should also change the workgroup name to be the same as the domain name. Why? To make browsing for resources easier, the members of a domain also form a workgroup of the same name (remember, workgroups are for browsing and domains are for security). When you open up Network Neighborhood, your workgroup is the starting point. You see the servers in your workgroup first. By putting your machine into the same workgroup as your domain, your domain resources will be more accessible. Also, if your Windows 9x workstation is running the server component (File and Printer Sharing for Microsoft Networks), it registers itself with the other servers in the workgroup.

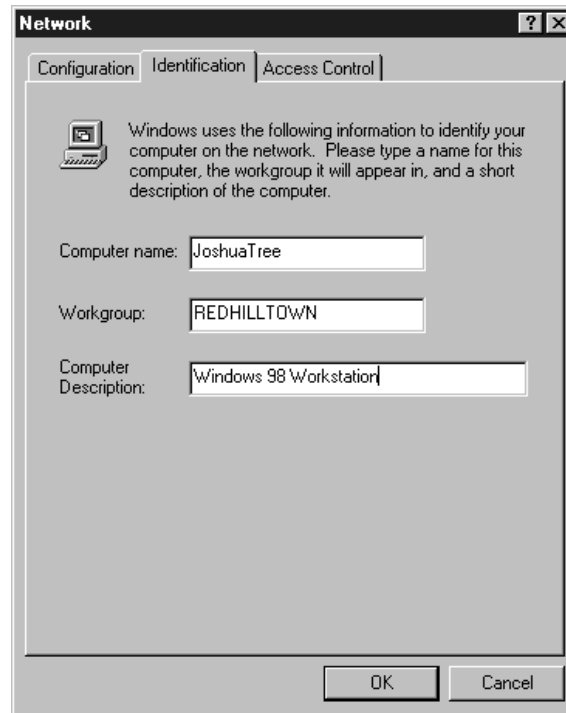

In the example that follows, assume that the domain where user accounts live is also a resource domain. That is, the same domain holds all the user accounts and all the computer accounts.

**NOTE** It is not a foregone conclusion that all the user accounts and all the computer accounts exist in the same domain; on some networks, the domain that contains user accounts (the user domain) is separate from the domain with the machine accounts and shared resources (the resource domain). In this case, your Windows 9x machine should join a workgroup with the same name as the resource domain, and you should configure Windows to log folks on to the user domain.

To specify a workgroup for your Windows 9x system, open the Identification tab in the Network Control Panel (see Figure 14.26) and type the name of the workgroup in the space provided. This system's unique computer name is JOSHUATREE. My workgroup name is REDHILLTOWN.

**FIGURE 14.26**

The Network Control Panel's Identification tab

To specify a logon domain for users, go back to the Configuration tab of the Network Control Panel. Select the Client for Microsoft Networks and click Properties to open the dialog box shown in Figure 14.27. Check the box labeled Log On to Windows NT Domain and type the NetBIOS name of the domain where the user accounts live. Click OK and close the Network Control Panel. Now restart your system.

After rebooting, users will be prompted to supply a network password for Microsoft networking. The default domain name in the Domain text box is the one you specified in the Network Control Panel. However, unlike our NT-based cousins, you can type any domain name in the Domain text box. Windows 9x does not require that you log on to the domain specified in the Network Control Panel.

**FIGURE 14.27**  
Client for Micro-  
soft Networks  
properties page

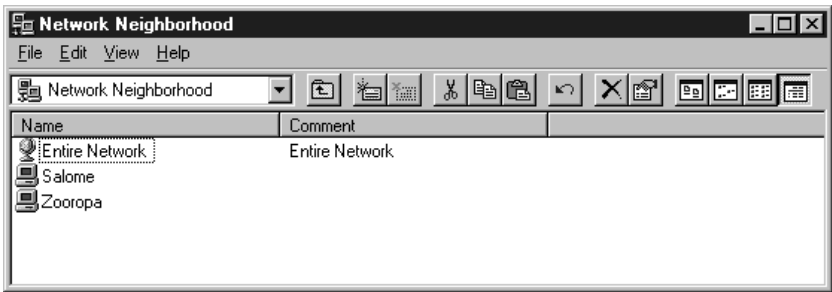

**NOTE** Unlike Windows XP, 2000, and NT, Windows 9x will not require users to log on to any domain at all. You can simply click Cancel at the logon prompt and you're in—to the workstation, but not the domain. This is good to know if you are having a problem with the configuration after you specify a logon domain. After all, you may need access to the system to solve the problem.

**Connecting to Network Resources**

Now it's time to find and connect to some network stuff. Double-click the Network Neighborhood icon on the Desktop (my Network Neighborhood is shown in Figure 14.28).

**FIGURE 14.28**  
Network  
Neighborhood

If you are following along on your own system, what you see in your Network Neighborhood is the browse list for your workgroup—or domain, if the name is the same. In my domain,

REDHILLTOWN, there are currently two servers on the browse list, Zooropa and Salome. Double-click a server on the list to see a list of its shares, as shown in Figure 14.29.

**FIGURE 14.29**  
Shared resources  
on Salome

In Figure 14.29, Salome has several shares. Double-click to open a share in a window and browse files and folders, or right-click and choose Map Network Drive to map a logical drive to a share.

By the way, Network Neighborhood will show printer shares as well as directory shares. To attach to a network printer, click Start/Settings and then Printers. Choose the option to create a new printer. A wizard starts and asks you if you are installing a locally attached printer or a network printer. Choose network printer and click Next. The wizard asks you where to find the printer. Type in a UNC name (`\\SERVERNAME\PRINTERSHARENAME`) or click the Browse button to find your printer on the browse list. Next, tell the wizard where to find the printer driver (the Windows installation CD-ROM or a vendor-supplied floppy, perhaps). When prompted, have Windows print a test page to verify the connection.

## Changing Passwords

If your password has expired, or it is your first logon since the account was created, a handy little message and a Change Password dialog box appears, complete with fields to type in the old password and the new password (twice for confirmation, of course). To change the domain password before it expires, however, open the Passwords applet in the Control Panel. As you can see in Figure 14.30, there are two options for changing passwords: Change Windows Password and Change Other Passwords. If you choose the option to Change Other Passwords, you can change your domain password but your local password will not be changed. It's important to keep your Windows password synchronized with your domain password, or chaos will ensue. To change your local Windows password and the domain password at the same time, click the Change Windows Password button and select the check box to change your Microsoft Networking password (see Figure 14.31).

It's important to keep your Windows password and your domain password synchronized because Windows keeps a separate password for each person who logs on to the workstation. This password allows Windows to distinguish between users and their individual settings and to access users' individual password files. The password file may contain a number of other passwords, including the domain password. When the Windows password and domain password are the same, users can log on to Windows and to the domain simultaneously. If they are different, however, domain servers may deny access to resources because Windows is offering up the wrong password.

**FIGURE 14.30**

The Passwords properties page

**FIGURE 14.31**

The Change Windows Password dialog box

## Accessing the Active Directory

Earlier in this chapter I mentioned that Directory Services Clients are available for Windows 9x clients. To install them, get your hands on a Windows 2000 Server CD. At this time the DS client is not included on the Server 2003 CD. DSCLIENT.EXE is in \CLIENTS\WIN9X on the Windows 2000 CD. It's an auto-extracting 3MB CAB file. The installation is a straightforward click-Next-to-continue and reboot process.

Once the Active Directory client is installed, what exactly has changed? You won't see a new program or anything because most of the changes are under the hood. There are a couple of new options and capabilities under the Find menu within Windows Explorer, though. Now you can search the Active Directory for printers. The DS Client also installs a new version of the Windows Address Book, which can find people published in the Active Directory. Clearly, this little client doesn't give you a direct tap into the heart of the Active Directory, but it does provide some essential functionality required to make Active Directory published resources visible to Windows 9x clients.

### **ARE YOU HAVING PROBLEMS LOGGING ON TO AN ACTIVE DIRECTORY DOMAIN FROM WINDOWS 9X?**

Here's a short list of possible problem areas to check:

- ◆ First, make sure you have installed all the recommended patches and security fixes on the client systems.
- ◆ Install the DS Client from the Windows 2000 CD-ROM (\CLIENTS\WIN9X\DSCLIENT.EXE). It upgrades several libraries that affect logon and authentication. The DS Client for Windows 9x requires Internet Explorer 4.01 or later.
- ◆ Windows 95/98 doesn't register with Active DNS, so try putting a WINS server on the network. Your Windows clients and your domain controllers should be configured to use it.
- ◆ Active Directory domain controllers use DNS for name resolution. Create static entries in DNS for your Win 9x clients. This also means that the Windows 9x systems will need to keep the same addresses all the time, so consider static addressing or DHCP reservations for these clients.
- ◆ Make sure you specify the NetBIOS domain name in the Network Control Panel. Use REDHILLTOWN instead of REDHILLTOWN.COM, for example.

## **Connecting Windows for Workgroups Workstations**

Windows for Workgroups computers are becoming more and more rare on today's corporate networks, but occasionally a business relies on an application or system that's stuck in the Windows 3.11 environment, so it might not hurt to be prepared. It's probably safe to say that we have all gotten too used to the Windows 9x, Windows NT, and Windows 2000 interfaces to be very efficient when sitting in front of an old Windows for Workgroups machine. Everything is in a different place. There's no Start menu! How embarrassing would it be to sit down at a workstation—you being the senior administrator—and not have the slightest clue how to connect to your servers? Well, relax. I'll walk you through the basic networking configuration of Windows for Workgroups and discuss how to connect to network resources.

Before trying to use a Windows for Workgroups client in a Windows Server 2003 environment, you need to be aware of two important issues. First, the Active Directory—and all the benefits that come with it—is not available. You are pretty much limited to basic network share access. Second, before WFW (or DOS) clients can log on successfully to an Active Directory domain at all, a domain controller security setting which requires digitally signed communications must be disabled. I'll discuss this second issue in more detail a bit later.

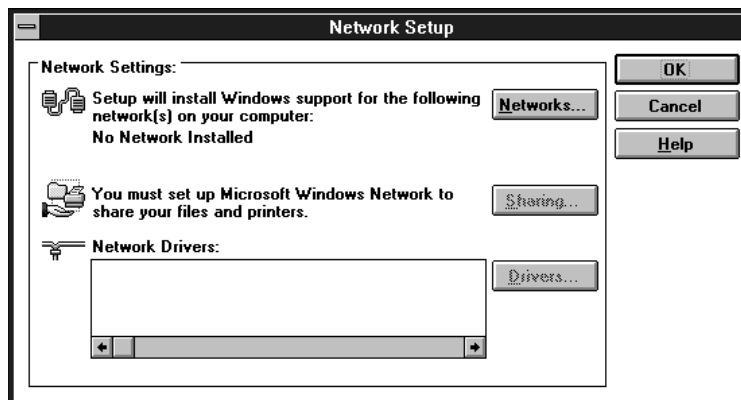

## Configuring the Workstation

All of the examples in this chapter use TCP/IP as the default protocol. However, WFW (also called Windows 3.11) does not ship with the TCP/IP protocol. If you want Windows 3.11 to use TCP/IP, you'll need to put it on a floppy or make it otherwise accessible during the installation. The 32-bit TCP/IP stack is available on the Windows NT Server 4 CD-ROM, under \CLIENTS\TCP32WFW\DISKS\DISK1. You can also download the latest version of the 32-bit TCP/IP stack from Microsoft's FTP site.

As you did with Windows 9x, start from the very beginning: assume that an NIC has been installed on the system but has not yet been configured and that no other networking components are installed. In the Program Manager window, find and open the Network program group. Now double-click Network Setup to launch the setup process. A dialog box like the one shown in Figure 14.32 will appear.

**FIGURE 14.32**

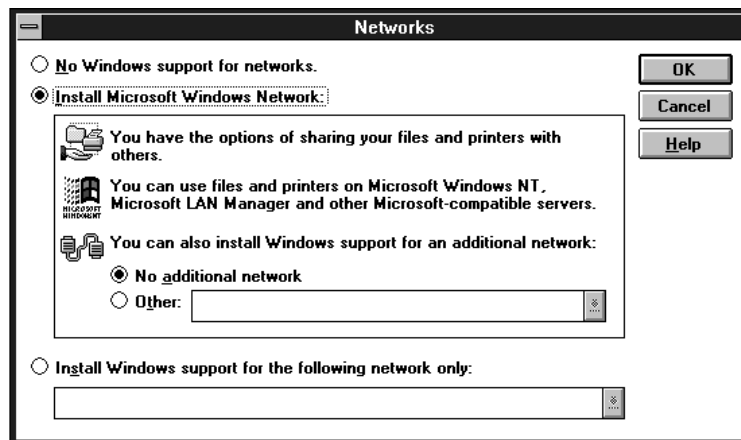

The Network Setup dialog box

The Network Setup dialog box reports that no network support is installed. Click the Networks button. In the Networks dialog box, choose Install Microsoft Windows Network (see Figure 14.33) and click OK. This tells Windows that you want to install the Client for Microsoft Networks.

**FIGURE 14.33**

Selecting a network client

Back in the Network Setup dialog box, it's time to install an adapter. Click the Drivers button. Although no components are present yet, the Network Drivers dialog box will be used to add both network adapters and protocols. To see how the Network Drivers dialog box will look after adding these components, look ahead to Figure 14.35. Click Add Adapter to see a list of supported network cards (see Figure 14.34). Locate and select your adapter in the list, or if you're feeling brave, click the Detect button to have setup attempt to detect your card. If you have a card that is not on the list, and you have the OEM disk with Windows 3.11 drivers, highlight Unlisted or Updated Network Adapter and click OK. Setup will ask you where to find the driver files. Type in the path for the files and click OK.

**FIGURE 14.34**  
Selecting an adapter

I say you have to be brave to use the Detect button because the Windows for Workgroups programming predates Plug and Play by quite some time. The risk of system lockup during this detection phase is substantial. Nevertheless, on my system with a 3Com EtherLink III ISA card, setup was able to detect the adapter.

After installing your adapter, setup will return you to the Network Drivers dialog box. As shown in Figure 14.35, a set of default protocols has been installed as well.

**FIGURE 14.35**  
Default protocols

Remove the components you don't need by highlighting them and clicking Remove. Answer Yes to the confirmation dialog box that will pop up. But wait. If you remove the last protocol, the setup program will also remove the adapter (Windows will tell you this if you try it). So you should

add the protocol you want to use as the default (TCP/IP in our case) before you remove the last unwanted protocol.

To add TCP/IP and set it to be the default protocol, click the Add Protocol button. If TCP/IP has not yet been installed on the system, choose Unlisted or Updated Protocol. When prompted, put your TCP/IP floppy in the drive, tell setup where to find the TCP/IP protocol files, and click OK. Setup should report that it has found driver files for Microsoft TCP/IP-32 3.11b. Click OK to copy the files to your system. Now setup kicks you back to the Network Setup dialog box. Highlight Microsoft TCP/IP on the list of installed drivers and click the Set as Default Protocol button. Now you can remove the last unneeded protocol.

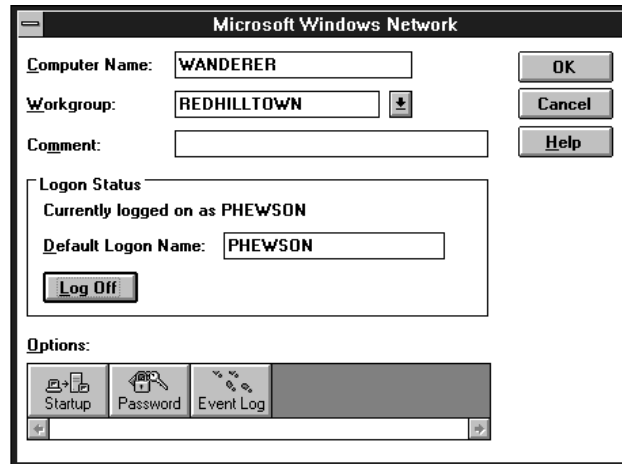

By default, the TCP/IP stack for Windows 3.11 does not use DHCP. If you wish to enable DHCP, highlight TCP/IP and click the Setup button. Check the box labeled Enable Automatic DHCP Configuration and click Yes when asked to confirm your choice. Now click OK to commit your changes and return to the Network Drivers dialog box. Close the Network Drivers dialog box and then click OK to close Network Setup. The system will inform you that it has modified some of your setup files and will ask you to restart.

When Windows restarts, verify your network connectivity. Open the MS-DOS prompt in the Main Program group and use the IPCONFIG and Ping commands as described in the previous sections.

Now we'll move on to configuring your workgroup and logon settings. Once you've set up a network, there is a new applet in the Main Program Group Control Panel. Find and open the Network applet in the Control Panel to see the Microsoft Windows Network configuration dialog box (shown in Figure 14.36). Type in a unique computer name for the system and provide the workgroup name. These settings determine how your system will register itself on the network and how it will browse lists of servers.

**FIGURE 14.36**

The Network Control Panel in Windows for Workgroups

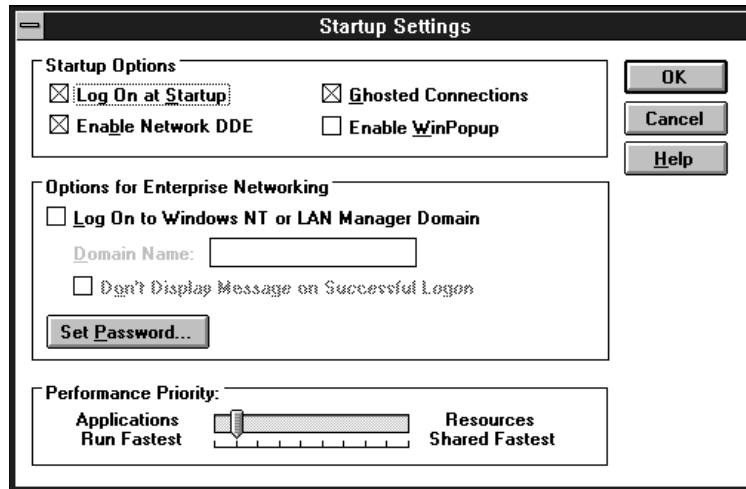

In Figure 14.36, the logon status section of the Network applet displays the currently logged on username and a Log Off button. Logging in to Windows for Workgroups is more simplistic than even Windows 95. Windows for Workgroups does not support user-specific settings at all. Every user receives the same program groups, Desktop, and program settings. User profiles do not exist. Since there is no need to keep up with user-specific information, you can log in and out using the Network Control Panel.

To configure the system for domain logins, click the Startup button in the Network applet. Figure 14.37 shows the default startup parameters for Windows networking. Log On at Startup, which is checked by default, tells Windows for Workgroups to present you with a logon dialog box before the Program Manager loads your Desktop. Check the box labeled Log On to Windows NT or LAN Manager Domain and supply a domain name to specify a user login domain. Use the NetBIOS name of the domain—REDHILLTOWN, in my case—and not the fully qualified domain name REDHILLTOWN.COM.

**FIGURE 14.37**

Startup settings

If you want your Windows 3.11 system to log on to a Windows Server 2003 domain, there's an important issue to consider: Server 2003 domain controllers will not communicate with WFW or DOS systems by default. This is due to a domain controller security policy setting that requires all clients to digitally sign SMB protocol packets. WFW and DOS clients can't do packet signing at all. When the client attempts to log the user on and does not agree to do SMB packet signing, the domain controller refuses the request. Users will see a message saying that the account is invalid or the password has expired.

Only domain controllers require client-side SMB packet signing by default. This behavior is controlled by the Default Domain Controller group policy. To disable this setting and permit domain logons for WFW (and DOS) clients, open the Domain Controller Security Policy tool in the Administrative Tools program group on a domain controller. Expand the Computer Configuration and open Windows Settings/Security Settings/Local Policy/Security Options. Locate and disable the policy called Windows Network Server: digitally sign communications (always). There is another setting called Windows Network Server: digitally sign communications (if client agrees). Leave this setting enabled; it tells the domain controller to negotiate for SMB packet signing whenever possible.

As you can see, the requirement for client-side SMB packet signing is easily disabled; however, you should fully understand the security implications of such a move before proceeding. SMB packet signing is designed to prevent "man-in-the-middle" attacks. In case you aren't familiar with this term

already, a man-in-the-middle attack occurs when a third system is able to monitor, capture, and modify communications between two other computers. Among other things, this type of attack can be used to capture authentication packets and decrypt them. If you don't require SMB packet signing between a domain controller and a client, you are downgrading the default security and leaving not only your system but also your entire domain open to a potential security breach.

If you want to have your WFW systems connect to shared resources without downgrading domain controller security, there is a workaround using pass-through authentication. For details, check out the sidebar “How Can My WFW System Connect to Shares and Printers without Downgrading Security on Domain Controllers?” in the next section.

## Connecting to Network Resources

Now that Windows for Workgroups is configured for networking, it's time to connect to some resources. If you checked the Log On at Startup option in the Network Control Panel, when Windows restarts you'll see a logon box with fields for your username, password, and domain, if configured.

Log in and open the File Manager (remember? It's the little yellow file cabinet in the Main program group). You will discover, as shown in Figure 14.38, that there are two new commands in your Disk menu: Connect Network Drive and Disconnect Network Drive. Select Connect Network Drive to open the Connect Network Drive dialog box (see Figure 14.39). From here you can browse the network for available shares. If you are the impatient sort, type in the UNC name of the server and share in the Path text box. Change the logical drive letter assignment if you wish, and click OK to connect. Now the drive will be listed along with your physical drives in File Manager.

**FIGURE 14.38**

File Manager  
network commands

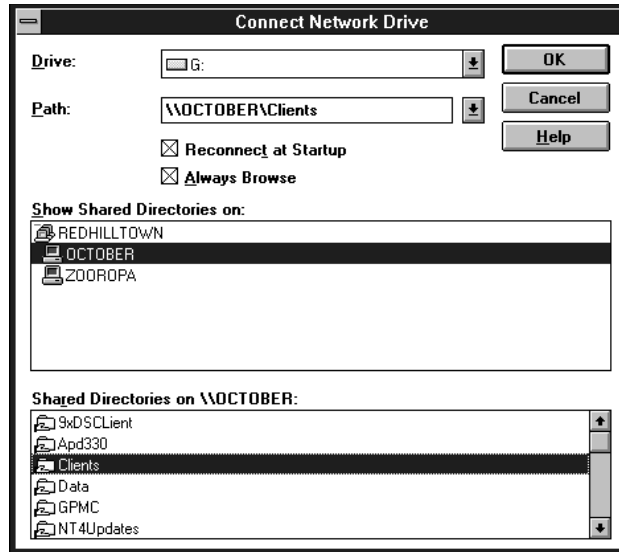

When I say that Windows for Workgroups doesn't distinguish between users and their settings, it applies to drive mappings as well. They are persistent by default. Occasionally you may need to disconnect a drive mapped by another user and recreate a mapping you need. To disconnect from a network drive, choose Disconnect Network Drive from the Disk menu, choose from the list of mapped drives, and click OK.

**NOTE** Sorry, but you can't view or access Active Directory information with a Windows for Workgroups client.

**FIGURE 14.39**

The Connect Network Drive dialog box

***TIP** One of the limitations of Windows for Workgroups systems is that they do not recognize UNC names as valid pathnames. For example, if I have a share on ZOOROPA named WFWUPDATE, which contains a batch file named UPDATE.BAT, I can't simply open File/Run in File Manager and run the command \\ZOOROPA\WFWUPDATE\UPDATE.BAT. Instead, I have to map a drive—let's call it Z:—to \\ZOOROPA\WFWUPDATE and then run Z:\UPDATE.BAT.*

### HOW CAN MY WFW SYSTEM CONNECT TO SHARES AND PRINTERS WITHOUT DOWNGRADING SECURITY ON DOMAIN CONTROLLERS?

In the previous section I broke the bad news that Windows Server 2003 Enterprise Edition does not support domain logons from Windows for Workgroups (or DOS) clients without disabling the SMB packet signing requirement on domain controllers. You can't fix this problem without compromising security. However, there is an unofficial workaround that allows a DOS or Windows 3.11 client to access shared folders on domain member servers.

To use the workaround, do not configure the workstation to log on to a domain at all. Instead, log on to the workstation with a username and password that matches a username and password on the domain. If you try connecting to shared resources on a domain controller server, access will be denied; however, you can connect to a member server on the domain. When your local workstation makes a connection request, the member server will take the username and password that Windows 3.11 supplies and check with the domain controller to see if that information is valid for a user on the domain. If your user ID matches up with a domain account ID and password, the DC gives the member server a “thumbs up” and the member server lets you connect. Pretty slick, eh? If you happen to have any workgroup servers on your network, Windows 3.11 and DOS clients can also connect to Server 2003 that do not belong to a domain, using a Windows username and password that matches a local account on the workgroup server.

## Changing Passwords

Unlike Windows 9x, Windows for Workgroups doesn't make it convenient to synchronize passwords. To change your Windows password, open the Network Control Panel in the Main Program Group. Click the Password button (shown back in Figure 14.36) to open the Change Logon Password dialog box. If you want to change a domain password, however, click the Startup button in the Network Control Panel. In the Options for Enterprise Networking section (shown back in Figure 14.37), click Set Password to open the Change Domain Password dialog box. In either case, (and like all change password boxes throughout history), type in your old password, then your new password twice, and click OK to finish.

## Connecting DOS Workstations

Now we enter into the realm of the forgotten GUI-less operating system: DOS. If you've perused the preceding section, you already know that Windows Server 2003 domain controllers will not authenticate users from a Windows 3.11 or DOS system. If this is new information to you, check out the sidebar at the end of the preceding section on Windows for Workgroups clients to learn how to work around this limitation.

I won't ask why the heck you still have DOS clients hanging around on your network. I myself used to work for a small technology company whose Customer Support department relied heavily on a DOS-based protocol analyzer. Any suggestions from IT people about replacing or upgrading the software or the system provoked loudly pronounced phrases like "over my dead body." Not all business decisions are rational. Once in a while you get stuck with supporting a dinosaur (um, I mean legacy operating system). And sometimes that legacy operating system needs access to the network. So here we go.

If you were working with Microsoft networks in the days of Windows NT 3.x and 4, you'll recall that NT had this Network Client Administrator utility in the Administrative Tools program group. The Network Client Administrator could make a bootable network startup disk to connect DOS clients to an installation source. It could also make a two-disk set of a DOS networking client stack called MSCLIENT 3.0.

Both of those little tools disappeared with Windows 2000 and are completely off the radar with Server 2003. This is probably due to the fact that DOS is no longer a supported operating system. Calling Microsoft with a DOS networking problem is likely to result in the sound of muffled laughter and faint snickers drifting over the phone line. Even in the days of NT 3.x and 4, the inclusion of DOS tools on the CD was mainly for the purpose of launching an install.

The emergence of new and improved installation methods makes DOS-based network startup disks largely unnecessary today. Instead of booting from a DOS diskette with CD or network drivers to connect to your install source, you can boot from the installation CD-ROM. Setup programs, particularly upgrades, are also smarter; it's usually unnecessary to wipe a machine clean before an installation.

Nevertheless, if you do find that you have a need to connect DOS clients to Windows Server 2003, Server 2003 doesn't come with any handy utilities to create network startup disks or MS Client disks. So you need to be resourceful. In the next section, I'll step you through the process of making MS Client disks and loading the network software on a DOS system.

**NOTE** You may search the Internet and find instructions for installing the Network Client Administrator (NCA) from the NT 4 Server CD. However, I recommend against using it to make a network startup disk, for a couple of reasons. The most important reason is limited support for network cards. NCA only includes drivers for a very short list of network cards; if your adapter isn't on the list, well, you're in that proverbial state of SOL. To add support for your card, you need to manually add the DOS driver to the disk and manually edit a couple of INI files. NCA also does not give you the opportunity to specify an I/O address or IRQ settings for the network card. In short, unless you will use the same floppy for a whole bunch of machines with the same adapter and network card settings, it's not worth the extra effort to configure a working startup boot disk.

## Making the MS Client Disk Set

Follow these steps to make a network client disk set for DOS:

1. Make a bootable floppy to use as Disk 1 of the set. Use another DOS-based system, or Windows 9x. In case this is before your time, the command to format a floppy and make it bootable is `format a: /s`. It's not necessary to make the first client disk bootable if the system can already boot to DOS (or if you want to carry around a separate boot disk).
2. Format a second floppy to use as Disk 2 of the set. It doesn't need to be bootable.
3. Go exploring on the Windows NT 4 Server CD-ROM. Find the DOS client files under `\CLIENTS\MSCLIENT\DISKS`. Copy the contents of the `DISK1` directory to the first floppy. Copy the contents of the `DISK2` directory to the second floppy. The second diskette has all the TCP/IP protocol files, so you definitely need it. Label the disks appropriately. I'll refer to them as Disk 1 and Disk 2.
4. If you don't have access to the NT Server 4 CD, download the MS Client disk files from Microsoft's FTP site: `ftp://ftp.microsoft.com/bussys/Clients/MSCLIENT/`. There are two self-extracting executable files: `DSK3-1.EXE` and `DSK3-2.EXE`. Download these two files and put them into separate directories. Double-click to extract the files into their current directories. Now copy the contents of the directories (minus the original executables!) to the two floppies as described in the previous step.
5. If you like, create an `autoexec.bat` file on the first floppy that includes the command `setup .exe`. If you do this, the MS Client setup program will launch automatically.

## Installing and Configuring MS Client

Now that you have made the MS Client disk set, take those two floppies and the OEM disk for the workstation's network card in hand and proceed to your workstation. Before running the MS Client installation program, I highly recommend that you use the OEM disk for your network card to make sure the card has no resource conflicts. The setup program usually cannot correct these. 3Com cards, which are very popular and well supported, usually have a diagnostics program and can automatically configure the card's settings.

Now boot your workstation with MS Client Disk 1. If you didn't put the setup command in an `autoexec.bat` file, type `setup.exe` at the command prompt. When you see the Welcome screen for the MS Network Client, press Enter to continue. Setup asks you where to put the network files. The default path is `C:\NET`. Actually, if you booted from the floppy, it's `A:\NET` and you don't want that, so type in the path you want to use and press Enter. Now setup asks you to select a network adapter

from a list (see Figure 14.40). Select an adapter from the list, or choose Network Adapter Not Shown on List to type in the path for the OEM driver you want to use.

**FIGURE 14.40**

Select a network adapter.

**TIP** DOS network card drivers are usually labeled *NDIS 3.0* or *NDIS 3* or *Windows 3.11* drivers on the OEM disk. They don't call them DOS drivers or MS Client 3 drivers.

Now the setup program offers to use more memory for greater performance. You can give this a try, but the TCP/IP stack uses a lot of memory (relatively speaking) so I usually press C to skip the extra buffers. In the next screen, type in a username for use on the network.

Setup presents a configuration screen labeled *Setup for Microsoft Network Client v3.0 for MS-DOS* (shown in Figure 14.41). There are three separate configuration sections: Names, Setup Options, and Network Configuration. You'll configure each of these in turn.

**FIGURE 14.41**

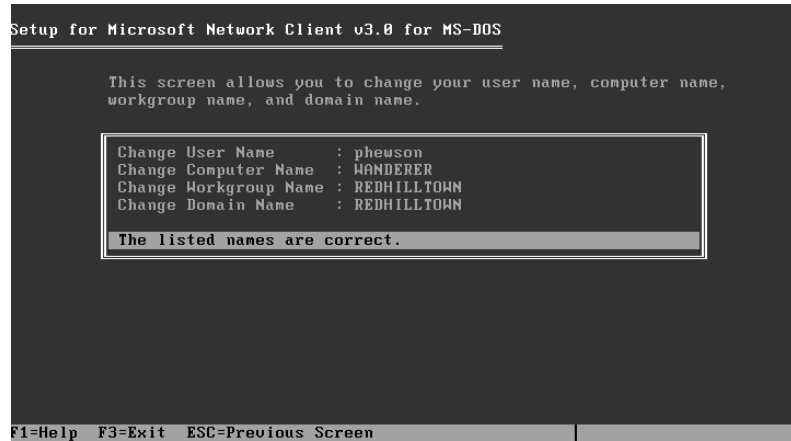

The main configuration screen

Use the up arrow to highlight Names and press Enter. You've already supplied your username, so go ahead and enter a unique computer name, your workgroup name, and a domain name if desired. Don't worry, you'll configure the option to log on to a domain in the next section. This tells setup what domain that will be if you enable the option. For each option, use the up and down arrows on the keyboard to highlight the desired item, and press Enter. In Figure 14.42, I have configured the system to log me on as PHEWSON with the computer name WANDERER, and REDHILLTOWN is the name of both my workgroup and my domain. When all the names are configured to your liking, highlight The Listed Names Are Correct and press Enter to return to the main configuration screen.

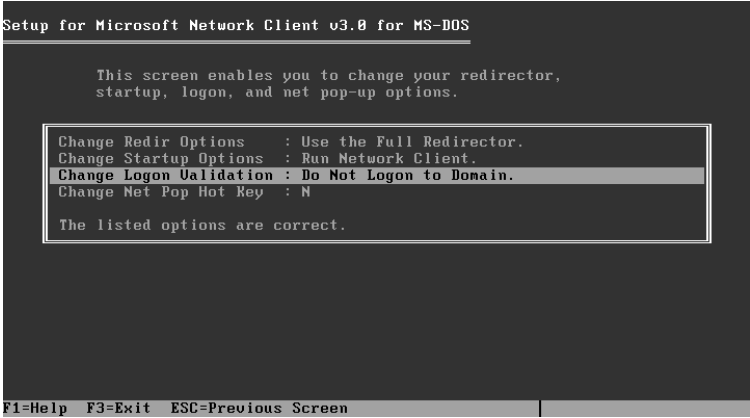

**FIGURE 14.42**

Configuring  
network names

Now go to the setup options. Figure 14.43 shows the default options. Do Not Logon to Domain is the default; to tell the software to log on to a domain, highlight the selection, press Enter, and change the option to Log On to Domain. Accept these options and go back to the main configuration screen. Choose Change Network Configuration to configure your network adapter and protocols. From this screen (shown in Figure 14.44) you can add or remove an adapter or modify the adapter's settings. The available adapter settings are often vendor and card-specific. The default protocol is NWLink IPX Compatible Transport. If your network is like mine, TCP/IP is the only protocol in use. To remove NWLink, use the Tab and arrow keys to highlight it, and then hop back down to the second box and click Remove. Setup will remove the protocol and ask you which protocol you want to use. If you choose TCP/IP, setup will automatically use DHCP for addressing. To configure static addressing information, highlight TCP/IP and choose Settings. To disable DHCP, change the values of the parameter named Disable Automatic Configuration from zero to one (see Figure 14.45). Notice also that the IP addressing syntax uses spaces instead of a decimal point to indicate octets; type in **192 168 1 1**, for example, instead of **192.168.1.1**.

**FIGURE 14.43**  
MS Client setup  
options

**FIGURE 14.44**  
Installed adapters  
and protocols

**FIGURE 14.45**  
Modify TCP/IP  
protocol settings.

When you are finished configuring TCP/IP parameters, indicate that the listed options are correct and press Enter. Back at the network configuration screen (Figure 14.44 again), highlight Network Configuration Is Correct and press Enter to return to the main configuration screen (shown in Figure 14.41). If you are finished configuring the client, highlight The Listed Options Are Correct and press Enter. Now setup begins to copy files. Keep the OEM setup disk handy if the driver is not included with MS Client. Insert the second MS Client disk when you are prompted. Next, the program will modify startup files (AUTOEXEC.BAT and CONFIG.SYS) and prompt you to reboot. From now on, if you need to modify any of these settings, run **setup.exe** from the \NET directory.

When the system restarts, watch the networking programs initialize. You might see something similar to Figure 14.46. If your network adapter fails to load (perhaps due to an unresolved resource conflict), it will be very obvious, and all of the dependent processes will fail. If everything initializes properly, log in and supply a Windows password. Now you are ready to connect to the network.

**FIGURE 14.46**

```

Be aware that DOS clients cannot do SMB packet signing, which is required by default on domain controllers. This will prevent the DOS client from authenticating a user on the domain, unless the policy requiring SMB packet signing is disabled. Disabling the policy downgrades default security settings and opens up domain controllers to man-in-the-middle attacks, but if you decide to do it anyway, the procedure is outlined in the previous section on configuring WFW clients. There is also a sidebar in the previous section with a workaround to permit DOS and WFW clients to access shares on nondomain controller servers in the domain.

## Connecting to Network Resources

With the Windows and NT-based clients, you used the graphical interface to browse the network and connect to shared folders and printers. Now you will use NET.EXE commands to accomplish these things.

**TIP** *NET.EXE is a self-standing utility. Typing **net** calls up your network program; the next parameter, like **use**, is the function you want to perform. Additional parameters or arguments tell the function how or on what to perform the function. Understand that **net** is a simple command-line utility, and everything else is a little less confusing. To learn about all of the possible **net** commands, type **NET HELP** at any DOS, Windows 3.11, Windows NT, Windows 2000, or Windows XP command prompt.*

**Net logon** is the command that logs you on to the network, or domain, as the case may be. The MSClient setup program will insert this command into the AUTOEXEC.BAT file to initiate the logon sequence at startup. To log on manually, type **net logon username**. Logon also accepts the parameter **/domain:domainname** for logging on to a Windows NT domain. The counterpart to **net logon** is **net logoff**.

To browse the network, use **net view**. The **net view** statement by itself will return a list of servers in your workgroup:

```
Servers available in workgroup REDHILLTOWN.
Server Name      Remark
-----
\\ZOOOROPA
\\OCTOBER
\\SALOME
The command completed successfully.
```

To see a list of shares on one of these servers, type **net view \\SERVERNAME**. A response to the command **net view \\OCTOBER** would return something like this:

```
Shared resources at \\OCTOBER
Sharename      Type      Comment
-----
Clients        Disk      Client Updates
Data           Disk      Database Directory
WFW311         Disk      WFW Source Files
HP4M           Print     Printer on 15th Floor
```

Once you've located your share, connect using the **net use** command:

```
net use E: \\OCTOBER\WFW311
```

**TIP** *DOS only allows five drive letters to be mapped by default. To allow more drive letters, add a **LASTDRIVE** statement to **CONFIG.SYS**. For instance, to permit mappings up to **J**, add **LASTDRIVE=J** to **CONFIG.SYS**.*

To see the full syntax of **net use** (or any other **net** command, for that matter), type the command followed by **/?** or type **NET HELP USE**. The basic syntax of **net use** is **net use DRIVE: \\SERVERNAME\SHARENAME**.

This syntax can also be used for connecting to printers: **net use PORT: \\SERVERNAME\PRINTSHARENAME**.

For the port, use a local port, such as **LPT1** or **LPT2**. This tells the network software to redirect any print requests addressed to the local port to the network share.

By default, network connections are persistent. To make a connection that is not persistent, add the **/PERSISTENT:NO** argument to the **net use** command. To delete existing connections, use the **/DELETE** argument: **net use E: /DELETE**. Or to delete all connections, type **net use \* /DELETE**.

## Changing Passwords

To change your password on a DOS client machine, type **net password USERNAME OLDPASSWORD NEWPASSWORD**. For example, if the user Paul Hewson wanted to change his password from bonovoxx to macphisto, he would type:

```
net password phewson bonovoxx macphisto
```

To change a password on the domain, just add the */DOMAIN:DOMAINNAME* argument with **net password**:

```
net password phewson /DOMAIN:REDHILLTOWN
```

DOS network clients are a bit more work than Windows clients, but look on the bright side. You'll be an expert at using the NET commands. With only minor syntax variations, NET commands work on every Microsoft Network client and server system, even Windows XP and Windows Server 2003.

## Chapter 15

# Macintosh and Windows Server Integration

THIS CHAPTER MAKES A couple of assumptions. One, that the reader is (or wants to be) primarily a PC/Windows professional (otherwise, why read this book?). Two, that you, the reader, need some information concerning integrating Apple Macintoshes into your Windows Server network (and on Macintoshes in general). In other words, you have inherited a graphics department that needs to have access to public data, printers, Internet, etc. Three, said graphics department has no intention of switching to PCs for your administrative convenience.

It is possible that you feel that you're better off leaving well enough alone and keeping the graphics department isolated from the rest of the network. That integration is a big hassle, nigh to impossible, and not worth the effort. Well, let's admit that some effort will have to be made. But not as much as you might think.

Over the course of this chapter, I will be giving you some ideas (and step-by-step instructions) about how and why you might want to give the Macs access to Windows resources, and vice versa. These are suggestions and they reflect my personal opinion and experience. Generally, I have a limited amount of time to do administrative tasks so I tend to want to do only quick and easy things that still get the implementation and maintenance effectively done. I figure you might only want to do those kinds of things too. Minimal effort, maximum results. That doesn't mean there will be no work up front, but certainly no more work than is necessary.

This chapter was created to give you insights as to what might be happening with the Macintoshes on your network right now and how to effectively integrate them with your Windows Server network with the minimum amount of stress for everyone involved.

## Macintosh Hardware and Operating System Inventory

In order to really get an idea of what kind of integration you can actually do with the Macs you have, you'll need to go look at them. Yes, I know that you want a fix that you can push over the network and without ever having to touch the workstations. For the most part, you will only have to touch them once or twice, but a brief "hello, Mac" can't be avoided. Here are some quick tips to give you some frame of reference when doing your inventory.

## Hardware

If you have any Macintoshes that were purchased before 1998, chances are they will not be able to do what you need them to do as well as you need them to. Think about trying to run Windows XP on a 486 and you'll get the picture.

Here is a good rule of thumb concerning Macintoshes: Try to avoid any Macintosh model prior to the Power Macintosh series. That means avoid LC ("low cost," Celeron type of processor), Quadra, most Performas, Centris, Classic, or II. Any Power Macintosh or newer Performa will have the model number/processor speed right on the case, such as Power Macintosh 7600/200.

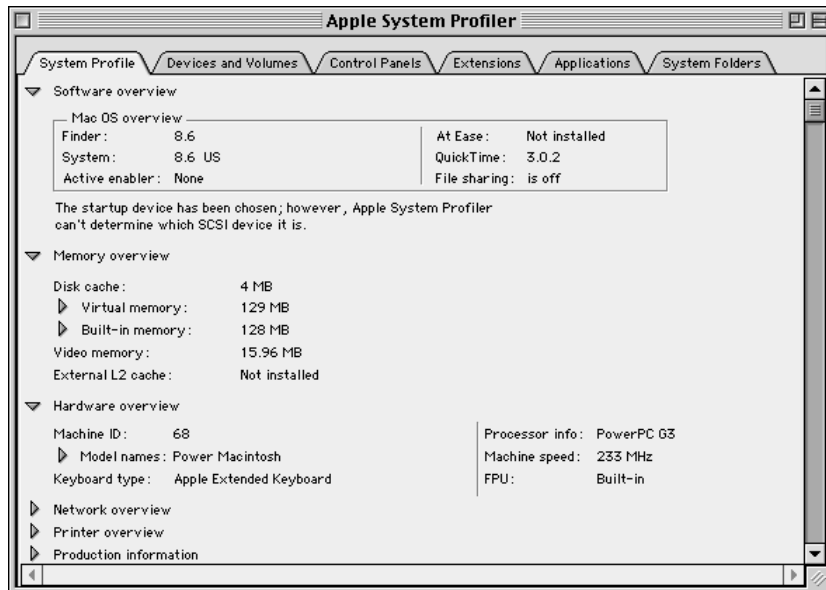

### IN CASE YOUR PREDECESSOR DID NOT LEAVE YOU A NICE, DETAILED INVENTORY OF THE MACS

To get a rundown of which Macintoshes are on your network, what they're capable of, and what they're currently running without visiting every machine, just have your users print out the Apple System Profiler.

The Apple System Profiler is a program that has come with essentially every Macintosh OS since 7.6.1. It should be right on the Apple menu. If not, use Find to locate it because the users may have moved it. Then tell the users to follow these steps from the Apple menu:

1. Click Apple System Profile.
2. Click File\New Report.
3. Keep all default settings, then click OK.
4. Select Text Document at the top of the page.
5. Save the report with their machine name as the filename.

Then have them e-mail the document to you.

To run OS 8.6 (the lowest operating system version I suggest you use to integrate with Windows Server—more on that in a moment), you will need to have a processor that runs at 180MHz or faster and have at least 64MB RAM. (I know, technically you can run OS 8.6 on 32MB of RAM, but would you want to run even Windows 98 on 32MB? I rest my case.) These requirements, enough hard drive space to install the operating system, and an Ethernet network card are basically all you need to do file sharing smoothly and easily with the Server 2003 network users.

Here is a short list of acceptable Mac models for integration with Server 2003:

- ◆ Power Macintoshes that have processors of over 180MHz
- ◆ Power Macintosh G3 (they're sort of the PIII of Mac processors)
- ◆ Power Macintosh G4 (P4)
- ◆ iMac (all-in-one models are G3s, the flat-screen "swivelheads" are G4s)
- ◆ eMac (G4s, so far)
- ◆ Powerbook G3 and G4 (laptop)
- ◆ iBook (G3)

All of these Macs are capable of having 64MB RAM installed, and many of them come with at least that much.

## Macintosh Operating Systems

Now you've checked out what machines you have. Chances are they're all capable of running OS 8.6 or higher. (I assume that because these days, graphics departments generally can't support Photoshop, Quark Express, and other high-end graphics and publishing software on older, low-end workstations.)

In January 2003, Apple started selling machines that only work with OS X or higher (It's a ROM thing). OS 9 came out in October 1999. Chances are good that you will have no Macs that have anything less than OS 9.1 on them. But, having said that, Macintoshes are hardy and seem to run forever. I'll be cautious and won't rule out entirely the fact that you could have some older machines on your network.

Still, you should only be working with hardware that can run OS 8.6 or better. Why? Well, previous versions may be able to do what you want, but it'll involve more work. In other words, previous versions of the Mac OS will require you to download several patches. If you don't want to have to download and patch anything, OS 8.6 is as old-fashioned as you should get, and from this point I'll assume that all your Macs are running OS 8.6 or higher. This means they can all do TCP/IP natively and they all have Ethernet network cards.

The newer and more likely OS versions you will be seeing are as follows:

- ◆ OS 9.1
- ◆ OS 9.2.2
- ◆ OS X 10.1.5
- ◆ OS X 10.2.x

You may note a bit of discrepancy in this list in so far as the versions are concerned. Well, there are many, many Mac OS versions. There was a time at Apple when an OS would be sent out that ended up needing enough patches that the patched version would be a slightly different version than

what it originally was, much like Windows 95a versus Windows 95b. So, you'd have 9.0 and 9.0.1 and then 9.1 and 9.1.1, and so on. To keep things simple, I am going to focus on the OSes that don't necessarily need any patches to function well—because if your users are using Macs without mishap, their OS version is probably one of the versions I just listed.

### TO GET TECHNICAL FOR A MOMENT

To do file sharing between Macintosh systems and Windows, you need AppleShare Client and something called Open Transport.

AppleShare Client is the equivalent of Windows Client for Networking. You need to have AppleShare Client version 3.8.x (preferably at least 3.8.3, which comes with OS 8.6) to work properly with Server 2003.

Open Transport is the networking service that manages TCP/IP (and AppleTalk) and handles Apple File Protocol (AFP, Apple's file sharing protocol) over TCP/IP or AppleTalk. Open Transport must be at least version 1.1.2. I much prefer version 2.0.3 or higher (OS 8.6 has 2.0.3). Open Transport goes hand in hand with AppleShare Client; you shouldn't have one without the other.

Note also that Windows Server has authentication modules that are based on AppleShare. The module that works with Apple File Protocol over TCP/IP is 5.0. It works only with AppleShare 3.8.x and higher (if you try it with a lower version, you get module 1.0, which may crash when trying to use TCP/IP). There also is an authentication module available for OS X. For more information, hit the Apple Web site. You'll have to troll the archives for some of this information, but it is there in abundance.

At this point, I'd like to comment on the fact that many network administrators feel that there are two main drawbacks to networking Macintoshes with a Windows network:

- ◆ Security
- ◆ AppleTalk

### DEBUNKING A SECURITY MYTH

Due to the fact that Active Directory saves Macintosh passwords in clear text (yes, I know, you'd think Microsoft could figure out how to not do that by now), some people may hesitate to integrate the Macs into their Windows network. If that's so, then don't worry about it. Macs can use Microsoft authentication to access Windows network resources, eliminating that concern. Instead, Macintosh users can log in with an account that you create and control. If you want to control their use of the printer, share the printer out to the Mac users with a specific logon account that you specify.

### THE TRUTH ABOUT APPLE TALK

Macs don't need it. They can easily use TCP/IP to access resources just like any other workstation. AppleTalk is a convenience because it broadcasts information rather than you having to go get it. Just like NetBEUI makes browsing network places easy by propagating the network window with icons, AppleTalk lets Mac users look in the Chooser window and see if there are any printers or file shares out there. Just like NetBEUI, AppleTalk can be chatty. It can be a problem for some networks, and therefore should be avoided. I repeat: AppleTalk is not a necessity. That is, not unless you are using Print Server for Macintosh Service, but more on that later. Also, be aware that Macs primarily use

AppleTalk these days to find resources; once they've found the resource, they prefer to connect via TCP/IP. You actually have to do some tweaking to get Macs to use AppleTalk if TCP/IP is available.

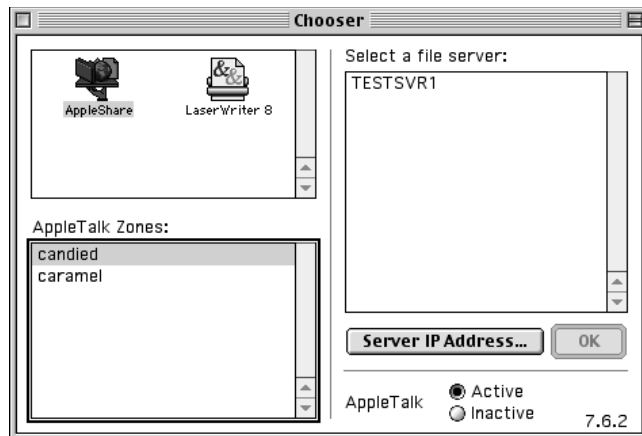

### A BRIEF LOOK AT APPLE TALK AND ITS PARTICULARS

When Apple wanted to network their Macintosh workstations, they were basically on their own in creating a standard. It was during the infancy of peer-to-peer or small-business networking that Apple came up with the easy-to-use and ingenious LocalTalk/AppleTalk network. They wanted something that was as simple and unbreakable as two cups on a string, with a media that was cheap and readily available.

LocalTalk, in addition to having its own access protocol (like Ethernet), defined the physical media. It had a connector on the printer port that used common everyday phone cord (RJ-11) to daisy chain the machines together. Pretty convenient. It was as slow as molasses, running at a blazing 230Kbps. Furthermore, although it was a great idea, it could only handle about 32 devices per network. Needless to say, it's highly unlikely that today your network is running over LocalTalk.

AppleTalk, like NetBEUI, is the stack of simple little protocols that make it possible for the machines to use the LocalTalk media (or Ethernet, or even Token Ring) to broadcast their unique existence to all others on the network, as well as receive broadcasts.

Because Apple tends to think ahead, despite LocalTalk's limitations, they assumed that their users would want to be able to browse for their network resources easily. You may have heard of AppleTalk zones? These zones were created to help organize how devices show up in the Chooser. It is purely a logical process and is not dependent on subnets, routers, domains, or workgroups. Anyone who is sitting at a computer that happens to be in one zone is not going to be cut off from anything in another zone. Zones were created for convenience, so resources would be listed in a logical fashion. Think of them as something like a Windows workgroup.

And finally, if you thought that AppleTalk, being so similar to NetBEUI, couldn't be routed, you're wrong. It can be. AppleTalk routers come in two flavors: seed routers (sort of the master browser of AppleTalk routers) and nonseed routers. A seed router keeps a kind of master list of all nearby networks (each identified with a number) and which zones those networks have in them. The AppleTalk routers on those networks get the overall view of the network from the seed router and use it to help them forward packets to the correct place. It's also at the seed routers that zones are created.

*Continued on next page*

### A BRIEF LOOK AT APPLE TALK AND ITS PARTICULARS *(continued)*

Server 2003 can not only be an AppleTalk router, but it can also be a seed router (just in case you don't have one and you have several subnets of Macintoshes on your network). To enable seeding and/or create some zones, right-click the AppleTalk routing connection in the RRAS console, and select Properties. To add a zone (such as “candied”), just click the New button.

## Integration Objectives

Now that you know which Macs you have and what they are capable of, what do you want them to actually do? In answer to that, I am going to go by the following list of objectives:

- ◆ Internet access using DHCP and DNS
- ◆ File sharing
- ◆ Printing to network printers

Essentially, the way you fulfill those objectives depends on which operating system you have, so I've divided the chapter into three subsets—the two major sections will deal with Mac classic OS clients (8.6 to 9.2.2) and OS X, respectively. In addition, at the end of the chapter I'll include a section about how to integrate Mac servers, for those lucky few of you who have them.

## Classic OS Client Integration

Chances are your Mac users are using the network gateway to get to the Internet. People are pretty stubborn and ingenious about getting their mail, sports scores and, ahem, other Internet-based info. But, just to be clear, I'll spend a moment explaining a few basics about this topic.

### USING DHCP AND DNS FOR INTERNET ACCESS

The Mac OS uses TCP/IP. DHCP and DNS are TCP/IP features. Because of that, the workstations absolutely do not need to have static IP addresses. If they have been an administrative pain because you have been changing their IPs manually whenever there have been changes on the network, stop that. They can communicate with the DHCP server. They understand DNS. They can see the gateway from here.

To configure DHCP on a classic Mac, follow these steps:

1. From the Apple desktop, go to the Apple menu.
2. Go to Control Panels and select TCP/IP (see Figure 15.1).

**FIGURE 15.1**

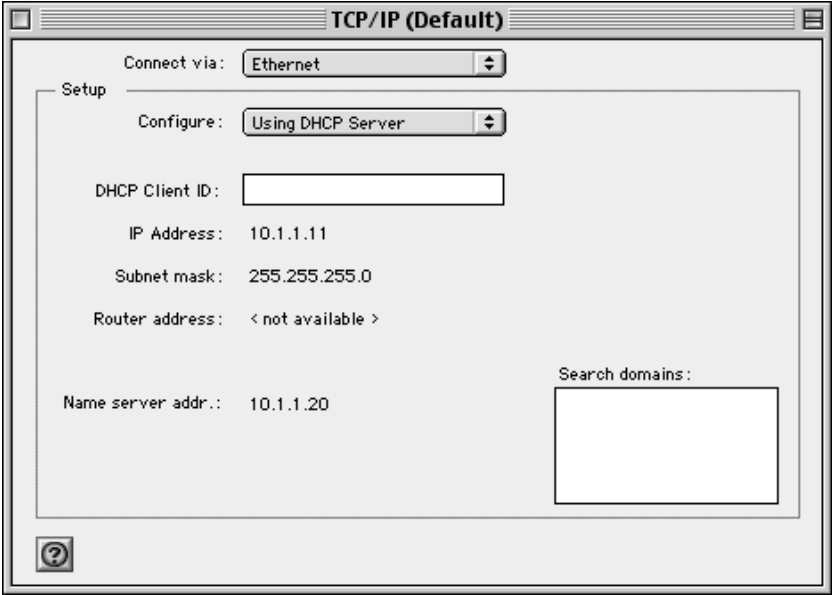

Opening the TCP/IP Control Panel

3. In the TCP/IP window (shown in Figure 15.2), you can configure the Mac to use a static IP, use a DHCP server, use a BootP server, or a RARP (Reverse Address Resolution Protocol) server to pull IP information. Choose Using DHCP Server.

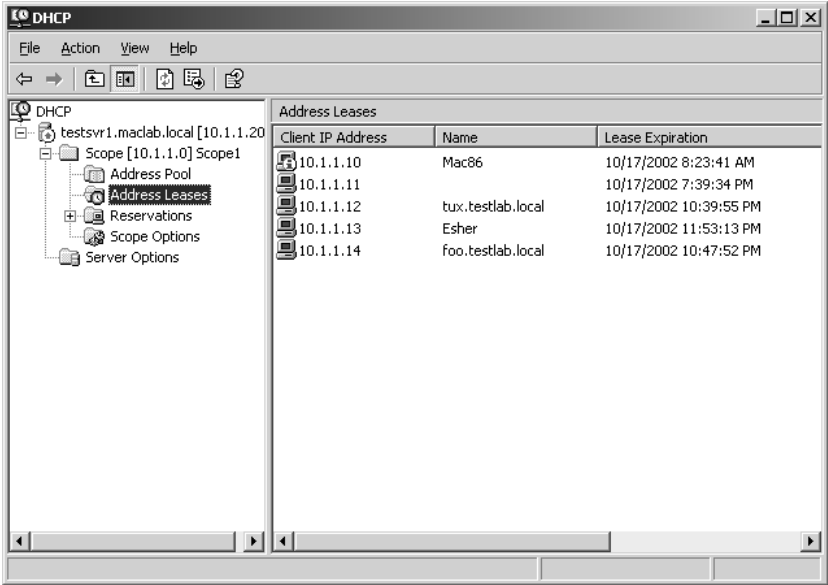

As soon as you close the TCP/IP window, the Mac will attempt to get an IP address via DHCP. No rebooting necessary. It will add the name server information to the bottom of the TCP/IP window to indicate the DNS server. If the DHCP server has an address for an Internet gateway, it will show up in the Router Address field.

**FIGURE 15.2**  
Setting up DHCP  
in the Macintosh  
TCP/IP Control  
Panel

That’s all she wrote. The Mac will now use the DHCP server to get its IP information. No more static addressing. Note, as shown in Figure 15.3, that the Server 2003 DHCP has assigned the Macintoshes Mac86 and Esher IP addresses as if they were Windows workstations.

**FIGURE 15.3**  
Server 2003  
DHCP assigning  
IP addresses to  
Macintoshes

## FILE SHARING

Until now, your Mac users may have thought the only way they could share a file with a coworker who uses a PC was to e-mail it. Well, that's not true. You can use a server as a drop-off point between the two types of workstations.

**NOTE** *If you are running IIS on your server, you can make files available to the Macintoshes through FTP. It's not the most convenient way of sharing files, but it works.*

Classic Macintosh OSes use a filesystem called Apple File Protocol (AFP) to share files. Microsoft uses Small Machine Block (SMB) protocol to share files. These two things are not at all the same. Since our network is a Windows network, and we have files we'd like to share with the Macs, it stands to reason that we should use the File Server for Macintosh (FSM) service.

This service will do a few things:

- ◆ Teach the Server 2003 how to speak AppleTalk, how to understand Apple File Protocol, and how to accept Apple authentication.
- ◆ Create a Microsoft User Authentication Module Volume (volume is Macintosh-speak for sharepoint).
- ◆ Add the capacity to create, monitor, and manage shares that can be accessed by Macintosh users.

Setting it up is easy. Just remember to create user accounts on the Server 2003 for the Macintosh users (so you can control their permissions). FSM has a few issues, but it works like a champ.

There are two parts to making it possible for Macintosh users to access a sharepoint on the Server 2003. The first part is preparing the Server 2003 to host the Macintosh volumes. The second part is getting the Macintosh workstations to find shared volumes and authenticate themselves to Server 2003 to access those shares.

Now, for all practical purposes, the whole file sharing process (after AppleTalk and Apple File Protocol are installed) hinges on one thing: authentication. The Server 2003 does not store Apple passwords in anything but clear text, which discourages anyone from allowing Macintoshes to use Apple authentication. Furthermore, allowing Microsoft authentication only is set as a default. But, to make it possible for the Macs to use Microsoft's authentication, Server 2003 creates a Macintosh shared folder on its hard drive with a Microsoft User Authentication Module in it. Are you sensing a problem here?

Have you ever seen that old western where the hero is unfairly locked in jail, while his jailer, asleep a few feet away, has the key dangling out of his pocket? He can see it, but he can't reach it. Tantalizingly close, but oh so far away. Well, that sums up the "I need to authenticate to get the authentication module, but I can't authenticate until I have the authentication module" process quite nicely. That is one of the issues I mentioned earlier. You can't just turn it on and go. You have to play with authentication first.

Now that I have mentioned that, the process of installing and setting up the File Server for Macintosh service will make a little more sense.

**Installing FSM on Server 2003**

You would think since FSM is a service, you could just add it to the network card properties, like file and print sharing, but no. You have to go to Add/Remove Programs and add File Server for Macintosh as a Windows component:

1. Go to Add/Remove Programs.
2. Scroll to Other Network File and Print Services.
3. Select Other Network File and Print Services (do not just put a check mark in the check box), and click the Details button.
4. There are three services listed in this dialog box (see Figure 15.4); put a check in the File Services for Macintosh check box only at this point (it's never good to have services running that you don't need. It wastes resources) and click OK, then click Next. Click Finish and you're done.

**FIGURE 15.4**

Adding File Services  
for Macintosh  
Windows  
Component

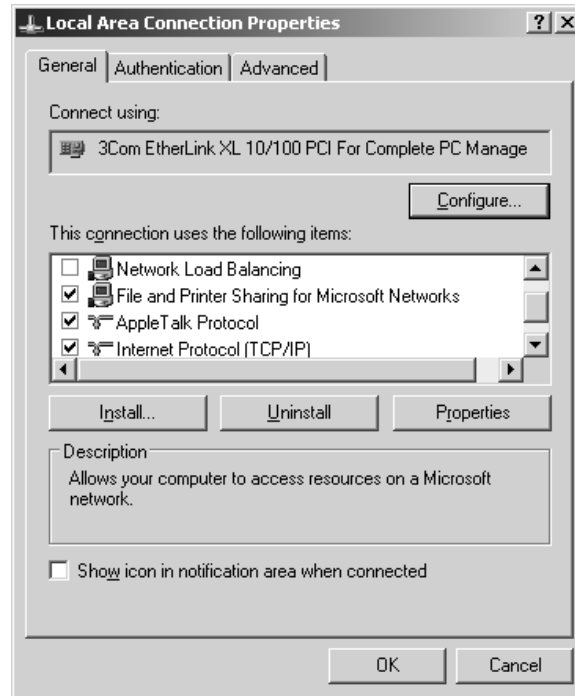

Now, let's check four things to be sure that File Server for Macintosh installed correctly.

1. Go to the Local Area Connections properties and see if AppleTalk Protocol is running. If it is, it will have a check mark next to it (see Figure 15.5).
2. Open the Services Console under Administrative Tools, and check to see if the File Server for Macintosh service is installed and started (see Figure 15.6).

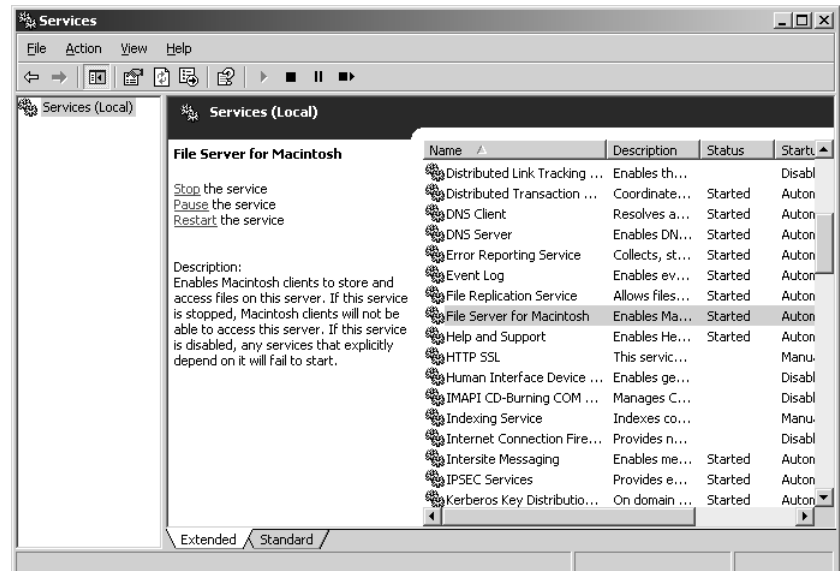

**FIGURE 15.5**

Confirming that AppleTalk is installed and enabled

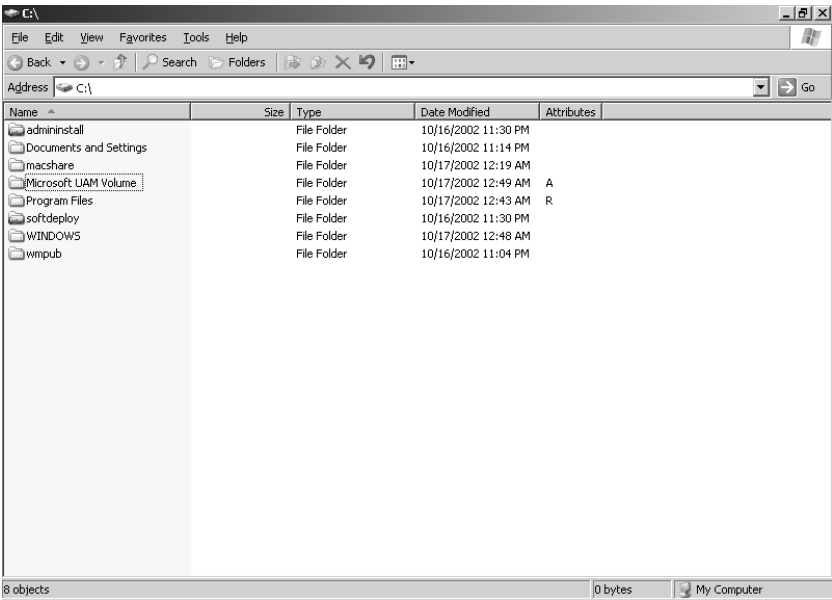

**FIGURE 15.6**

Confirming that File Server for Macintosh service is installed and started

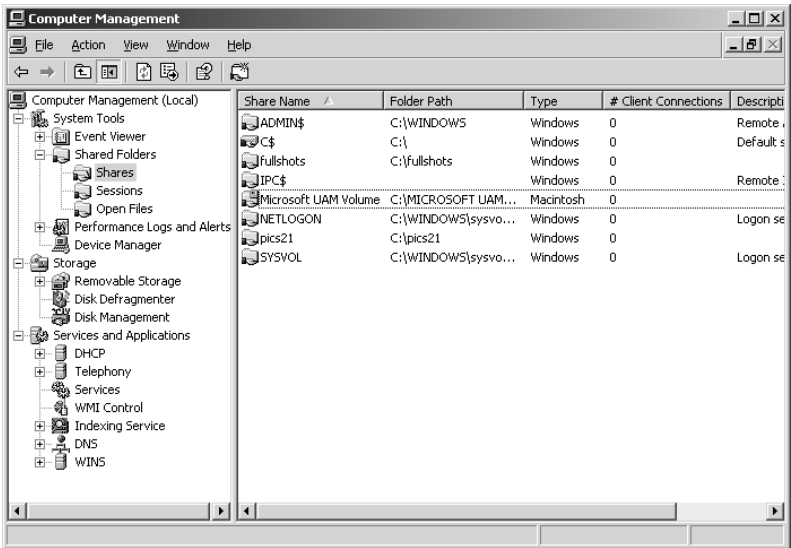

3. Go to the C: drive of the server and see if there is a new folder called Microsoft UAM Volume (see Figure 15.7). It will not look as if it has been set up as a sharepoint. That is because it has not been shared to Microsoft machines.

**FIGURE 15.7**  
Confirming the Microsoft UAM volume has been created

4. And finally, open the Computer Management Console under Administrative Tools. It is from here that you will manage your Macintosh file shares (see Figure 15.8), and you should see the new Microsoft UAM Volume share for Macintoshes.

**FIGURE 15.8**  
Confirming the creation of a Macintosh share of the Microsoft UAM Volume

Now that you are sure that FSM is functioning, it's time to configure it. In the Computer Management window (see Figure 15.9), right-click Shared Folders and from the context menu, select Configure File Server for Macintosh.

**FIGURE 15.9**  
Configuring File  
Server for Macintosh

This will take you to the Configuration tab of the File Server for Macintosh Properties dialog box (see Figure 15.10). Let's look over this dialog box before we proceed. At the Configuration tab are the following options:

**Server Name for AppleTalk Workstations** This is what will show up in the Chooser window on the Macintoshes.

**Logon Message** Anything you type in here will show up in a pop-up dialog box announcing that the Macs have successfully logged in and accessed a sharepoint (which mounts on the desktop as a volume). This message can get annoying after a couple of days, so don't be too verbose. The example is a little congratulatory message.

**Security** In this area you can have the user save their password locally to make it easier to log in, but this is not a secure idea.

**Enable Authentication** What you choose here is really important if you want to overcome the "can't authenticate to get the authentication module" problem. There are several choices:

**Microsoft Only** The default.

**Apple Clear Text** Unencrypted Apple authentication only (which means, somewhat ironically, that a Mac that has the Microsoft UAM installed will not be able to authenticate).

**Apple Encrypted** Encrypted at the Apple end, but stored as clear text at the Microsoft end. Again, Apple only; the UAM would fail to authenticate for this one too.

**Apple Clear Text or Microsoft, or Apple Encrypted or Microsoft** Either of these choices allows Microsoft or Apple authentication, making it possible for the Macs that have installed the Microsoft UAM to log in, and for Macs that haven't to log in to get it. In my world, it doesn't matter which I choose, but having the passwords encrypted at least until they reach the Server 2003 isn't a bad thing.

Enable Authentication helps you jump the first hurdle in the race to get Server 2003 to share nicely with the Macs. You may prefer the encrypted Apple password, but I like to set this to Apple Clear Text or Microsoft. I prefer to allow Apple authentication *only* until all of the Macs have installed the Microsoft UAM. Once I am sure that everyone has installed the Microsoft UAM, then I set authentication back to Microsoft Only.

**FIGURE 15.10**

Configuration tab of the FSM properties page

**NOTE** There is another way to allow Mac users to access the Microsoft UAM Volume if your company insists on not allowing Apple authentication: you can enable the guest account. If a Macintosh cannot use Apple authentication, and the FSM has been configured for Microsoft only, it can authenticate as a guest. Not my favorite option, but it is there.

**Sessions** Below the security area of the dialog box is the Sessions section, where you can set how many sessions can be running simultaneously. I tend to leave it at Unlimited.

The next two tabs in the FSM properties page are File Association and Sessions. File Associations are used to specify what extensions link to what program so the Macintoshes can understand flat file extensions and open the correct application with a double-click. Sessions displays the Usage Summary (see Figure 15.11), which displays how many sessions are running and includes a text area to send a message to all Mac users of this system. That comes in handy when you need to warn the users that the server is going to go offline.

**FIGURE 15.11**  
Sessions tab

Once you have configured your FSM to your liking, click OK. The changes will be applied and the dialog box will close.

## RESOURCE FORKS, FILE EXTENSIONS, AND WHY OS X DOESN'T CARE

The Microsoft filesystem is a flat database. It lists all files with two parts: data and extension. The extension part of the file does two things: it defines the file type and it defines what application opens the file. Those extensions are listed in a File Associations database kept in Windows so extensions can be associated with the application that opens them. This database can be edited anytime. Of course, you already know that.

*Continued on next page*

**RESOURCE FORKS, FILE EXTENSIONS, AND WHY OS X DOESN'T CARE (continued)**

The Macintosh filesystem is not flat, it's layered. In this two-dimensional, two-prong (so to speak) file structure, all files have two parts, data and resource. The resource "fork" of the file does two things: it defines the file type and defines the file Creator (that is, which application opens the file). Although they do similar things, Macs have a problem understanding Windows file extensions, and Windows systems have a problem understanding resource forks. If you move a file from a Macintosh to a PC and then back again, the Mac will have no idea what kind of file it is because the PC stripped it of its resource fork. Also, those pesky Macs leave resource fork files all over the place when they browse Windows resources. It's how you can know they've been there...

With the File Server for Macintosh service for Windows Server installed, Windows Server knows what resource forks are and will try to help map extensions to resource fork "creators" so Mac users can use the Windows files. And, on the Macintosh end, PC Exchange maps extensions to resource fork information for Windows users.

Despite the assistance FSM and PC Exchange give, it is best to teach your Mac users to go ahead and add extensions to the end of all of the files they intend to share with PC users. Also, remind them of the characters that are not allowed to be used in Windows filenames. It is just good network etiquette.

Finally, after all these years of covert file interpreting, OS X uses a flat file structure like Windows, extensions and all. It still supports the Macintosh layered filesystem for backward compatibility, but otherwise, it's just like any other Windows filesystem. It's a shame really—that two-layered file structure was pretty clever.

Now that File Server for Macintosh is running and AppleTalk is installed, you need to think about how you are going to handle sharing folders.

Right now there is only one Macintosh share on the server, the Microsoft UAM Volume. Macintosh users on the network can see the fileserver in the Chooser because AppleTalk is doing its job and broadcasting it. It's a good idea not to build any more shares right now. Why? Because if there were other Macintosh shares on the server, and Apple authentication is turned on, Mac users will be able to easily access the other folders without getting the Microsoft UAM.

While you wait for your Macintosh users to actually install the Microsoft UAM, let's go over some ground rules about making Mac shares on a Server 2003:

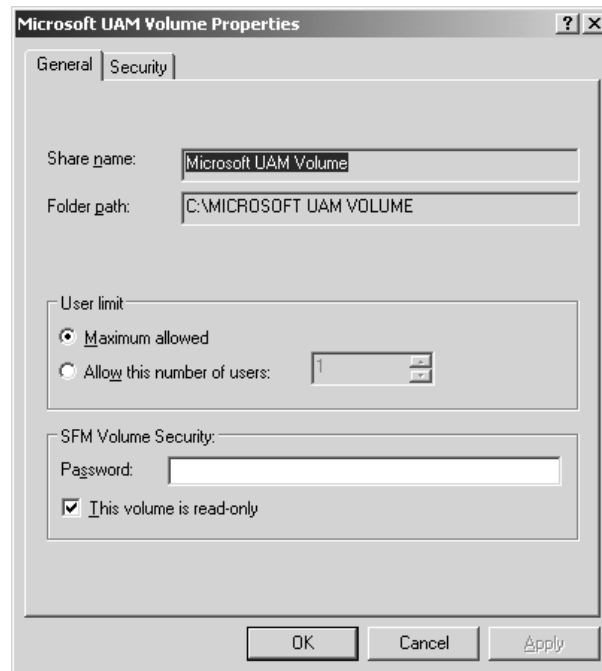

- ◆ Macintoshes prefer share names that are 31 characters or less.
- ◆ The Finder (the Mac's equivalent of Windows Explorer) can only handle 50 volumes with 27-character length names. That means, in total, you can have only 1350 characters for all the mounted volumes on the desktop. So, just in case, keep your names short. It is possible to have more than 50 shared volumes; you just have to have really short share names of only several characters each. Windows will compensate for illegal characters in Mac filenames and will keep track of short filenames for DOS-level work, but Windows won't worry about the exact length of long filenames. You are going to have to keep that in mind on your own.
- ◆ Macintoshes can't handle directory paths that are more than 260 characters, so be careful about nesting folders.
- ◆ If you have a shared volume, don't bother trying to create a shared volume within it. If a folder is a shared Macintosh volume, then all nested folders within it are shared by default.

- ◆ By the same token, you cannot decide to share a volume that already has a shared volume nested in it. Basically a folder cannot be shared twice. Either it is in a shared folder or it is the shared folder.

It's important to note that, by default, all Macintosh shared volumes created on the Server 2003 are set to read-only (another FSM quirk). No matter what permissions you give the Macintosh user accounts concerning the volumes, you will have to manually turn off the read-only setting in the individual share properties. This is great for the Microsoft UAM volume, because it is meant to be used only to install the authentication module, nothing else. Later though, when you want to allow the Mac users to add things to the shares and make changes to documents stored there, the read-only setting will become a problem. To see what I am talking about, right-click the Microsoft UAM Volume in the Computer Management window and select Properties. As you can see in Figure 15.12, the This Volume is Read-Only check box is on by default.

**FIGURE 15.12**

Read-only default permission on Macintosh shares

## THE CHOOSER

Going to the Chooser to find a printer is as natural to a Mac user as breathing oxygen, but it may seem like breathing water to a Windows person.

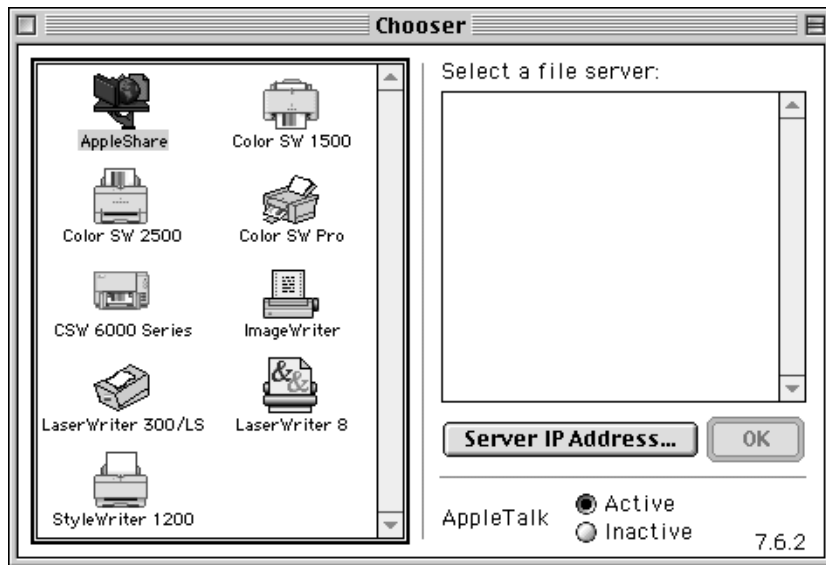

The Chooser is an archaic application that came out with Macintosh OS1 (back when it was known as System 1). It was originally intended to let the user choose which serial port they were going to use for what device. That led to choosing a printer, which led to using AppleTalk to choose a network resource, which led to the Chooser becoming a network browser. Now the Chooser, no longer aptly named, is used to connect to file servers and printers, as well as locally-attached devices.

*Continued on next page*

**THE CHOOSER (continued)**

The Chooser started out listing the different drivers you might have installed, like a serial printer or modem, on the left side of the window. Upon clicking the driver, the right side of the window shows you the ports (and the device attached to that port) that driver can use. You choose a port, then the job is sent to that port packaged in the way the driver likes it.

Now you can see the drivers on the left side of the Chooser window, such as AppleShare for file servers or LaserWriter8 for printers, or a fax driver for the modem. If you click one of the drivers, whatever device (network or local) that uses that driver will display on the right.

After choosing AppleShare (which is poorly named—it's really Apple File Protocol), you can click the Server IP Address button on the right side of the window and type in the IP address of the server you want to access. This is especially useful, since most file servers are not AppleTalk enabled these days.

Also on the right side of the Chooser window, you can set AppleTalk to Active or Inactive.

You might be wondering why there isn't a TCP/IP or IPShare or some such icon on the left side of the Chooser so you can click it and use it to display a list of all of the IP file servers on the network. Funny, that. It seems that Chooser, being an old-timer, generally only lists things that have been broadcast to it through AppleTalk. AppleTalk is nearly as old as the Chooser—it's very chatty and easily announces all of its available resources any time the Chooser asks. IP, on the other hand, doesn't broadcast nearly as much (or as continuously) and therefore the Chooser doesn't list it automatically. With an IP resource, you are just going to have to type it in.

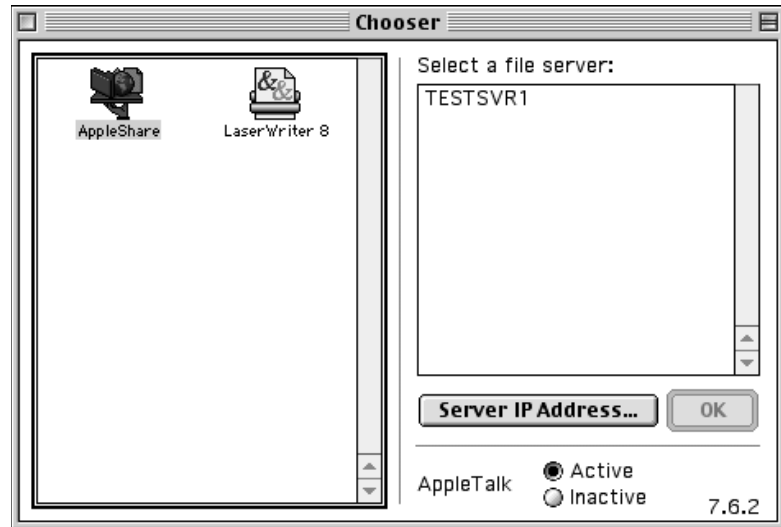

### **Connecting a Macintosh to the Server 2003 Share and Installing UAM**

The hard stuff is already finished. Now you just have to install the Microsoft UAM onto the Macintosh (or have the Mac users do it).

1. Go to the Apple menu on the Macintosh desktop.
2. Select Chooser.
3. In the left side of the Chooser window, click AppleShare.
4. As you can see in Figure 15.13, on the right side of the window is listed all resources that can be accessed using AppleShare. The only resource that should be listed is the Server 2003 running AppleTalk and FSM (my server is TESTSVR1), since no other shares have been created. If the server name does not display after you select AppleShare, check to see if AppleTalk is active.

**FIGURE 15.13**

AppleTalk Active in the Chooser window

5. Click the server name and then click the Server IP Address button, which makes it possible to access the server without AppleTalk. Type in the IP address of the server to access the share that way (thus eliminating the need for AppleTalk on your network).
6. Click the OK button.
7. This will bring up a dialog box prompting the user to enter a username and password (see Figure 15.14). The username will default to the owner name of the system (so wouldn't it be clever if you created user accounts that matched? Less typing, fewer calls to the help desk). Below the password field is a note that indicates how the data will be sent (mine is in clear text). After typing in the username (if necessary) and password (which you can change...don't know why you'd want to, though), click Connect.

**FIGURE 15.14**

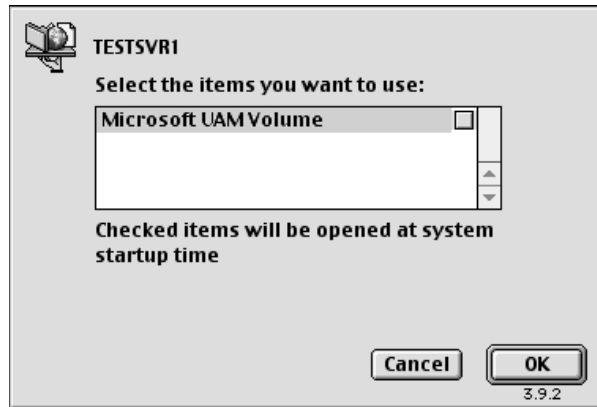

Authenticating to  
Microsoft UAM  
Volume

8. The next dialog box displays the Macintosh volumes available on the server (see Figure 15.15). The only volume there at the moment is the Microsoft UAM volume. Select it and click OK.

**FIGURE 15.15**

Displaying the  
available Macintosh  
volumes

**NOTE** Note the little gray box to the right of the volume in the list. Do not check that box. It allows Apple authenticated shares to be mounted on the desktop at startup. If you later change authentication to Microsoft only, you will get authentication errors upon startup. In OS 9, you would have to remove any reference to the share from the servers folder under the System folder. In OS 8.6, you would have to re-enable Apple authentication on the Server 2003, let the Mac log in, and uncheck any volumes to ensure that they will not open at startup. Then you would again be able to set authentication back to Microsoft on the Server 2003.

The next dialog box should have the congratulatory logon message and a notice that you reached the server via TCP/IP (see Figure 15.16). Note that, although AppleTalk was used to display the server name in the Chooser, the Mac actually connected using TCP/IP. It's faster that way.

**FIGURE 15.16**

Connection confirmation and welcome message

Now, as you can see in Figure 15.17, the Microsoft volume will show up on the right side of the desktop in whatever free space is available. It looks like a network drive icon with a Microsoft flying window over it.

**FIGURE 15.17**

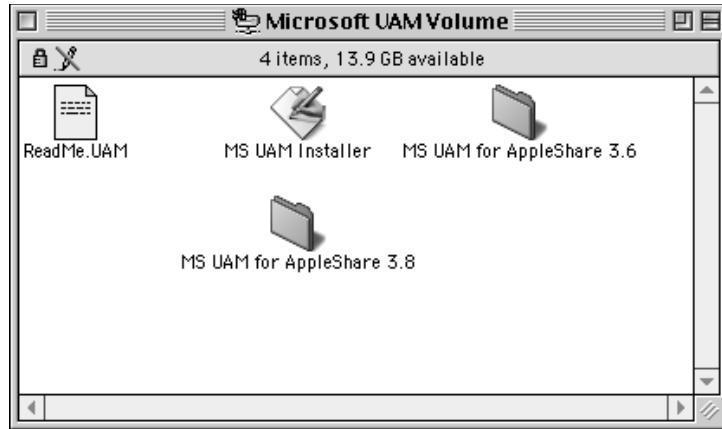

Microsoft UAM Volume on the desktop

9. Close out of the Chooser (click the box on the left side of the title bar); you're done with it for now. Double-click the new Microsoft UAM Volume icon, which will open to a window like the one in Figure 15.18.  
In the open window there will be several items. The important one is the MS UAM Installer. Double-click the installer. A dialog box will come up confirming the installation (see Figure 15.19).
10. Click Continue. You'll soon see a dialog box announcing the successful install (see Figure 15.20). If you don't see a dialog box like this, don't assume it installed.

**FIGURE 15.18**

Opening Microsoft UAM Volume

**FIGURE 15.19**

Installing the Microsoft UAM

**FIGURE 15.20**

Confirmation of installation of MS UAM

To see if the Microsoft User Authentication Module works, you'll need to close the existing connection with the server. Currently the mounted volume is authenticated via Apple authentication. Closing the connection is simple: just drag the volume icon into the trash. No, seriously, it's what you're supposed to do. (You can make CDs eject by dragging their icons to the trash, too.)

### ***Creating Mac Shares on the Server 2003***

Let's assume that all of your users have installed the MS UAM. Now it is time to reset authentication to Microsoft only. To do this, open the Computer Management Console, right-click the shared folder, configure File Server for Macintosh and change the Enable Authentication field to Microsoft Only.

**FIGURE 15.21**

Returning  
Macintosh share  
authentication to  
Microsoft Only

Now you can create all of those shares that you've been looking forward to:

1. To create a share, right-click Shares in the Computer Management Console. From the context menu, select New Share (see Figure 15.22).

**FIGURE 15.22**

Creating a new share

2. The Share a Folder Wizard starts (see Figure 15.23). You need to indicate what folder you are going to share with the Macintoshes. Make sure the folder path is not too long. I am going to create a folder called **macshare** on the C: drive.

**FIGURE 15.23**

Share a Folder Wizard, Folder Path screen

3. You need to indicate if it is going to be shared by Windows users and/or Macintosh users. The **macshare** folder I created is going to be available to both sets of users as a common sharepoint to exchange files. Note the length of my share names. If I were planning to have more than 50 Macintosh shares on the server, I would seriously consider using a very short Macintosh volume name. However, I don't plan to have more than 12 shared Mac volumes, so **macshare** is fine for a Macintosh share name.

**FIGURE 15.24**

Making the share accessible to both Windows and Macintosh clients

4. Set permissions on the share. These permissions are primarily for the Microsoft users at this point because no matter what you set here, the folder will still be read-only for Mac users until

you explicitly set it otherwise in the share properties. For all users to be able to read and write to the share, select the third option, as shown in Figure 15.25.

**FIGURE 15.25**

Setting access permissions

5. The summary page of the wizard confirms your decisions concerning the new share (see Figure 15.26).

**FIGURE 15.26**

Confirmation of the new share

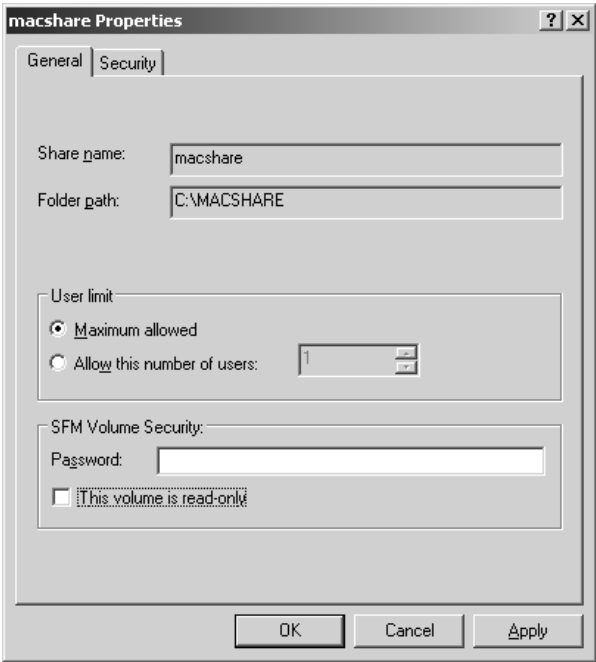

6. In the Computer Management Console (see Figure 15.27), you'll see the new share. It will show up twice because there are two different kinds of shares applied to it. The one with the tiny Mac Classic computer on the top right corner of the folder is the Macintosh share. (Pretty clever, actually. The icon is pretty small, but kudos for trying.)

**FIGURE 15.27**  
macshare folder  
in the Computer  
Management  
Console

- 7. To make sure that the new Macintosh share is not read-only (despite whatever permissions you may have set for the users), right-click it, select Properties, and remove the check from the This Volume is Read-Only check box (see Figure 15.28). Remember, this overrides any permissions you may have given the Mac user accounts for this folder.

**FIGURE 15.28**  
Turning off the  
read-only default  
on the macshare  
folder

### Connecting the Mac to a Shared Volume using the UAM

All right then, back to the Macintosh. It's time to see if the Microsoft User Authentication Module works:

1. Open the Chooser. Select AppleShare. Select the server (TESTSVR1, in the example). Click Connect.
2. In the Authentication dialog box, enter the appropriate username and password and click Connect (see Figure 15.29). Notice that it no longer says Clear Text under the password and that TCP/IP is indicated in the lower-left corner of the box.

**FIGURE 15.29**

Authenticating from a Macintosh using the Microsoft Authentication Module

3. In the next dialog box (see Figure 15.30), select the new share (which is macshare, in the example). Click OK.

**FIGURE 15.30**

Selecting the macshare volume

4. A message dialog box will display to indicate a successful login and connection to the share. The share will show up on the desktop as shown in Figure 15.31.

**FIGURE 15.31**

The macshare volume on the desktop

The final test, of course, is to add a file to the macshare volume. I saved a big important contract on a Macintosh to macshare (I made sure that I added the .doc extension). It shows up fine in Figure 15.32, which is on Server 2003.

**FIGURE 15.32**

Copying a file to the new macshare volume on Server 2003

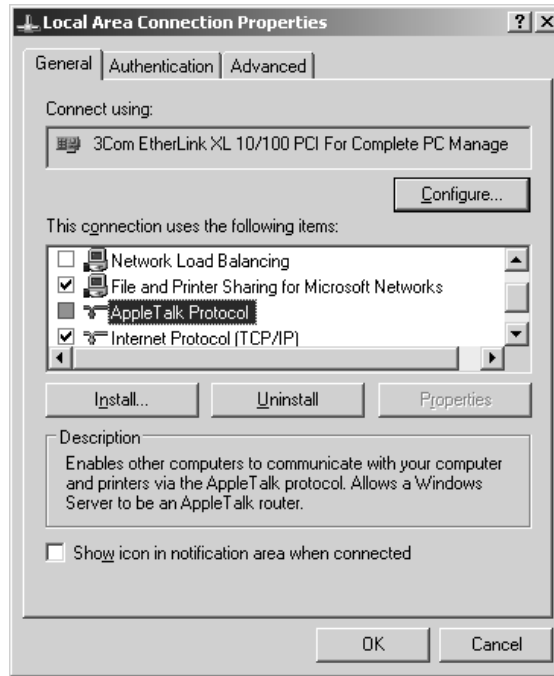

One final note about file sharing: let's take a quick look at how to do it without AppleTalk.

1. Disable AppleTalk on the server by going into the Local Area Connection properties and removing the check mark in the AppleTalk check box (see Figure 15.33). Be patient: when you click OK, it might take a moment to think about it.

**FIGURE 15.33**

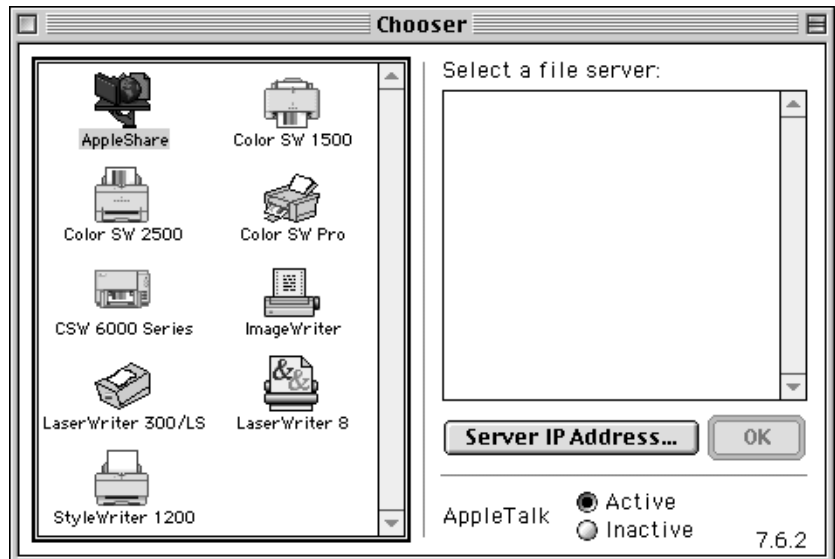

Disabling  
AppleTalk  
Protocol

2. Go to a Macintosh workstation that can do Microsoft authentication. Go to the Chooser, select AppleShare, and you will see that the server does not show up in the resource list on the right. As you can see in Figure 15.34, the OK button is grayed out.

**FIGURE 15.34**

File sharing in  
Chooser when  
Server 2003 is not  
using AppleTalk  
to broadcast its  
resources

3. You still can access the shares; you just have to use the Server IP Address button. Click it and type in the IP address of the Server 2003 in the dialog that comes up (see Figure 15.35). The authentication and connection process will proceed as usual.

**FIGURE 15.35**

Using TCP/IP to access Server 2003 Macintosh shared volumes

Although disabling AppleTalk does mean that users will need to learn the Server 2003's IP address or DNS name, you can file share on just TCP/IP.

### CLASSIC OS PRINTING TO THE NETWORK PRINTER

Chances are good that, just as they are already using the Internet, Mac users are already printing to the network printer. You just may not know it.

Macintoshes print using Adobe Postscript Printer Language. Luckily, most network printers, such as HP LaserJets for example, can support both Postscript and PCL (printer control language, which is what PCs use). However, you may want to check and see which of your printers support Postscript (or just find out what printers your Mac users can print to).

Most network-caliber printers can support Postscript and even speak AppleTalk. By default, AppleTalk usually is on, and you have to manually turn it off.

#### ***If a Printer Is AppleTalk Enabled***

To see if a network is AppleTalk enabled, at a Mac workstation, go to the Chooser. Click the LaserWriter 8 driver icon (which can be used as the default driver for any Postscript printer). The network printer(s) should show up in the box on the right (see Figure 15.36). If it doesn't show up, it either can't use AppleTalk or AppleTalk is not enabled (if you didn't set AppleTalk as active in the Chooser of that machine, click the Active button, which is on the bottom right of the window). Using AppleTalk for printing is pretty standard because it's so easy to use and hard to break.

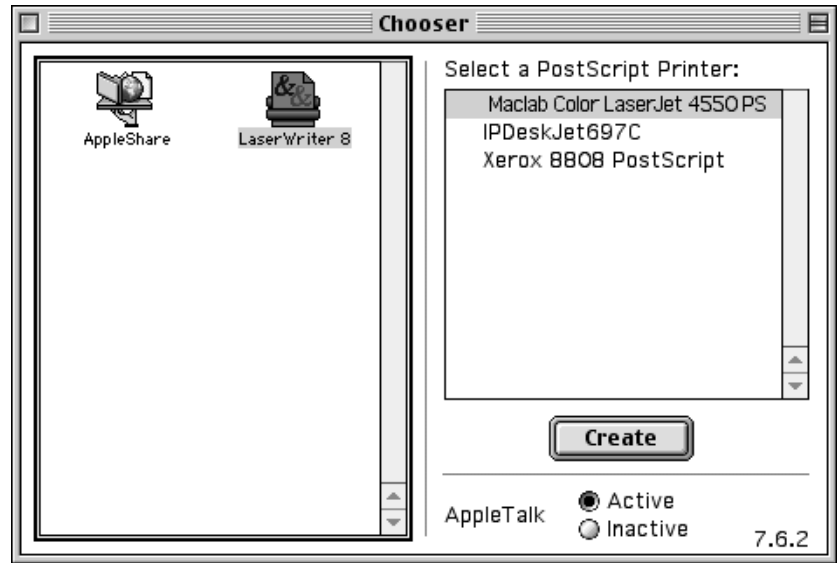

If the printer can do Postscript, then it might have a driver file, a PPD (Postscript printer definition) file, or both, which the Mac can use to really get the most out of the printer's features. But if you think that not having those printer-specific file(s) is going to stop the Mac users from printing, you are wrong. If the printer is out there and it's AppleTalk ready, then the user can use their default Postscript driver (that non-intuitively named LaserWriter 8 icon), to print standard Postscript documents. It's that easy. And remember, there are no securities being applied to these users—they are using AppleTalk to get to the printer and bypassing any domain restrictions. That may be why all those pretty pictures keep printing out on the printer in the accounting department.

Even if the printer can't do AppleTalk, as long as it can do Postscript, the Macs can still get to it. They just have to use the Desktop Printer Utility, which comes with the Mac OS. It's not rocket

science, and Mac users are usually “if there’s a will, there’s a way” kind of people. They’ve grown used to having to take care of themselves. Half of them are probably using it right now.

**FIGURE 15.36**

Chooser window displaying AppleTalk-enabled printers

### USING DESKTOP PRINTER UTILITY TO DO TCP/IP PRINTING

To use TCP/IP to connect to a printer, a Macintosh user does not go to the Chooser. The Chooser only shows printers that are AppleTalk enabled or printers that are being shared by a Server 2003 using AppleTalk. If the Postscript printer in question is on the network and has an IP address, a Macintosh user can just run the Desktop Printer Utility. It comes with the OS and is usually located in a folder called Apple LaserWriter Software (as shown in Figure 15.37), in the Apple Extras folder on the hard drive. It is really easy to get to.

**FIGURE 15.37**

Desktop Printer Utility in the Apple LaserWriter Software folder

To run the utility:

1. Just double-click the Desktop Printer Utility. It will open into a list of ways to access the printer (see Figure 15.38). LPR (Line Printer Remote, a common Unix printer protocol using TCP/IP) is the choice for TCP/IP printing. Choose that. Click OK.

**FIGURE 15.38**

List of available printer connection types

2. The next dialog box that opens has two parts, as you can see in Figure 15.39. The top part is where you choose the correct PPD for the network printer you want to use. Using the correct PPD is always the best option, but if you don't have it, the generic one (the default) will work.

**FIGURE 15.39**

Creating a desktop printer

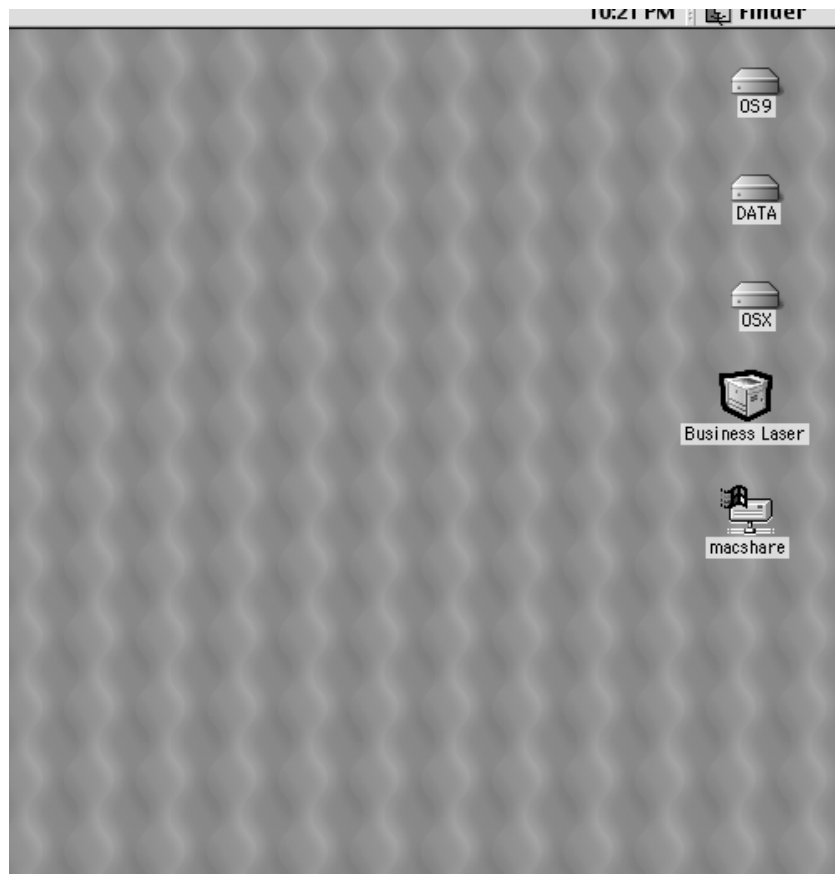

3. The bottom part is for specifying the IP address of the printer. Click the Change button (I know, you haven't added anything so how can you change it? They're just thinking ahead, that's all).
4. It will give you a dialog box to add the IP address of the printer (see Figure 15.40). If it is attached to a print server that is serving several printers, you can specify which queue as well as the IP. Be sure to click the Verify button so the utility can check to see if there is a printer at the IP/queue you've specified. Once the address has been verified, click OK.

**FIGURE 15.40**  
Specifying the  
printer IP address

5. Back at the main dialog box, click Create. You'll be prompted to pick a location to save the printer icon. The desktop works for me. I named my printer Business Laser (as you can see in Figure 15.41) and put it on the desktop. Now I can print to it from any application or I can just drag and drop documents onto the printer icon.

**FIGURE 15.41**  
IP printer icon on  
the desktop

### **Classic Mac Printing to a Non-Postscript Printer**

What if you find a printer that does *not* support Postscript? Well, as long as you don't want the Mac print job to be in color or to use any of the specific printer's fancy features, you can have the server intercept the print job and convert it to PCL.

Yes, you heard me right, the Mac can print to non-Postscript printers on a Windows Server network.

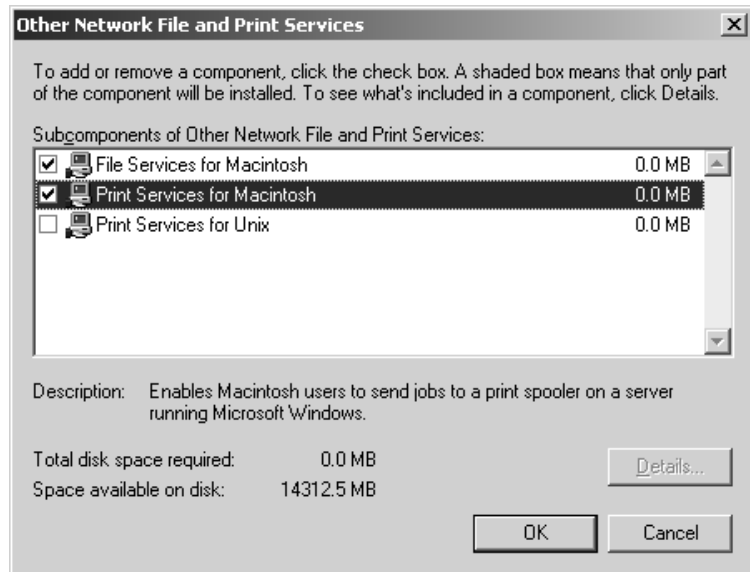

By using the Print Server for Macintosh service, you can share out a local or network printer through the Server 2003 to make it possible to print Mac print jobs on a non-Postscript printer. This does work, but what it does is take a snapshot of the Macintosh print job (as if it were a fax machine) and send it "as is" to the printer. At this point, that means it doesn't do color. Also, it is not always effective with special feed print jobs, such as envelopes. But, when a Mac absolutely, positively, must print on a non-Postscript printer, it can be done.

### **Installing Print Server for Macintosh on Server 2003**

1. Installing the Print Server for Macintosh service is exactly like installing the File Server for Macintosh. You go to Add/Remove Programs\Add Windows Components.
2. Scroll to Other Network File and Print Services and select it. Click Details. In the dialog box that appears, click the check box next to Print Services for Macintosh (see Figure 15.42). Click OK and click OK again.

**FIGURE 15.42**

Installing Print Services for Macintosh

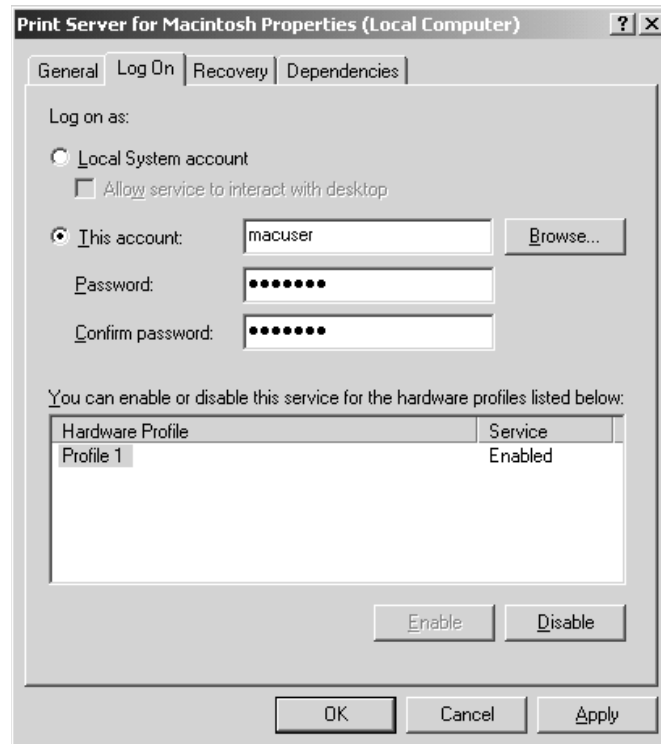

That's it. Print Server for Macintosh service is installed. You can make sure it's in the Services console if you'd like.

Even if you disabled AppleTalk while working with File Server for Macintosh, it will be enabled for the Print Server for Macintosh service. You see, Server 2003 can't run the service without it. Due to the fact that it is going to be doing Macintosh Postscript to PCL print job translation on the fly, I'm not really going to argue. If it wants to make it easy for the Mac to see the printer in the Chooser window, that's fine with me. But seriously, the Print Server for Macintosh service will not work without AppleTalk.

If you want to, you can have the Print Server for Macintosh service log on to the printer share as something other than the usual local system. If you are particularly concerned about security and want to track print jobs, just go to the Print Server for Macintosh service in the Service console (or under Services in the Computer Management Console), open its properties, click the Log On tab, and change the default logon to the account of your choice. I myself am not that worried about it. But the option is there if you need it, as shown in Figure 15.43.

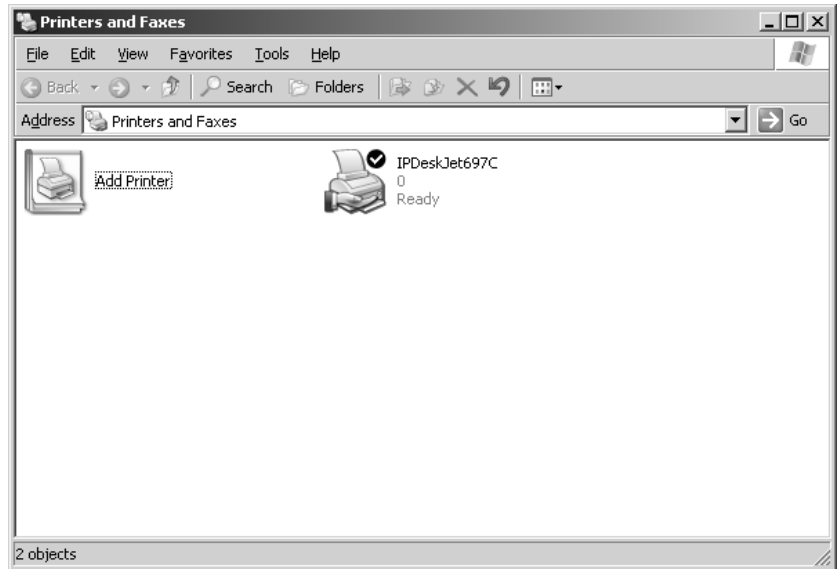

**FIGURE 15.43**  
Changing the Print  
Server for Macintosh  
logon account

Now any printer that uses the Server 2003 as its print server can take print jobs from the Mac, even if it does not support Postscript.

To prove it, I had the Server 2003 be the print server for my HP DeskJet697c (see Figure 15.44). The DeskJet definitely does not use Postscript.

**FIGURE 15.44**  
Shared printer on  
Server 2003

The second half of this Print sharing equation is, of course, the Macintosh.

1. At the Mac, go to the Chooser. Select LaserWriter 8 from the drivers list (be it short or long). Select the printer from the resource list (mine will be the trusty DeskJet), as shown in Figure 15.45. Click Create.

**FIGURE 15.45**  
Listing of shared  
Server 2003 printer  
in Chooser

2. It will try to auto-detect the PPD for the printer (see Figure 15.46). If it can't, it will prompt you to choose the PPD. In this case, click the Generic button.

**FIGURE 15.46**

Suggested drivers for the shared printer

That's it. A desktop printer icon will be built that sends print jobs to the Server 2003 (see Figure 15.47). It may only be in black and white, but it will let the Macintosh print where it may never have printed before.

**FIGURE 15.47**

Shared printer icon being created on the desktop

## OS X Client Integration

To start, make sure that you avoid using any OS X version before 10.1.2; previous versions needed a lot of patches.

An important concept to understand is that OS X is not just an upgrade of OS 9. It is fundamentally different. Its core is now Unix. It has a command line and practically everything has either gotten a new name, gotten a new look, been put in a different place, or all three. On the Windows side, the service File Server for Macintosh will still work with it. OS X can run in Classic mode. If you dual boot between OS 9 and OS X, OS X will run an emulator called Classic during OS X to let you work with pre-OS X applications. OS X is a pretty grand departure from all that came before it.

Obviously OS X can do everything that OS 9 and earlier can do, so I am primarily going to cover the interface differences and some significant upgrades. There are basically three main flavors of OS X so far: OS X 10.0 to 10.0.4 (not a spectacular OS version and not something I am going to go into), OS X 10.1 to 10.1.5, and OS X 10.2 to 10.2.3.

The biggest difference between OS X 10.1 and 10.2 is that 10.2 can support SMB natively (that is, it can recognize the file sharing protocol that Windows uses). 10.1 can support SMB, but you have to download a free SMB client for Unix, such as Samba. Oh, and OS X 10.2 doesn't need a server to intervene on its behalf to authenticate to an AD server that has an OS X-ready schema. More on that later.

OS X will be the only OS available on machines purchased as of January 2003. As of this writing, Macintoshes are being sold with both OS 9 and OS X installed.

### CONFIGURING DHCP

So let's get to it. To begin with, an OS X workstation can be a DHCP client just like OS 9, but the interface is a bit different.

The TCP/IP settings are no longer in the Control Panel. The Control Panel has become the System Preferences. To access System Preferences, you can:

1. Go to the Apple menu and select System Preferences. Alternatively, you can go to the Dock. (The Dock is rather like the quick launch area on the taskbar in Windows 98. Like the taskbar, it normally is at the bottom of the desktop.) Click the System Preferences icon, which looks like a light switch with an Apple logo on it.
2. In the System Preferences window, click the Network button. In the Network window, make sure you are on the TCP/IP tab (note that there are several tabs, including one for AppleTalk).
3. Beneath the TCP/IP tab are all of the familiar settings. Choose Using DHCP from the Configure list box (see Figure 15.48), just as you would in OS 9.

**FIGURE 15.48**

Configuring TCP/IP on an OS X workstation

**NOTE** *Macintoshes don't see domains, they only see "workgroups". That means that they also don't see normal workgroup/domain boundaries. They may well be able to see servers they shouldn't. They don't log in to a domain, they just consider themselves as part of a workgroup as a sort of network courtesy. This may seem strange, but domains are a Microsoft thing. Many network operating systems don't have them. Instead, they rely on directory services.*

### FILE SHARING

In a departure from tradition that is sure to break Mac users' hearts, OS X no longer has a Chooser. To access printers and file shares, you will have to get used to both a different interface and a few new features. In addition, there is a new Microsoft UAM for OS X at the Microsoft Mactopia Web site. If you're going to do any file sharing with Windows machines, be sure to download the new UAM and make it available to the OS X systems. Also, several updates have already been made available to make OS X better at file sharing with Windows.

### XP DESKTOP ON THE MAC

With Terminal Services enabled on the Server 2003, Macintosh users can be treated like any other Terminal Services Client. Just install Microsoft's remote desktop client for OS X, and the Mac becomes able to run Windows applications as if it were an XP workstation. Very useful for those users who need to use a PC-only application on a Macintosh. This is frequently an issue for graphics departments who have Mac-only drawing software but must use a PC-only product, such as a time-tracking package for billing purposes. Although the OS X remote desktop client is a free download from Microsoft, you must have a legal Terminal Services client license for it. (Don't think of me as a member of the Microsoft police, I'm more like a crossing guard. Just looking out for your safety.)

If you have pre-OS X Macintoshes, you can use Citrix to do Terminal Services (it is sort of a rider package). Citrix enhances Microsoft Terminal Services in many ways, one of which is providing additional non-standard clients, such as Macintosh classic OSes, with access to the terminal server.

Be warned: Citrix is not cheap. You need a Citrix Client license and a Terminal Services Client license for each user. But if you have a few but crucial OS 9.2 Macintoshes, and you are already running Terminal Services, it might be worth looking into.

### Accessing the Server 2003

OS X can access file shares on a Server 2003 just as any classic OS could (with the correct Microsoft UAM). But, instead of going to the Chooser, you go to the Go menu at the top of the desktop, as shown in Figure 15.49. From the Go menu, select Connect to Server.

As soon as the window opens, OS X 10.1 scans the local network for all AppleTalk zones and AFP (Apple File Protocol) accessible servers. My Server 2003 TESTSVR1 for example, would show up next to the candied AppleTalk zone as well as next to the local network, because the workstation found it by using both AppleTalk and TCP/IP.

OS X 10.2 goes one step further and can recognize SMB, or Windows resources, as well as AFP. This is why TESTSVR1 also appears in Maclab (the NetBIOS name for the Server 2003 domain)—OS X 10.2 will display resources in Windows Workgroups or Domains. As of this writing, however, SMB tends to like to authenticate locally, which can be a problem at the server level. For shares on the server, I suggest using AFP for the time being. Using OS X 10.2 workstations to do SMB is still new to Apple and may have some growing pains, but it is a great convenience.

**FIGURE 15.49**

Connecting to a file share with the Go menu

You can select the resource you wish to access in the Connect to Server window, or type in an address in the Address box below the resource list.

By the way, OS X requires URL syntax for these addresses. For example, to connect to a server with a Macintosh shared volume through AppleTalk, you would type: **AFP://at/machine:zone** (as shown in Figure 15.50).

**FIGURE 15.50**

Connecting to a server using Apple File Protocol

To connect to an AFP server through TCP/IP, you would type: **AFP://IPADDRESS** or **AFP://SERVERNAME.DOMAINNAME**.

For OS X 10.2 and higher, to connect to a Windows server that has a shared folder on it, you can choose not to use AppleTalk or AFP, and just use SMB by typing: **SMB://IPADDRESS** or **SMB://SERVER.DOMAINNAME** (see Figure 15.51).

**FIGURE 15.51**

Connecting to a network share using SMB

Remember, the Macintosh user does need a user account to authenticate to the Server 2003. Once authenticated, the shared volume will show up on the desktop, as usual (see Figure 15.52).

**FIGURE 15.52**

Shared volume on the desktop

**TIP** Are your OS 9 workstations authenticating to a Server 2003 share, but your OS X workstations aren't? Check the authentication setting under *Configure File Server for Macintosh*. Make certain that you don't have *Apple Encrypted* set as your authentication type. OS X has a problem with *Apple Encrypted* authentication because Windows does *Apple Encryption* in a random, one-way exchange, and OS X wants a two-way exchange. To fix it, either use *Apple Clear Text Authentication*, or *Microsoft Authentication Only* if they have the new UAM.

## OS X PRINTING

To access printers on the network in OS X, the Macintosh user will have to go to the Applications folder on the hard drive and look in Utilities. This process is somewhat reminiscent of using the Desktop Printer Utility.

Within the Utilities folder is the Print Center (see Figure 15.53). For some reason, when you open the Print Center, the title bar of the window says *Print List*. Don't let that put you off, it is the Print Center, but the window does list Printers, so I guess they opted for a task-oriented title. This is the window within which almost every printer activity occurs. From this window, by clicking the *Add* icon, a Macintosh user can connect to a *AppleTalk*, *TCP/IP*, or even a shared printer on a *Server 2003* that is running *Print Server for Macintosh* service.

**FIGURE 15.53**

Print Center window

In the *Add* window, you can choose the kind of connection you'll be using to get to the printer, as shown in Figure 15.54.

**FIGURE 15.54**

Choosing a connection type

If you chose AppleTalk, you will once again see the list of AppleTalk network printers, as shown in Figure 15.55.

**FIGURE 15.55**

List of AppleTalk printers in the Print Center

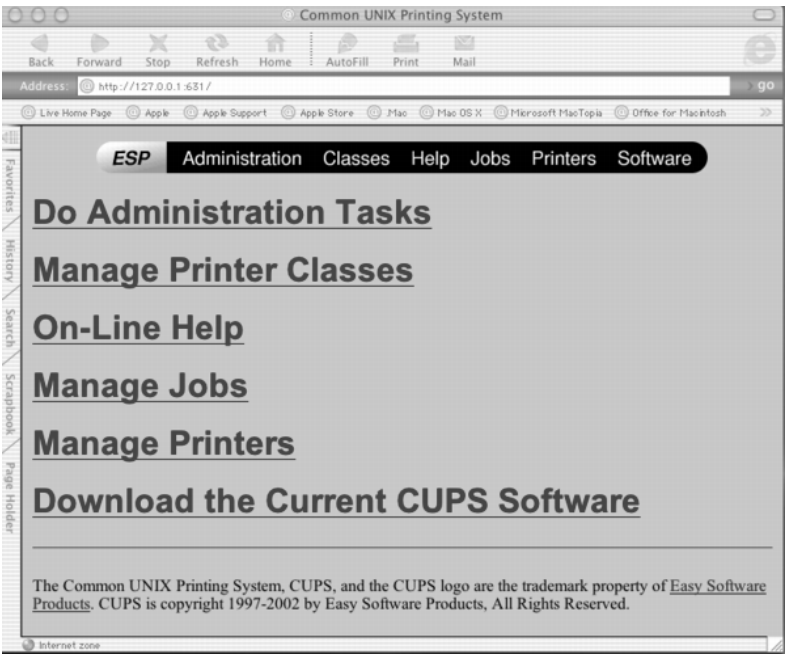

That would normally be it for new printer activities—except for the introduction of CUPS in OS X 10.2.1.

### **CUPS Printing**

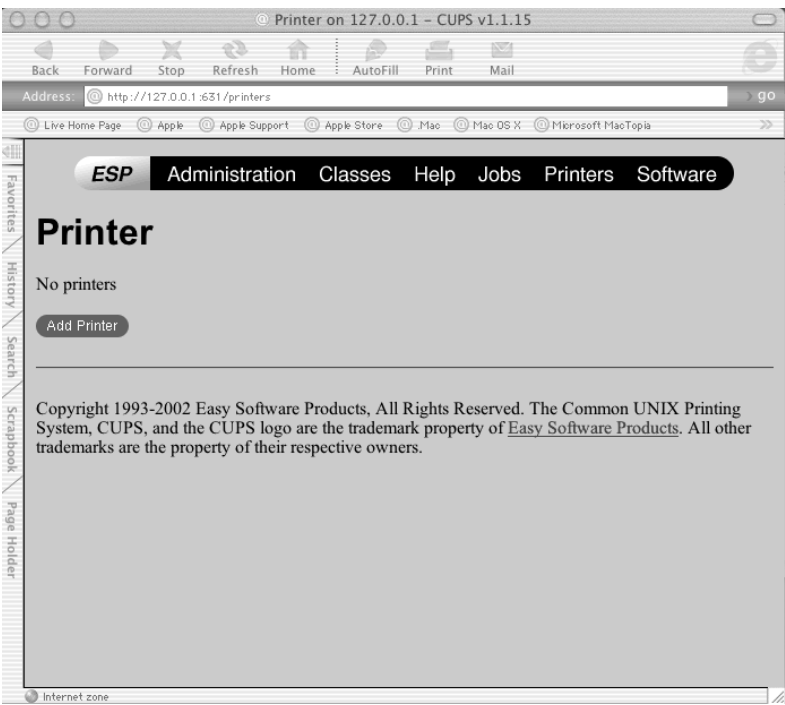

CUPS stands for Common Unix Printing System. It is a Web browser–based printer administration environment. With this system, an OS X 10.2 workstation can print to a non-Postscript printer (a DeskJet697c, for example) *in color* without the assistance of Server 2003's Print Server for Macintosh. It's extremely convenient to set up, and it has a surprising number of non-Postscript print drivers organized by manufacturer. The drivers are made to apply by model series, taking advantage of the fact that there are few differences between printers in a single model line.

1. To use CUPS, open a Web browser.
2. In the address field, type **http://127.0.0.1:631** (127.0.0.1 being the machine's loopback address, and 631 being the port that CUPS uses).
3. As you can see in Figure 15.56, CUPS will take you to a page with text links concerning managing printers. To add a printer, click Printers from the bar along the top of the page.
4. At this point, there are no printers in the Print Center, so this page doesn't list any (as you can see in Figure 15.57). If you had any printers already added in the Print Center, they'd show up here. To add a printer, just click the Add Printer button.
5. The next screen (see Figure 15.58) asks you to enter the name, location, and description of the printer you are adding.
6. Next, you will get a chance to select the type of connection you will use to access the printer (see Figure 15.59). I chose LPR since my printer is connected to an external TCP/IP print server (Jet Direct). Different connection types will require different connection information later.

**FIGURE 15.56**  
CUPS printer  
administration  
page in browser

**FIGURE 15.57**  
Adding printers

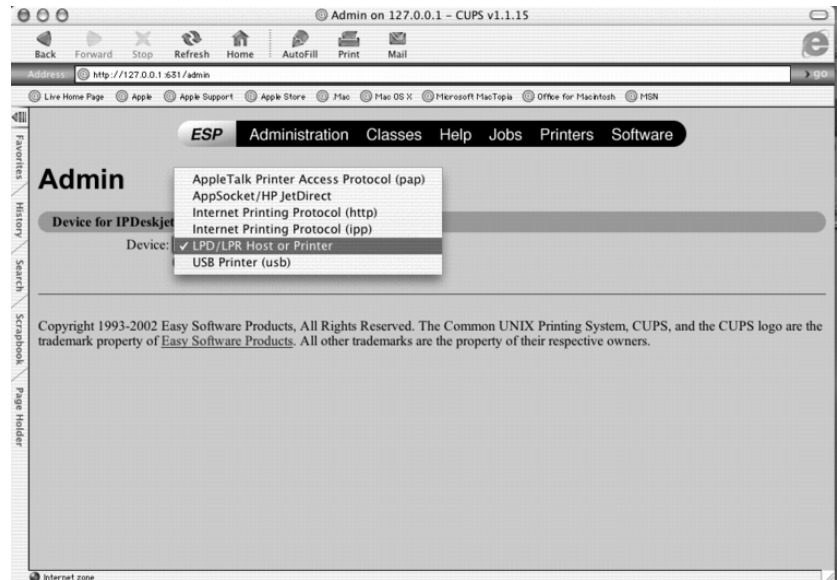

**FIGURE 15.58**

Naming the added printer

**FIGURE 15.59**

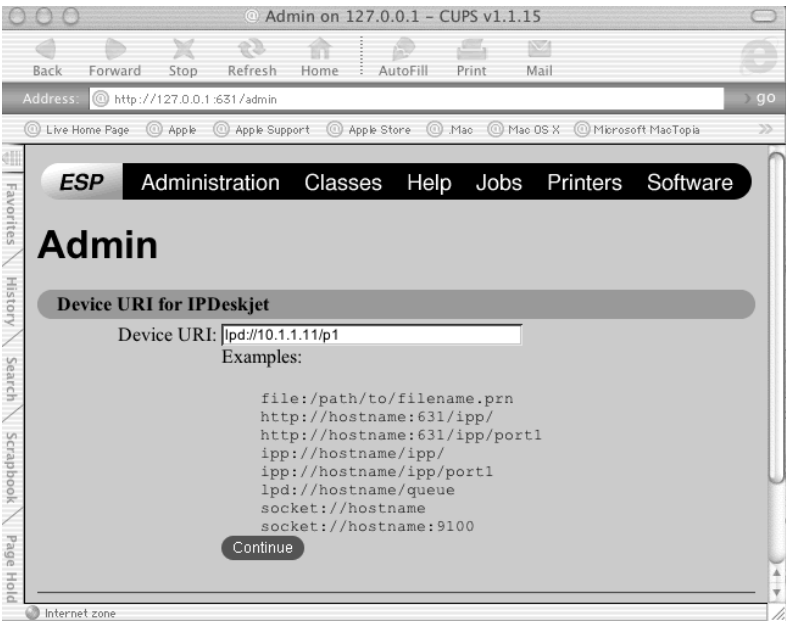

Choosing the printer connection type

7. The next screen (see Figure 15.60) prompts you for the address of the printer. In addition to the IP address, I also specified /p1, because my printer is on the first port on the Jet Direct print server.

**FIGURE 15.60**

Entering the IP address of the printer

8. The next screen lets you choose the manufacturer of the printer, and the following screen (see Figure 15.61) lets you choose from a series of driver types from that manufacturer. Since I have an HP printer, I chose that manufacturer, then HP DeskJet series.

**FIGURE 15.61**

Choosing a driver for a particular manufacturer's printer series

That's it; the printer has been successfully set up. If you look in the Print Center window (see Figure 15.62), you'll see the printer ready for action. When I sent a print job from the OS X 10.2 workstation to the DeskJet printer, it printed out in full color.

**FIGURE 15.62**

New printer added with CUPS in Print Center window

With OS X 10.2, you, as an administrator, can now tell your users that they can print in color to printers they never could print to before. Being able to say yes always makes you look good.

## Integrating with a Macintosh Server

Now it's time to go full circle. You know that if you have the File Server for Macintosh service running on Server 2003, Macintoshes can access file shares. Well, if you have a Macintosh server, it can be configured to support Windows file shares too. This is convenient if you don't want the Mac users in the graphics department to be copying several gigabytes of pictures on to Server 2003 when they could just leave it on their Mac server and have the Windows users go get them.

It may not be easily apparent to you which Mac is a server since prior to OS X, there was no specific Mac Server OS. To turn a workstation into a server before OS X, you just had to load AppleShare IP (ASIP), preferably 6.1 or higher, onto a workstation, and voila, you've got a server.

The coolest thing about ASIP is that now the Macintosh server can be indistinguishable from a Windows server, as far as Windows clients are concerned. By clicking a check box in ASIP, you can teach the Mac server to speak SMB. Windows users can see the files on the ASIP server and save to it. The Mac users can use it natively, of course. The only additional work to be done is to be sure that the Windows users have an account to log in with, since the Mac server will want to do some sort of authentication.

### ENABLING SMB FILE SHARING ON A CLASSIC OS SERVER

1. Go to the Apple menu.
2. Select AppleShare IP Admin.
3. Select Mac OS Server Admin.
4. Enter the administrator's username and password.

5. When a bar of server tools (otherwise known as a control strip) comes up (see Figure 15.63), select the File Server icon (a document in an open folder). From the pop-up menu, select **Configure File Server**.

**FIGURE 15.63**

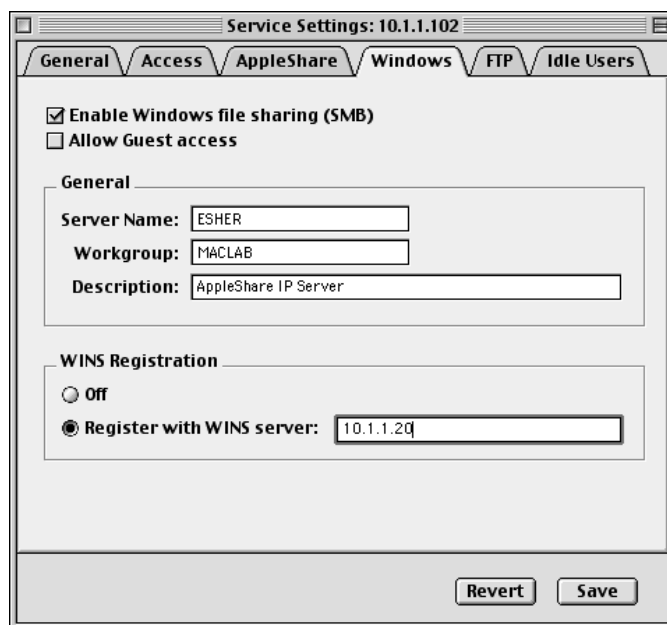

Mac OS Server  
admin tools

6. In the System Settings panel, click the **Windows** tab.
7. Click the **Enable Windows File Sharing** check box.
8. In the **General** section (see Figure 15.64), you can enter the server name, the workgroup, and a description. In the **WINS Registration** section, choose whether or not this server will register itself to an existing WINS server for the Windows users' convenience.

**FIGURE 15.64**

Server settings  
for Windows  
file sharing

Then, whenever a shared volume is created it can be accessed by Windows users. The Mac server treats the Windows users (at that point) exactly as if they were Mac users. If the Windows user has a valid account on the server, they will be given access to the folders they have permission to.

**NOTE** There can be a certain amount of redundancy with the accounts on both the Apple and Windows side of the network. To use the Mac and Windows servers together most effectively, it helps to have identical accounts on both servers for each user. That way, the users can securely access resources anywhere on the network without worrying about being unnecessarily restricted or confused as to which username or password should be used when.

### ENABLING WINDOWS FILE SHARING ON AN OS X SERVER

To file share with an OS X server, the same rules apply: you just have to enable Windows file sharing in the server service and Windows users will be able to use the shares (with the proper authentication, of course).

**NOTE** In addition to file sharing, the OS X server is a full-featured network server with the capability to do DNS, DHCP, SLP, Web services, e-mail services, and print services to a number of different clients, including Windows.

1. Go to the Server Settings Utility, which is located either on the Dock (that quick launch-type bar, usually located at the bottom of the desktop) or in the Utilities folder under Applications.
2. At the prompt, authenticate with the administrative username and password.
3. When the Server Settings control strip appears (see Figure 15.65), click the Windows button.

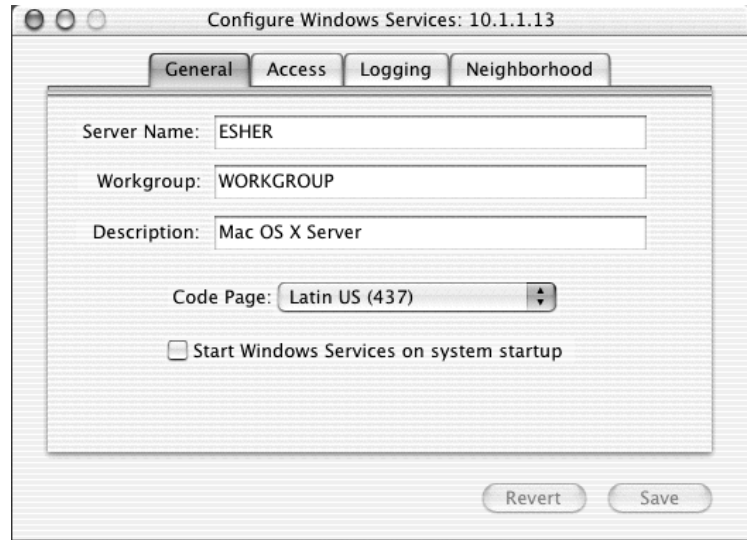

**FIGURE 15.65**

Server Settings control strip

4. The pop-up menu will contain Start Windows Services and Configure Windows Services (does all of this sound familiar?). When you configure Windows Services (see Figure 15.66), you can set the server name, workgroup, and description under the General tab; guest access and simultaneous SMB connections under the Access tab; and logging under the Logging tab.
5. The last tab, Neighborhood (see Figure 15.67), is where you can specify whether or not the server will register with a WINS server and (not to be out done by ASIP) whether or not it should be a master browser for the Windows clients, either locally or for the whole domain (oh, how thoughtful—scary, but thoughtful).

**FIGURE 15.66**  
Configuring  
Windows Services

**FIGURE 15.67**  
Configuring WINS  
and Master Browser  
settings

With Windows Services configured, a user can browse from an XP workstation to the OS X server in Network Places (see Figure 15.68) as if it were any other Windows computer.

**NOTE** If you experience any problems authenticating to the OS X server from an XP workstation or Server 2003, check to see if Password Server is enabled on OS X. Earlier versions of Windows, such as 2000 or 98, can authenticate to an OS X server shared volume without any problems. The issue arises due to the increased security on later versions of Windows.

**FIGURE 15.68**

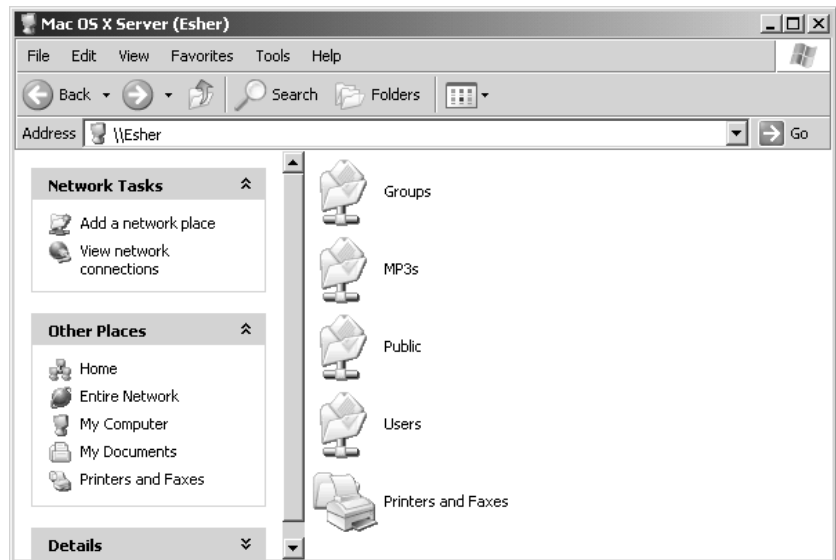

Browsing for the OS X server on an XP workstation

From there, the user can double-click the OS X server icon, be authenticated with an OS X server account name and password, and access whatever shares are permissible to them (see Figure 15.69).

**FIGURE 15.69**

Opening the shared folder to access resources

### THE COUP DE GRACE: AUTHENTICATION

It used to be that when sharing Windows resources with Macintosh clients, there were some authentication obstacles that made things awkward. When sharing resources through a pre-OS X server, both Windows and Macintosh clients got access to additional resources, but still, no matter what, there was that dual platform, dual login issue. Well, with some work, the dual login problem can be resolved.

Currently, integrating OS X's authentication through its directory service (Net Info) with Microsoft's Active Directory involves mapping Net Info fields to Active Directory's Schema objects. It is a painstaking task (not to mention something that should be done only in a test lab first). However, if you set up Net Info properly, do a little file copying of some Kerberos files, and follow some step-by-step instructions on how to modify the Net Info directory domain and the Windows AD (scary, yes, but when this puppy works, it really works), then you can have a seamless integration between the Apple OS X server's user database and the Windows user database. This will create one single directory structure that encompasses both OS X and AD servers. No dual user accounts, no security issues.

This solution is still in its infancy, and I predict that any information I might give you now (particularly in meticulous, step-by-step instructions) would be obsolete by the time you read this, as Apple is sure to release patches and upgrades to make integrated authentication easier. Furthermore, there will probably soon be a snap-in of some sort from Apple that will make the Net Info/AD schema changes for you, wizard style. If it doesn't come to pass, or you just can't wait, then you don't have to do this work alone—there are many hands to hold. On the [www.apple.com](http://www.apple.com) Web site, there are links to excellent PDFs concerning Net Info and step-by-step instructions on how to do the directory integration. Another great site to help you with Mac/Windows integration is, of course, [www.macwindows.com](http://www.macwindows.com). This is the site for up-to-date information on current integration issues and other important insider information about how to make integration tools really work. Apple also has discussion groups that can help you with any problem you might be having with your Macs.

---

I hope this chapter has solved some Macintosh mysteries and has been able to give you some insights as to how easy it is to share resources between Macs and Windows computers. With any luck, this information will free you from the drudgery of manually changing IP settings and the frustrated complaints of Mac users who can't access Server 2003 resources.

## Chapter 16

# Supporting Clients with Windows Terminal Services

MULTIUSER WINDOWS, SERVER-BASED computing, thin client computing—whatever you call it, it's part of the core Windows Server OS. Multiuser Windows has been around for quite a while. Citrix created MultiWin, the set of extensions to Windows NT that enables it to run multiple user sessions from the same machine. The first MultiWin product was multiuser NT 3.51, Citrix's WinFrame. Starting in July 1998, Microsoft began shipping its Terminal Server Edition of NT 4 (TSE). Terminal Services first became part of the core OS with Windows 2000, and in Server 2003 is installed (if not enabled, for security reasons) by default. There's even a very limited version of Terminal Services in Windows XP, making Remote Desktop Connection possible. And in Server 2003, Terminal Services has gained a number of new client- and server-side features that make the service attractive even without using the once unavoidable MetaFrame.

Installing Terminal Services is easy. Creating a working terminal server capable of supporting multiple users, all running different applications and wanting to use their client-side resources, may not be. You'll need to do a fair amount of tweaking once you get past the basic step of running Notepad from the terminal server. If you're serious about administering a terminal server, I *highly* recommend you make the Terminal Services section of the Microsoft Knowledge Base your favorite pleasure reading because this is relatively new territory to Microsoft and it's still working the bugs out. This chapter will do the basic legwork for you, however.

**NOTE** To help you keep up with the Knowledge Base updates, I've restarted the free thin client newsletter that (among other things) summarizes recent Terminal Services–related updates. You can sign up at [www.isinglassconsulting.com](http://www.isinglassconsulting.com).

## Why Care about Terminal Services?

Terminal Services gives you secure remote access to a computer and requires little enough bandwidth that you can use it over low-speed connections. So?

The first reason to care about Terminal Services applies to anyone using Windows Servers, not just people wanting to support an application server. Terminal Services has two modes: Remote Administration (the default, discussed at the end of this chapter) and Application Server (which I'll concentrate on in this chapter). Remote Administration enables you to manage Windows Server computers from across a network, without limiting your access to tools within the

Microsoft Management Console (MMC) or even requiring you to use Windows Server 2003 or 2000 as the managing operating system. If you don't use Terminal Services for anything else, use it for managing servers without having to physically move from console to console. Turn to the section "Using Remote Administration Mode" to read more about the requirements for remote management access, how to enable it, how to connect, and what you should know about it.

In this chapter, however, I'll focus on how you can use Application Server mode—the "terminal server" part of Terminal Services—to support clients. If any of the following are important to you, then seriously consider how you could use Application Server mode:

- ◆ Simplifying application deployment and management
- ◆ Reducing the impact of hardware failures or misconfigured computers that keep people from working
- ◆ Getting out of the hardware rat race that constantly requires more updates to support the latest and greatest software
- ◆ Using computers in environments that are not compatible with desktop computers
- ◆ Simplified help desk and training support

## Centralized Deployment of Applications

One great benefit to Terminal Services is how it simplifies application deployment to the clients. Windows Server 2003 has some application deployment tools in the form of group policy objects (GPOs), and Chapter 9 discusses those tools in detail. If you use GPOs to deploy applications to the Desktop you can create packages that enable you to run applications on the client computer while making those applications "maintainable" from a central point. GPOs have their failings, however. First, you can't use GPOs with just any Win32 operating system; instead you must use Windows 2000 Professional or Windows XP clients—and you will need to check the version information for the GPOs, as some require Windows XP clients. Second, setting up GPOs effectively is not necessarily a simple matter. Third, you can't always use GPOs to deploy applications across a low-bandwidth network connection well—the application packages may not be small. Finally, all these factors make GPOs a questionable method of application deployment for any applications that need to be updated frequently (as some database clients do). The more often you need to deploy an application across the network, the greater the chance something weird will happen along the way. (The technical term for the time between unexpected and inexplicable failures is *Mean Time Between Weirdness*—MTBW—and the concept is probably familiar to you.)

Using Terminal Services to deploy applications has its own difficulties—namely, getting all the applications and all the users to play nicely in the same space and keeping users connected to the server—but it avoids the problems and limitations associated with GPOs. For example, when you update an application installed on a terminal server, it's instantly updated for everyone using that server. Any operating system that has a Remote Desktop Protocol (RDP) client (and, these days, that can include Macintosh and Linux clients as well as Win32) can use the terminal server, so you're not limited to deploying applications to the higher-end clients. A Terminal Services connection requires little bandwidth, so you can use it on busy or slow network connections. And, because you're not actually sending applications or data across the network or installing applications on the clients, the MTBW rating for clients using Terminal Services is low—so long as nothing changes and it's working right in the first place.

Running applications on a terminal server is not a trouble-free process; getting things set up properly and keeping people from fiddling with the terminal server can be tricky. Some applications won't work at all in a multiuser environment. And in case you thought installing applications on a terminal server meant you could support many users with a single license, think again—you'll still need to pay for application licensing for each user or computer connecting to the applications published on the terminal server. However, this basic fact remains true: Set a compatible application up once on the terminal server, and its updates are available to everyone who has access to the terminal server, without the need for any changes to the client.

## Supporting PC-Unfriendly Environments

The dream of "a PC on every desktop" will remain a dream, if for no other reason than in some environments the conditions are bad for the PC or the PC is bad for the conditions. In other words, you can't run a PC everywhere.

First, there are environments that are bad for PCs. PCs do not like dust, excessive heat, or vibration, and *you* will not like maintaining the PCs if you try to use them in an environment that has any of these characteristics. PCs are also a commodity item; if you leave them unattended and unguarded where just anyone can get to them, they will disappear. For these reasons, Windows terminals are becoming a popular choice in environments that are PC-unfriendly but still need access to Windows applications. Warehouses and unattended trucker kiosks (where the truckers can log in to display and print their shipping orders from a terminal) are two good examples of how to use Windows terminals in PC-unfriendly environments. I've also seen terminals in health club cafés and coffeehouses set up so that only the monitor is visible, thus reducing the chances of someone dropping a strawberry-banana low-fat smoothie with a shot of wheatgrass juice down the vents. For that matter, if someone does drop said smoothie down the terminal's vents, then, because the applications are installed on and running from the terminal server, replacing the device to provide an identical environment is as simple as unplugging the sticky terminal and plugging in a new one. If you drop the smoothie down a computer's vents, then restoring an identical working environment is significantly more complicated.

What about PCs being bad for the conditions? Clean rooms where chips and boards are made are good candidates for Windows terminals. You can't have dust in a clean room, and the fans in a PC kick up dust. Additionally, becoming sanitized to enter a clean room is neither simple nor inexpensive; you don't want to put devices that need care and feeding from the IT staff in there. Another factor applies to many situations, not just clean rooms: Anyplace where space is at a premium is a good candidate for Windows terminals.

This section isn't to sell you on the idea of Windows terminals but to point out that sometimes they're useful, even required—and you can't use them without a terminal server.

## POWER STRUGGLES

Another aspect of the environment-unfriendly PC applies to the power a desktop PC uses. Inspired by the California energy crises of 2000 and 2001, my cohort Steve Greenberg and I did a couple of lab and real-world studies to see how desktop-centric computing and server-based computing compared in terms of power usage. What we found was sobering: A server-based computing network required less power to provide application support than did a desktop-centric environment, even when the client computers for accessing the terminal server were desktop computers instead of terminals. In fact, the Windows terminals used so little power that the use of terminals increased the difference dramatically.

*Continued on next page*

**POWER STRUGGLES (continued)**

If you're interested in the results of our research, you can download the main study at [www.thinclient.net](http://www.thinclient.net) (look in the "What's New" section for the link), but here are the highlights: The desktop PCs we tested had a constant power draw of about 85 watts when running applications locally (excluding a 15" CRT monitor, which drew an additional 85 watts). Running applications from a terminal server, the desktop PC power usage dropped to 69 watts—not a big difference on a small scale, but this difference increases as the network grows. The terminals we tested drew less than 10 watts, or 24 watts with a built-in LCD display. If you're assuming (as many did) that the power use of the terminal server was great enough to offset the gains realized by using server-based computing, think again. Although a terminal server used an average of 141 watts in our testing (the power draw fluctuated depending on how many people were using it), a terminal server can support many clients, so its greater power draw is offset by the number of people it's supporting.

The power savings realized become more dramatic as the network gets larger—and as power gets more expensive. If you'd like to figure out how much you're spending on power, then calculate the result of  $n * p * h * 52$  to get the number of kilowatts (kW) your client computers use each year, where  $n$  is the number of desktop devices,  $p$  is the power (in kW) used by each device,  $h$  is the number of hours each week that the devices are turned on, and 52 is the number of weeks in a year. For example, say your network has 5,000 client computers, each powered on 50 hours a week. If the 5,000 clients are PCs with CRT displays running applications locally (.17kW), then they'll use  $5000 * 0.17 \text{ kW} * 50 * 52$ , or 2,210,000 kW each year. If the 5,000 clients are thin clients with integrated LCD panels (.024kW), they'll use  $5000 * 0.024 \text{ kW} * 50 * 52$ , or 31,200kW each year. Say those 5000 thin clients need 200 servers (.141kW) to support them, and those servers are on 24/7. In that case, the calculation is  $200 * 0.141 \text{ kW} * 168 * 52$ , or 246,355.2, giving you a total of 277,555.2kW.

Based on these calculations, at 0.20 per kW, serving applications with the PC network costs \$442,000 to run each year. Serving applications via a thin client network—with servers on all the time—costs \$55,511.04. And we haven't even begun to talk about other aspects of Total Cost of Ownership or the investment required to keep IT hardware up and running. Nor have we talked about how reducing power usage reduces power costs because dissipating two units of heat (generated by power-sucking devices—put your hand on a CRT lately?) requires one unit of energy.

Saving on power costs is not the only reason to use Windows terminals, but, if you're tossing around the idea of replacing PCs with terminals, it's a compelling argument in favor of it.

**Less Processing Power Required on the Client**

First, about those ever-more-powerful computers: Does it take a 2GHz Pentium 4 with 256MB of RAM installed to check e-mail, do accounting, and poke around on the Web a bit? Of course it doesn't, but, as of late 2002, that's not an unusual hardware profile for a desktop computer. Not that these computers are too expensive in absolute terms; I'm wryly amused that every time I buy a new computer, I pay less for a system more powerful than the last one I bought. But although they're not too expensive in absolute terms, the new computers aren't always worth it because what you're doing doesn't demand all that much from your hardware. Ironically, unless your job is something demanding such as computer-assisted design, you're often more likely to need a powerful computer at home than at work because game hardware requirements are so high. It takes more

computing power to play a few swift rounds of WarCraft III than it does to write this chapter. (Fighting orcs is hard work!)

The trouble is, sometimes you do need those more powerful computers if you're planning to keep up with existing software technology. True—you don't need the world's fastest computer to do word processing. You may, however, need a computer faster than the one you have if you're going to keep up with the latest and greatest word processing package that everyone's using. If you want to be able to read all those charts and graphs, you can't always do it when the word processor you're using is six years old, even if it still suits your in-house needs. Trouble is, if your computer is also six years old, it may not be able to run the newest word processor, or the latest OS, since (for example) Microsoft announced in October 2002 that it would support the next version of Office only on Windows 2000 SP3 and Windows XP. If you're using Terminal Services to support applications, the client only displays applications running on the terminal server, rather than running them locally—you don't have to concern yourself with whether the applications will run on the client computer, just the server. If the application will run on the terminal server, then it will display on the client. As I'll discuss in this chapter, you may need to tweak an application to make it run *well* on the terminal server and some applications won't run well at all, but you can use Terminal Services to get an application to a computer that would not normally support it, thus lengthening your client upgrade cycle.

## **Simplifying the User Interface**

Another potential benefit to Terminal Services is it can simplify the user interface (UI). I'm not sure why Microsoft keeps talking about how using a computer is getting easier and easier. Speaking as the favorite source of free tech support for my parents (and some of my friends and *their* parents), I, for one, am not buying this idea. Experienced users may find it easier to customize their interface, but those who are less experienced find all sorts of pitfalls when it comes to using their computers: so many options that they get confused, and too many ways to break something. Colorful icons with rounded corners do not a simple UI make.

Terminal Services does not automatically make the UI simpler. In fact, to use Terminal Services effectively, you'll need to make sure you've locked down the user environment pretty securely because many people will be using the same computer, and one deleted file can screw up a lot of people. But, as I'll explain later in this chapter, it's possible to run either a complete desktop from a terminal server or a single application. If the people you're supporting only need a single application, then you can save yourself and them a lot of grief by providing a connection that runs it and nothing else. This is particularly true with Windows-based terminals, which are little more than a monitor, a box, a keyboard, and mouse.

## **Providing Help Desk Support**

Finally, Terminal Services can make application support easier, not just in terms of installing new applications and applying fixes but in helping people learn to use those applications. Remote Control lets administrators connect to another person's terminal session either to watch what they're doing or to interact with the session. (This isn't the security hole it may seem—you must have permission to do this, and by default the person to whom you're connecting has to permit the connection before you can see their screen.) When you have remote control of another user's session, you can either watch what they're doing and coach them (perhaps over the telephone) or actually interact with the

session so that you can demonstrate a process. This beats standing over someone's shoulder saying, "Click the File button at the top left. No, *File*. The FILE button..." or trying to figure out what they're doing when your only information comes from their description of the screen. I'll talk more about how to use Remote Control later in this chapter.

## The Terminal Server Processing Model

I mentioned the many versions of Terminal Services earlier in this chapter. Regardless of which one you're using, in a broad sense they all work pretty much the same way. *Thin client networking* or *server-based computing* (same thing, different emphasis) refers to any computing environment in which most application processing takes place on a server enabled for multiuser access, instead of a client. The terms refer to a network by definition, so it leaves out stand-alone small computing devices such as personal digital assistants (PDAs) or handheld PCs, although you can add thin client support to some of these devices. What makes thin client networking and computing "thin" is neither the size of the operating system nor the complexity of the apps run on the client, but how processing is distributed. In a thin client network, all processing takes place on the server, instructions for creating video output travel from server to client, and all video output is rendered on the client.

### Son of Mainframe?

You may have heard thin client networking described as *a return to the mainframe paradigm*. (I have heard this less politely phrased as "You just reinvented the mainframe, stupid!" Sheesh. You kiss your mother with that mouth?) This comparison is partly apt and partly misleading. It's true that applications are stored and run on a central server, with only output shown at the client. However, the applications being run in the thin client environment are different from those run in a mainframe environment; mainframes didn't support word processing or slideshow packages, and the video demands on the graphical Windows client are necessarily greater than they were with a text-based green-screen terminal. Yet the degree of control that thin client networking offers is mainframe-like, and I've heard one person happily describe thin client networking and the command it gave him over his user base as "a return to the good old mainframe days."

Why the move from centralized computing to personal computers and back again? Business applications drove the development of PCs—the new applications simply couldn't work in a mainframe environment. Not all mainframes were scrapped, by any means, but the newer application designs were too hardware-intensive to work well in a shared computing environment. But those applications came back to a centralized model when it became clear that the mainframe model had some things to offer that a PC-based LAN did not:

- ◆ Grouping of computing resources to make sure none are wasted
- ◆ Centralized distribution and maintenance of applications
- ◆ Clients that don't have to be running the latest and greatest operating system with the latest and greatest hardware to support it
- ◆ Client machines that don't require power protection because they're not running any applications locally

All in all, reinventing the mainframe has its advantages. Just as PCs didn't replace mainframes, server-based computing isn't replacing PCs, but it's nice to have more options that allow you to tune your computing model to meet your environmental and administrative needs.

## Anatomy of a Thin Client Session

A thin client networking session has three parts:

- ◆ The *terminal server*, running a multiuser operating system
- ◆ The *display protocol*, which is a data link layer protocol that creates a virtual channel between server and client through which user input and graphical output can flow
- ◆ The *client*, which can be running any kind of operating system that supports the terminal client

### THE TERMINAL SERVER

Terminal Services is one of the optional components you can choose to install during Setup, similar to Transaction Services or Internet Information Services. If you've enabled Terminal Services, when the server boots up and loads the core operating system, the terminal service begins listening at TCP port 3389 for incoming client connection requests.

**TIP** Because Terminal Services is essential to the operation of a terminal server, you can't shut this service down. If you try it from the command line with the `net stop termserv` command, you'll get an error. Click the service in the Services section of the Computer Management tool, and you'll see that the options to pause or stop the service are grayed out in the context menu. If you want to keep people from logging onto the terminal server for a while (perhaps while you're doing maintenance on it), then open the Terminal Services Configuration tool and disable RDP. This will end any current connections and prevent anyone else from logging on until you enable the display protocol again.

### Understanding Sessions

When a client requests a connection to the server and the server accepts the request, the client's unique view of the terminal server is called its *session*. In order to start these sessions as quickly as possible, the terminal server creates two dormant sessions. When clients connect to the dormant sessions, Terminal Services will create more dormant sessions so that it's always got two ready to go. In addition to the remote sessions, a special client session for the console (that is, the interface available from the terminal server itself) is created.

**NOTE** Some have asked if there's any way to make Windows 2000 Professional multiuser. Nope—no Microsoft desktop operating system includes full-fledged Terminal Services, and there is no way to add it. Even Windows XP, which has the Remote Desktop feature that allows someone to connect to the computer via the RDP display protocol, can only support one connection at a time—console or terminal session. The Terminal Services I discuss in this chapter is solely a server-class feature.

All sessions have unique Session IDs that the server uses to distinguish the processes (processes are roughly equivalent to executable files) running within different terminal sessions on the same computer. The console session is assigned Session ID 0. When a client connects to the terminal server, the Virtual Memory Manager generates a new Session ID for the session and passes it to the Session Manager once the SessionSpace for that session has been created.

Every session, whether displaying an entire Desktop or a single application, runs the processes shown in Table 16.1.

**NOTE** *In NT-based operating systems, an executable file is internally known as an image. This is because, technically speaking, an application isn't the piece getting processor cycles but instead is a collection of commands called threads that get processor time to do whatever they need to do. The threads have an executing environment called the process that tells them where to store and retrieve their data. You don't really have to worry about these details except to understand what these processes and images the administration tool refers to are. Technically speaking, a process is an environment for the parts of an application that run, not an executable component itself. The EXE is the executable image of this process—the part that includes the code that needs processor cycles. For the sake of consistency with the interface, I'll refer to programs running on the terminal server as processes.*

TABLE 16.1: PROCESSES COMMON TO TERMINAL SERVICES SESSIONS	
COMPONENT	FUNCTION
Win32 Subsystem	Win32 subsystem required for running Win32 applications (including the Win2K GUI).
User Authentication Module	Logon process responsible for capturing username and password information and passing it to the security subsystem for authentication.
Executable Environment for Applications	All Win32 user applications and virtual DOS machines run in the context of the user shell.

The other processes in the session will depend on the applications the user is running. The crucial points to be learned from this are that every session has its own copy of the Win32 subsystem (so it has a unique Desktop and unique instances of the processes that support the Desktop) and its own copy of the WinLogon application that authenticates user identity. In practical terms, what this means is that every separate session a single person runs on the terminal server is using memory to support these basic files. I said earlier that you could set up terminal sessions that display only single applications—no Desktop. The flip side of this convenience is that supplying a full suite of applications connected separately requires a lot more memory on the terminal server than supplying all those applications from a single Desktop in a terminal session. That is, if you create one session to use Microsoft Word, one session to use Outlook, one session to use AutoCAD, and one session to use Solitaire, this will place a heavier strain on the server than running all those applications from a single Desktop session.

**NOTE** *With each generation, Terminal Services has become more parsimonious with memory allocation. The amount of memory reserved for the SessionSpace has been reduced from 80MB to 60MB, and the per-session mapped views was reduced from 48MB in TSE to 20MB in Win2K. Server 2003 has changed the way that it reads user Registry information into memory, reducing one serious crunch on another area of memory outside SessionSpace. Being more frugal with memory is a Good Thing—greater efficiency in memory allocation means support for more users, all else being equal.*

The terminal session keeps per-session processes from corrupting each other or viewing each other's data. However, although the sessions are allowed to ignore each other, they still have to coexist. All sessions use the same resources—processor time, memory, operating system functions—so the operating system must divide the use of these resources among all of the sessions while keeping them separate. To do so, the terminal server identifies the processes initiated in each session not only by their Process ID but by their Session ID as well. Each session has a high-priority thread reserved for keyboard and mouse input and display output, but ordinary applications run at the priority they'd have in a single-user environment. Because all session threads have the same priority, the scheduler processes user input in round-robin format, with each session's input thread having a certain amount of time to process data before control of the processor passes to another user thread. The more active sessions, the greater the competition for processor time.

The number of sessions a terminal server can support depends on how many sessions the hardware (generally memory but also processor time, network bandwidth, and disk access) can support and how many licenses are available. When a client logs out of his session, the virtual channels to that client machine close and the resources allocated to that session are released.

### **Memory Sharing on a Terminal Server**

The terminal server does not necessarily have to run a separate copy of each application used in each session—in fact, ideally it does not. When you start an application, you're loading certain data into memory. For example, say that running WordMangler loads files A–E into memory. If you start a second instance of WordMangler, is it really necessary to load a second instance of all those files into memory? You could do this, but as more and more sessions started up on the terminal server the duplicated DLLs and EXEs would cause the server to quickly run out of memory. But if you let all instances of WordMangler use the same copies of A–E, then if one instance needs to change a file that's in use, all other instances will be affected by that change. To get around the wasted-space/data-corruption dilemma, the server uses *copy-on-write* data sharing. “Helper files” are available on a read-only basis to as many applications that need them and are able to reference them. Let an application *write* to that data, however, and the memory manager will copy the edited data to a new location for that application's exclusive use. Copy-on-write works on any NT-based operating system, not just a terminal server, but because terminal servers are likely to be running multiple copies of the same application simultaneously, they greatly benefit from this memory-sharing technique.

The catch to copy-on-write is that only 32-bit applications really benefit from it. The reason for this has to do with how 16-bit applications run in a 32-bit operating system. Namely, they don't: To run a 16-bit application, NT-based operating systems have to create a 32-bit operating environment called a *NT virtual DOS machine* (NTVDM) that contains the 16-bit application. The NTVDMs can do copy-on-write data sharing, but the 16-bit applications they're hosting cannot. Therefore, all else being equal, Win16 and DOS applications will use more memory than Win32 applications.

With the advent of 64-bit Windows on the horizon, it's reasonable to ask how a larger memory space will affect terminal servers. Right now, it's a little hard to say. Having a larger memory space to work with should reduce the memory bottleneck on the servers. However, the overhead required to chunk 32-bit applications into a 64-bit operating system—much like that required to make those 16-bit applications run on a 32-bit operating system—may reduce some of the benefit. 64-bit Windows on Itanium is showing some pretty serious overhead in this regard; it's hoped that it will

perform better on AMD's 64-bit chip. The bottom line is that 64-bit Windows should help alleviate the memory bottleneck, but the full benefits of the new architecture may not really materialize until we've got 64-bit applications to run on the terminal servers. Incidentally, 16-bit applications won't work at all on 64-bit Windows, since Microsoft has not included a 64-bit NTVDM for them to execute in.

### THE REMOTE DESKTOP PROTOCOL

You can run all the sessions you like on the terminal server, but that won't do you any good unless you can view the session output from a remote computer and upload your input to the terminal server for processing. The mechanism that allows you to do both is the *display protocol*.

#### How RDP Works

A display protocol downloads instructions for rendering graphical images from the terminal server to the client and uploads keyboard and mouse input from the client to the server. Terminal Services natively supports the Remote Desktop Protocol (RDP), and with Citrix's MetaFrame add-on to Terminal Services, it supports the Independent Computing Architecture (ICA) protocol. RDP is based on the T.120 protocol originally developed for NetMeeting, and as such has some theoretical capabilities that aren't realized in the release product. The way it's implemented now, RDP provides a point-to-point connection dependent on TCP/IP that displays either the Desktop or a single application on the Desktop of a client running RDP.

**NOTE** *Yes, you can run multiple sessions from a single client and even multiple sessions for a single user (although for reasons of profile maintenance and memory usage, this may not be the best plan—I'll get into this later). However, each session is still a point-to-point connection rather than a one-to-many connection such as that possible with Citrix MetaFrame's Seamless Windows connection.*

The processing demands placed on the client are reduced by a feature called *client-side caching* that allows the client to "remember" images that have already been downloaded during the session. With caching, only the changed parts of the screen are downloaded to the client during each refresh. For example, if the Microsoft Word icon has already been downloaded to the client, there's no need for it to be downloaded again as the image of the Desktop is updated. The hard disk's cache stores data for a limited amount of time and then eventually discards data using the Least Recently Used (LRU) algorithm. When the cache gets full, it discards the data that has been unused the longest in favor of new data.

**NOTE** *The image on the screen is updated about 20 times per second when the session is active. If the person logged in to the session stops sending mouse clicks and keystrokes to the server, then the terminal server notes the inactivity and reduces the refresh rate to 10 times per second until client activity picks up again.*

Note that in addition to each client session, there's also a session for the server's use. All locally run services and executables run within the context of this server session.

#### Understanding RDP Channels

The way that the Desktop or single application in a terminal session look and interact with the client's computer depends on the *channels* used in the display protocol. Channels work like roads between two

locations in that they must be open on *both sides* to work. For example, Route 29 in Virginia presents a straight shot between two cities: Charlottesville and Gainesville. If either Gainesville or Charlottesville shut down their end of the road—in other words, if the road became unavailable on either side—then traffic could no longer travel along that road. It doesn't matter that Gainesville's end is open if Charlottesville is closed. Channels work the same way: They're like roads between the terminal server and the client. If the road is not available on one side, it's closed—it does not matter if it's available on the other.

The capabilities of any one version of RDP are entirely dependent on what channels that version exploits. RDP has room for lots of channels for doing different things, and each version of RDP enables more of them. However, channels must be enabled on both the client and on the server to be useable, as shown in Figure 16.1. That's why, even though the Remote Desktop Connection tool downloadable from Microsoft's Web site can map client-side drives to terminal sessions, this feature does not work when you use this client to connect to a Windows 2000 terminal server. The virtual channel required to support this feature is not enabled on Windows 2000 Server.

**NOTE** Although you can update the RDP client component by downloading the latest client from the Microsoft Web site or getting it from the Setup CD for Windows XP, you cannot update the RDP server component that goes on the terminal server. There is no way to make a TSE terminal server or a Windows 2000 terminal server as capable as a Server 2003 terminal server.

**FIGURE 16.1**

RDP is a collection of channels conveying data between the terminal server and terminal client.

Notice something about channels: The more capable the RDP version—that is, the more channels it uses—the more bandwidth is required to support those channels. Because each version of RDP is written more efficiently than its predecessors, this doesn't mean TSE connections are more responsive than sessions using Windows XP's Remote Desktop. In fact, quite the opposite is true—the most recent version of RDP is pretty snappy even when connecting to an older terminal server. However, the more channels your RDP connection is using, the more bandwidth they'll need. Therefore, you will not always want to enable all these channels. I'll show you how to selectively enable and disable them in the course of this chapter.

## THE CLIENT

So you've got a terminal server running sessions and a display protocol to pass information to and from the sessions. All you're missing now is someone to use the sessions.

A client session is *connected* when a client computer chooses a terminal server from the RDP interface and gets far enough to see the login screen. The session becomes *active* when the user successfully

logs onto the domain or onto the terminal server's local account. During this session, client input in the form of mouse clicks and keystrokes is uploaded to the server via a virtual channel. The commands to render bitmaps showing the interface are downloaded to the client via another virtual channel. If client-printer mapping is enabled for the connection, the communication between terminal server application and client-printer takes places along yet another channel. A buffer supports the shared Clipboard data for local and remote sessions, too.

**NOTE** *Session 0—the console session—does not use the same keyboard and video drivers that client sessions use. Whereas Session 0 uses the normal video and keyboard drivers, the client sessions use drivers based in the RDP.*

Once the graphics-rendering instructions download to the client, the client resources create the images for display. During the course of the session, the user can work on the terminal server as though he or she were physically at the terminal server, using the client machine's keyboard and mouse. As the client runs applications, loads data into memory, and accesses shared resources on the network as though logged on directly (clients are not restricted to accessing the terminal server, but can access any available network resources), the client uses the hardware on the server. The only restrictions on the client are those defined by security settings.

### What's New in Server 2003?

Although the model in general applies to any version of Terminal Services, some virtual channels are version-dependent and only available in Server 2003. Additionally, some features of Server 2003 don't have anything immediately to do with the client experience but will make your life as an administrator a lot easier.

On the user side, the client experience is a lot richer. The maximum color depth is greater, RDP now supports sound, and drive mapping is an option. You can also limit users to a single session if you like.

Client enhancements are good, but as administrator types we're probably more worried about the server component. As you'll see in the course of this chapter, most of the tools in Server 2003 work very much like their counterparts in Windows 2000. The biggest difference for anyone running Server 2003 is the new support for group policies, which greatly simplifies server management. Those using Enterprise Server will have another option: a simple form of clustering. Using Network Load Balancing or another third-party load-balancing tool, you can arrange multiple servers into a cluster with a single IP address, so that users are always connected to the least-stressed server in the cluster. If a user disconnects from a session, the Session Server Database maintained for the cluster tells the session manager which session the disconnected user was using, so that they're able to reconnect to their old session.

It's now also possible to use group policy objects to create licensing security zones defining which servers are allowed to draw licenses from the license pool. This reduces the possible damage introduced by rogue application servers in the domain taking licenses from a pool planned for a certain number of users.

### DO I NEED THIRD-PARTY TOOLS?

That's a look at Server 2003 Terminal Services in a nutshell. But you can't talk about Windows Terminal Services and ignore MetaFrame.

Microsoft didn't invent multiuser Windows—a company called Citrix did. Citrix still makes its multiuser Windows product, now called MetaFrame—MetaFrame XP in its latest version. Although MetaFrame is dependent on the presence of Windows terminal services, it adds a lot to it. With the advent of Microsoft's Remote Desktop version of the RDP client, the RDP client has just about caught up with ICA, MetaFrame's display protocol. But for some purposes you may still need MetaFrame even after Server 2003 and its updated RDP server component are available.

**NOTE** *Incidentally, MetaFrame XP's name has no relation to Windows XP.*

I don't have room here to discuss MetaFrame in real detail, but let's take a look at some features that might make MetaFrame XP a valuable addition to your Windows terminal servers. As you'll see, most of these features have to do with the servers, not the clients. These aren't *all* the features that MetaFrame adds to Terminal Services, but it's a good sample.

**Multiprotocol Support** Terminal Services uses RDP to pass user input and terminal output between client and server. RDP depends on TCP/IP, which means that both the client and the server must be running it. This isn't all that big a deal because the Win32 clients that Terminal Services supports all come with TCP/IP. The ubiquity of the Internet makes TCP/IP the transport protocol of choice on most networks anyway, but Terminal Services does lock you into one protocol. The ICA protocol used with Citrix's MetaFrame, in contrast, supports IPX/SPX and NetBEUI.

**Application Publishing** Terminal Services can create client connections that supply only applications, but the user must know which server is running the application and make an explicit connection to it. With MetaFrame, you can create general client connections to a set of servers running a certain application without the client having to know or care which server is providing the application. These connections may be displayed on the user Desktop (for Win32 clients) or in a folder called **Program Neighborhood** or in a browser using MetaFrame's NFuse Web-based application publishing. NFuse is not the same as the TSAC, which is an RDP client in the form of an ActiveX control. All TSAC does is build the RDP client into a Web page so that people can connect to the terminal server through Internet Explorer. TSAC doesn't have any application-publishing features at all.

**Seamless Windows** Seamless Windows—the display of applications or a Desktop that fits perfectly into the local environment—is important for a couple of reasons. From the client perspective, Seamless Windows means you can see the entire Desktop or entire published application without having to scroll or display the session in full-screen mode. From the server perspective, all sessions displayed using Seamless Windows and running on the same MetaFrame server are actually running from the same session, and are thus using up less memory than connecting to each application individually.

**Load Balancing** Load balancing is not unique to multiuser Windows; it's the ability of multiple servers to work in tandem so that the least-busy server processes client requests. Windows 2000 Server does not support load balancing. Server 2003 supports Network Load Balancing for user logons, but it's restricted to load balancing according to client IP address. To get application load balancing for Win2K Server, you'll need the load-balancing version of MetaFrame XP: XPa or XPe.

MetaFrame XP's load balancing allows you to allocate work among servers according to processor load, memory load, the client's IP address, the applications being run, and other rules. (Windows Server 2003, Enterprise Edition supports load balancing, but only in a limited sense.)

And that's just the core product of MetaFrame XP. Citrix also releases Feature Releases (FR), which are like service packs (they have those, too) for features. FR1, for example, adds a sort of generic printer driver to MetaFrame so that you don't have to worry about supporting user printers. (It's a limited printer driver in that it supports only 300 dpi and black and white printing, but it works.) As of late 2002, Feature Release 3 is in the works.

All that said, Terminal Services is a perfectly serviceable tool for implementing server-based computing in your network, particularly for smaller environments. And Server 2003 has one *great* advantage over third-party products: price. Although Terminal Services Client Access Licenses (TSCALs) aren't free for most client platforms, if you install MetaFrame you'll have to purchase both the TSCALs and *additional* licenses for the MetaFrame access. And MetaFrame isn't cheap. If you only need a small set of MetaFrame's capabilities, then I'd recommend checking out some of the other third-party solutions out there. I like MetaFrame, but not everyone needs it and it's not the only game in town.

## Server and Client Requirements

The computing model for thin client networking means that the horsepower is typically concentrated on the server end, not the client end. Because the server will be supporting a couple of dozen people—maybe more—this is not the time to skimp on power.

### Server Hardware

The notion of using a bigger server so that you can skimp on client-side hardware isn't new. That's all a file server is: a computer running a big, fast hard disk so that you don't have to buy big, fast hard disks for everyone in the office. Terminal servers are designed on a similar principle: If most of the processing takes place in a single location, you can concentrate the hardware resources needed to support that processing in a single location and worry less about power on the client end.

#### CORE HARDWARE RECOMMENDATIONS

For the purposes of running an efficient terminal server, the bare minimum required to run Server 2003 won't cut it. It was technically possible to run a TSE session from a terminal server with a Pentium 133 and 32MB of RAM—I've done it. It worked fine...so long as only one person wanted to use the terminal server. Although there are no hard and fast specifications for a terminal server, some general guidelines for server sizing follow.

**Processor** Faster is better...to a point. More important than a fast processor is one with enough cache so that it doesn't have to reach out to the (slower) system memory for code and data. Faced with a choice between more cache and more speed, go with more cache. It's a good idea to at least *plan* for a multiprocessor computer. Although only multithreaded applications will actually use more than one processor, if there are two processors, then threads needing execution can line up at both. At this point, however, I'd stick with two processors. Processor time is not the only

bottleneck in a terminal server and using more servers instead of fewer removes some of the other bottlenecks.

**Memory** Terminal servers tend to be memory bound, not processor bound. Get high-speed, error-correcting memory, get plenty of it, and be prepared to add more as you add more users or applications to the terminal server. The amount of memory you'll need depends on the applications that people use, the number of concurrent sessions, and the memory demands of the files opened in those sessions—CAD programs will stress the system more than, say, Notepad. Because memory is relatively inexpensive these days, most terminal servers I've seen use at least 1GB of RAM.

**Disk** Use SCSI disks on a terminal server if at all possible. A SCSI disk controller can multitask among all the devices in the SCSI chain, unlike an EIDE disk controller that can only work with one device at a time. This is an important capability in any server, and especially so in a terminal server.

**Network** Even if it were easy to get ISA network cards these days, you'd want to use PCI and its higher data-transfer speeds instead. On a busy terminal server, consider load-balancing network cards, which can assign multiple NICs to the same IP address and thus split the load of network traffic. Another alternative is a multihomed server with one NIC dedicated to terminal session traffic. So far as network *speed* goes, sending application output and client-side input back and forth requires little bandwidth, but client-print jobs sent to mapped printers can take quite a bit. Mapped drives may also increase the load by making it possible to copy files back and forth across the RDP connection. Be sure to only support client-mapped printers and other bandwidth-intensive features over networks that can handle it, or get helper software to compress print jobs sent to mapped printers.

### USING THE SYSTEM MONITOR

The System Monitor discussed in Chapter 18 can help you get an idea of how test terminal sessions are stressing the server. Server load will scale linearly with the number of people using the server, so as long as you pick a representative group of around five people, you should be able to extrapolate your needs for larger groups. The key objects and counters for measuring general server stress introduced in that chapter will help you size terminal servers, too. But, a couple of Terminal Services-specific System Monitor objects are worth examining.

First, the Terminal Services object has counters representing the number of active sessions (sessions where the user has connected to the terminal server and successfully logged on), inactive sessions (where the user is still logged onto the terminal server but has stopped using the session), and the total combined. Mostly, this object is useful for keeping track of how many sessions a terminal server has to support. Chapter 18 discusses performance logging and alerts; if you find that a terminal server functions best below a certain number of connections, you could set up an alert log with that threshold and then, if the server breaches that tolerance, use the `change logon /disable` command to disable the server for new connections and send you a message to alert you. (Do disable connections at the upper limit, or else you'll go mad intercepting the alert messages telling you that the threshold has been breached.)

Although you can get some session-level information from the Terminal Services Manager, a performance object called Terminal Services Session provides quite a bit more. Use the Terminal

Services Manager to find the session you want to monitor (because they're identified to System Monitor by their session numbers, not user login name) and then add counters to monitor that session. Each session object has processor and memory counters that should look familiar to anyone who's used System Monitor, but it's also got session-specific counters such as the ones in Table 16.2. I haven't included all the counters here, just the ones to show you the kind of information that will be useful when you're calculating the load on the server and looking at the kind of performance the sessions are getting.

**NOTE** *If you click the Explain button in System Monitor when adding counters, you'll see a description of these counters, but the explanations for counters similar to those found in other performance monitoring objects may have been copied straight from there. Don't worry about this—just substitute session for process.*

TABLE 16.2: KEY TERMINAL SERVICES SESSION SYSTEM MONITOR COUNTERS		
COUNTER	DESCRIPTION	SEE ALSO
% Processor Time	Percentage of time that all of the threads in the session used the processor to execute instructions. On multiprocessor machines the maximum value of the counter is 100 percent times the number of processors.	
Total Bytes	Total number of bytes sent to and from this session, including all protocol overhead.	Input Bytes, Output Bytes
Total Compressed Bytes	Total number of bytes after compression. Total Compressed Bytes compared with Total Bytes is the compression ratio.	Total Compression Ratio
Total Protocol Cache Hit Ratio	Total hits in all protocol caches holding Windows objects likely to be reused. Hits in the cache represent objects that did not need to be re-sent, so a higher hit ratio implies more cache reuse and possibly a more responsive session.	Protocol Save Screen Bitmap Cache Hit Ratio, Protocol Glyph Cache Hit Ratio, Protocol Brush Cache Hit Ratio
Working Set	Current number of bytes in the Working Set of this session.	Virtual Bytes, Page Faults/Sec

**WARNING** *When experimenting with terminal sessions to find out how many users you'll be able to support for each session, do not set up a license server; let the terminal server issue its temporary 120-day licenses for this purpose. Although this sounds counterintuitive, using the temporary licenses prevents you from unwittingly assigning per-seat licenses to test equipment. See the "Terminal Services Licensing" section for an explanation of how licensing and license allocation works.*

Client Hardware

When connecting to a terminal server via a native RDP client, you'll use a PC with a Win32 operating system loaded, a Windows terminal, or a handheld PC using Windows CE.

**NOTE** In this context, a native RDP client means one available from Microsoft and thus implies Win32 or (rarely) Win16. Although Microsoft does not support other platforms (except for their OS X Macintosh client, available for download from the Web site), Hoblink sells a cross-platform (Windows, Mac, Linux, DOS) Java client at [www.hob.de/www\\_us/produkte/connect/jwt.htm](http://www.hob.de/www_us/produkte/connect/jwt.htm), and there is a free Linux RDP client available at [www.rdesktop.org](http://www.rdesktop.org).

## WINDOWS TERMINALS

In its narrowest definition, a Windows terminal is a network-dependent device running Windows CE that supports one or more display protocols such as RDP or ICA, the display protocol used to connect to MetaFrame servers. Many Windows terminals also support some form of terminal emulation.

**NOTE** In this section, a Windows terminal is any terminal device designed to connect to a Windows terminal server; it can run any operating system that's got an RDP client. A Windows-based terminal (WBT) is such a device that's running a Windows operating system locally—CE or (more rarely) Embedded NT—and follows the Microsoft system design requirements for WBTs.

The main thing defining a Windows terminal is its thin hardware profile: Because the main job of most Windows terminals is to run a display protocol, they don't need much memory or processing power, and they don't use any storage. A Windows terminal includes a processor, some amount of memory, network and video support, and input devices: a keyboard (or equivalent) and mouse (or equivalent). The terminals don't generally have hard disks, CD-ROMs, or DVD players. The operating system (these days, PocketPC, one version or another of NT or XP Embedded, or Linux) is stored in local memory. Beyond those similarities, Windows terminals range physically from a "toaster" form factor to a pad to a small box that can attach to the back of a monitor—or even be part of the monitor itself. Some new models of Windows terminals are wireless tablets, intended for people (such as doctors and nurses) who would ordinarily use clipboards and folders to store information.

Although most Windows terminals are entirely dependent on their terminal server, a small set of them can run applications locally. The devices still don't have hard disks; the applications are stored in ROM like the operating system. The types of applications available depend on the terminal's operating system since locally stored applications must run locally instead of just being displayed. Generally speaking, however, it's more common for Windows terminals to depend on a terminal server for applications.

Windows terminals are most popular in environments where people are using a single application, where supporting PCs would be logistically difficult, or anywhere else that PCs aren't a good fit. However, PCs still outnumber Windows terminals as thin clients, if for no other reasons than that companies already have PCs, and taking away a powerful PC to replace it with a less-powerful PC can be a difficult political decision—even for people who don't need a whole PC.

## PC CLIENTS

At this point, people are using more than twice as many PCs as Windows terminals for terminal server client machines. This isn't surprising. First, unless they're starting afresh, people already have the PCs. Even though WBTs are a little less expensive than low-end PCs—not much, though—they're still

an added cost. Second, not all applications work well in a terminal server environment. It's often best to run some applications from the terminal server and some locally. Unless you're buying new hardware and don't anticipate any need to run applications locally, you're likely to have to work with PCs for at least some of your terminal clients.

To work with Terminal Services, the PCs must be running a Win32 operating system, have the RDP display protocol installed, and have a live network connection using TCP/IP and a valid IP address.

### HANDHELD PCs

I'm surprised that handheld PCs (H/PCs) aren't more popular than they are, given how handy they are and how much time I spend explaining to curious people what mine is. They're a terrific substitute for a laptop—inexpensive, lightweight, and thrifty with their power so that you can actually use them during the entire flight instead of having to give up two hours after takeoff. (You can also use one on a plane without worrying that the person in front of you will suddenly recline their seat and crack your laptop's display.) Usually, they run PocketPC and, thus, only compatible applications such as Pocket Office. But by downloading and installing the Terminal Services client for handheld PCs and getting network support if it isn't already built in, you can use wired, wireless LAN, or dial-up connections to connect to a terminal server.

**NOTE** *Because Microsoft rearranges its Web site regularly, there's no use providing a link to the RDP client—it'll be outdated by the time you read this. Look in the Downloads section of the WinCE area on [www.microsoft.com](http://www.microsoft.com); you should be able to find it there.*

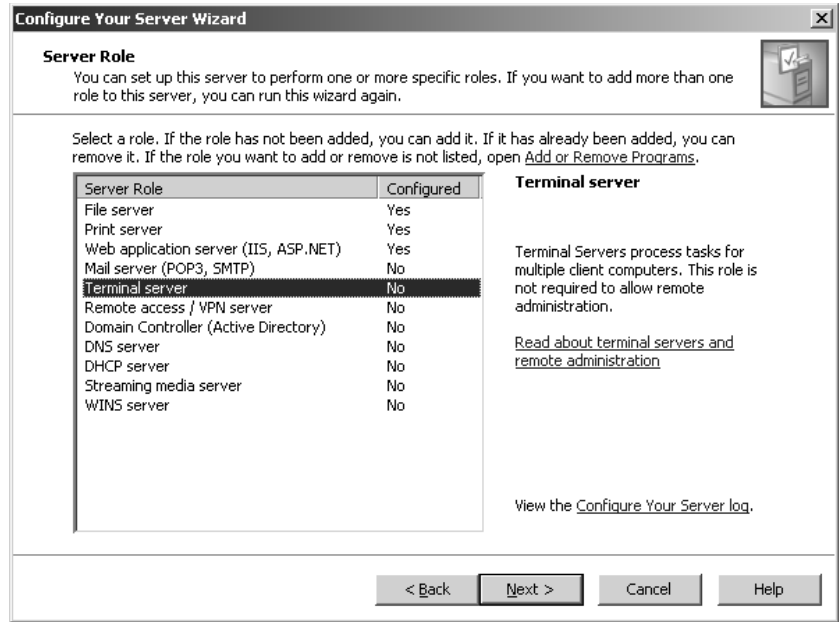

What a H/PC looks like depends on who makes it. Some (mine among them) look like a laptop's baby brother. Others fold into a little portfolio shape or are a flat tablet. Some devices known as H/PCs are small pocket-sized deals that are, in my personal opinion, too small to really work on. Some—the ones I prefer—have keyboards; others have only pointers. What all this comes down to is that a H/PC isn't really in a position to replace a desktop PC. Instead, it's usually used in cooperation with a desktop machine with which it's partnered.

## Installing (or Removing) Support for Terminal Services

Terminal Services is preinstalled on Server 2003, but you still need to set it up to be an application server. The easiest way to do that is by assigning the appropriate role to the server, using the Manage Your Server tool. Doing so will permit the server to accept incoming connections and tweak the server to make it perform well as a terminal server.

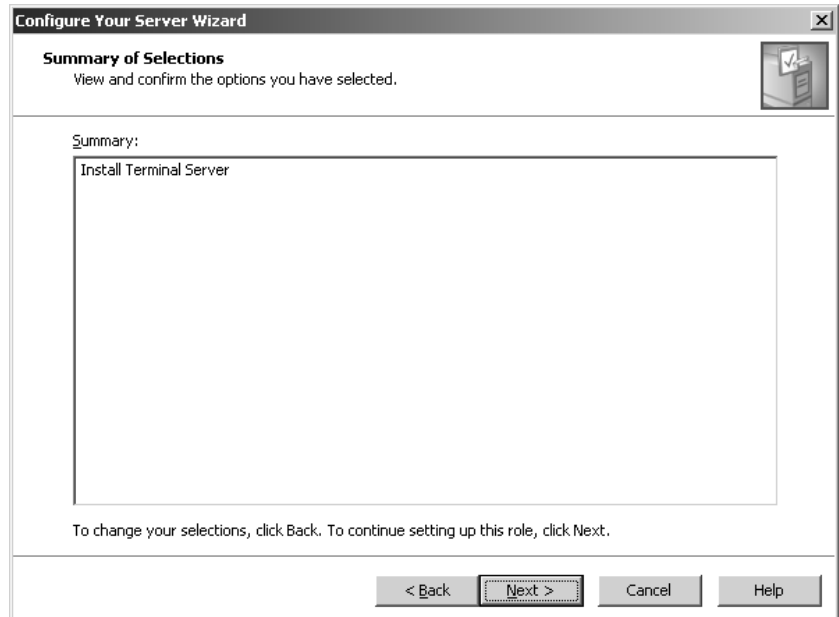

Assigning the Application Server role is dead simple. From the Manage Your Server tool, click the Add or Remove a Role button near the top. You'll see a short checklist of things to make sure of before adding a role (network's connected, path to installation media in case you need it, Internet connection if it will be necessary—by this point in this book, you've probably seen this screen a few times). Click Next to open the dialog box displaying the available roles (see Figure 16.2). Select that role, and click Next.

**FIGURE 16.2**  
List of available  
roles for the server

Confirm that you want to assign the selected role to the server, as in Figure 16.3.

**FIGURE 16.3**  
List of available  
roles to add

When you click Next, you'll see the status bar begin chugging away and a dialog box warning you that the Configure Your Server Wizard will restart the computer. Click OK and close any open dialog boxes. In a minute or two, the server will automatically restart. After it's rebooted, it's ready to be an application server.

To remove the role and make the server function like an ordinary server, run the wizard again and select the enabled role. When confirming that you want to remove the role, you'll need to check a box confirming its removal. When you do so, the wizard will remove that role and restore the normal Server 2003 performance.

**NOTE** Every time you add or remove a server role, when you reboot the final page of the Configure Your Server Wizard, it will display the changes you made and offer a link to the change log (stored in `%systemroot%\debug.configure.your.server.log`) that records all such changes and the time and date you made them. The System log will also record Event ID 7036 when the Terminal Service starts.

## Creating a New Terminal Server Client

The procedure for connecting a client to the terminal server varies slightly depending on whether you're talking about PC clients, handheld PCs, or WBTs.

### PC-Based RDP Clients

To connect a PC-based client to Terminal Services, you have to run a short installation program on the PC to install client support for RDP. This process is quite simple and (wonder of wonders in the Windows world) does not require that you reboot the computer afterward to use the client. The only catch is that you have to *get* those installation files to the client.

If that client is a Windows XP or Server 2003 computer, then you're done—the client is preinstalled on both operating systems. Other Win32 clients that can use the Remote Desktop Connection (which I strongly recommend, as it is not only required for the richest client environment but is also noticeably faster than the older versions of the RDP client) will need it installed. The client files are no longer installed with Terminal Services, but you can get them off the Server 2003 installation CD. Better yet, download `msrdpcli.exe`, currently available from the Microsoft Web site (look in the Downloads section) and run the executable to install Remote Desktop Connection on any Win32 computer.

Once you run the EXE and start the installation wizard, follow these steps:

1. Agree to the terms of the EULA.
2. Enter your name and company if Setup does not populate these fields for you and indicate whether you want the Remote Desktop available to anyone who uses the computer or just you.
3. Click Install to let the Setup Wizard copy the files, and the Remote Desktop icon will be added to Programs/Accessories/Communications.

You don't need to reboot when you're finished.

### Setting Up and Connecting a Windows-Based Terminal

Setting up a WBT for the first time is pretty simple. It's largely a matter of plugging everything in (power supply, monitor, network connection, mouse, and keyboard) and supplying the information

the WBT needs to interact with the terminal server. For this example, I'll set up a Windows CE-based Windows terminal on a LAN. Although some Windows have different options from others, the basic setup information required is the same on all CE-based Windows terminals.

**NOTE** *Setting up Linux-based Windows terminals gets a bit more complicated because the UI is not necessarily consistent across terminal manufacturers. Sadly, there is no standardized way of doing this, so you'll need to peruse your Linux terminal's documentation for instructions. You'll be providing much the same information to the Linux-based terminal that you're providing to the Windows-based terminal. In some newer Linux-based terminals, the setup is similar to the CE-based setup I'm describing here, using the same tabbed configuration tools.*

### SETTING UP THE TERMINAL

Once everything is plugged in and you've powered on the unit, choose to begin creating a new connection. The Setup Wizard walks you through the following steps:

1. First off, you're faced with the EULA, which states that use of the unit with Terminal Services is predicated upon your having a valid Terminal Services user license and that you must follow the licensing for any applications run from the terminal server. You must click Accept to continue with the wizard.
2. Indicate whether the WBT is connecting to the terminal server via a LAN (the default) or a dial-up connection.
3. Choose the display protocol that should be used to make connections. You have the option of the Microsoft Terminal Server Client (the default, which I'll use here) or the Citrix ICA client, which you'd choose if connecting to a terminal server running WinFrame or MetaFrame. Most modern Windows terminals also offer some kind of terminal emulation support, but you will not use this to connect to a Windows terminal server.
4. The Setup Wizard will attempt to locate a DHCP server on your network. If it can't find one, the wizard will tell you so. You'll have the option of telling the wizard to use the IP information supplied by DHCP or supplying a static IP address.

**TIP** *If you have a DHCP server and the wizard doesn't detect it, make sure the DHCP service on the server is up and running properly and that the server is connected to the network. If they are, then restart the wizard to see whether it finds the DHCP server. Don't tell the wizard to use DHCP information if it's not able to find it, or you may run into problems in getting an IP address assigned to the terminal. No IP address, no connection to the terminal server.*

5. If you choose to supply a static IP address, you'll be prompted for it, the subnet mask, and (if applicable) the default gateway. The IP address, recall, is the identifier for the network node, and the subnet mask identifies the network segment that the node is on. The default gateway is only necessary if the network is subnetted and the terminal will need to connect to another subnet.
6. Next, you'll be prompted to supply the servers used for name resolution: WINS, DNS, or both. You'll need to know the IP addresses of the servers, as there is no browse function. If you're using one of the name resolution services, be sure to check the box that enables that service. Otherwise, the connection won't work, and you'll have to edit it to use the IP address instead of the NetBIOS name. To establish support for WINS, you'll need to reenter the unit's network setup.

7. Choose a video resolution. One possible option is Best Available Using DDC. DDC, which stands for Display Data Channel, is a VESA standard for communication between a monitor and a video card. If it supports DDC, a monitor can inform the video card about its capabilities, including maximum color depth and resolution.

When you click the Finish button in the final screen, you'll be prompted to restart the terminal to make the settings take effect. After restarting the system, you'll begin the second half of the terminal setup: the connection.

**TIP** *To manually restart a WBT, turn the unit off and back on again. If you're one of those people (like myself) who normally leave a PC on, don't worry. Turning off a WBT is equivalent in seriousness to turning off a printer. Doing so will disconnect any current sessions you have open, but it's not like rebooting a computer.*

### CREATING A NEW CONNECTION

To create a new connection, follow these steps:

1. Choose a name for the new connection and the name of the terminal server to which you're connecting. If you're using a dial-up connection instead of a LAN, be sure to check the Low-Speed Connection box so that RDP will compress the data a little further.
2. To configure the terminal for automatic logon to the terminal server session, fill in the name, password, and domain of the person using the terminal. If you leave this section blank, you'll have to explicitly log in each time you connect to the terminal server. For tighter security, leave it blank; if it doesn't matter whether someone can log in to the terminal server, you can set it up for automatic login.
3. Choose whether you want the terminal server session to display a Desktop or run a single application. Once again, there's no browse function, so you need to know the name and path (from the server's perspective) of any application you choose. If you don't provide correct path information, the connection will fail.

At this point, the connection is set up and you're ready to go. The Connection Manager displays a list of the available connections. To use one, select it and click the Connect button. You'll see a logon screen (assuming you didn't set up the connection for an automatic login). Type your name and password, and you're in.

### Setting Up a Handheld PC

To use a handheld PC (H/PC) to connect to a terminal server, you must install the RDP client on the H/PC and then create a session on the client.

First, you must get the RDP client. Go to the Microsoft Web site and navigate to the Downloads section of the WinCE section. You'll have to go through some screens where you agree that you understand that having the RDP client installed does not imply that you're licensed to access a terminal server. (There's also a link to a place where you can buy more licenses if needed.) Download the 1MB-client setup program (`hpcrdp.exe`) to the desktop partner of the H/PC.

**NOTE** *As of this writing, the Windows CE RDP client is located at [www.microsoft.com/mobile/downloads/ts.asp](http://www.microsoft.com/mobile/downloads/ts.asp), but it may have been moved by the time you read this.*

To install the RDP client on the H/PC, follow these steps.

1. Turn on the H/PC and connect it to the desktop partner. Make sure that they're connected.
2. Run `hpcrdp.exe` to start the installation wizard.
3. Click Yes to agree to the EULA.
4. Choose an installation folder for the client on the desktop partner. The default location is a subfolder of the **Windows CE Services** folder, which you'll have installed in the course of partnering the desktop machine and the H/PC.
5. The installation program will start copying the files to the H/PC. This may take a few minutes if you're using the sync cable instead of a network connection—a sync cable is a serial connection.
6. Once the files have been copied, click **Finish** on the desktop side to end the Setup program.

To set up a connection, go to the H/PC and look in **Start/Programs/Terminal Server Client**. There are two options here: the **Client Connection Wizard** and the **Terminal Server Client**.

To use the default connection settings, click the **Terminal Server Client** and type in the name or IP address of the terminal server to which you want to connect. Click the **Connect** button, and the client will search for that terminal server. You'll need to log in as if you were logging into the server or domain.

For a little more control over the connection settings, run the **Client Connection Wizard**. You don't have as many options as you do when running the similar wizard for the PC client, but you can specify a connection name, provide your username and password for automatic logon, and choose whether to run an application or display the entire Desktop. Click the **Finish** button, and the wizard will put a shortcut to that connection on your H/PC's Desktop.

## Creating, Deleting, and Modifying Connections

Now that the client is installed, you're ready to connect to the terminal server. Let's take a look at how to do this from a PC.

To set up a connection on the Remote Desktop client, open it (**Programs/Accessories/Communications/Remote Desktop**). When you first run the tool, no servers will be selected, but you can either type a server's name or browse for them by clicking the down-arrow button in the **Computer** box and choosing **Browse for More** to open the dialog box shown in Figure 16.4.

When you've found the terminal server to connect to, double-click it or click it **OK** to return to the main login window, which should now have a server selected, as shown in Figure 16.5. To connect to this server with the default settings, just click the **Connect** button. This will connect you to the

selected terminal server and prompt you to log in. When you have successfully logged in, by default the session will run in full-screen mode with a sizing bar at the top so that you can easily minimize or resize the window to show the local Desktop.

**FIGURE 16.4**

Browsing for terminal servers from the Remote Desktop

**FIGURE 16.5**

To use the selected terminal server with the default settings, click the Connect button.

Notice that I didn't touch the Options button in Figure 16.5. If you're using the default settings, you'll never need to touch it. Let's take a look at what those settings involve.

When you first click the Options button, you'll see the General tab, as shown in Figure 16.6. From here, you can choose user credentials to log in with, to save or open shared connection settings, and, if you like, pick another server to log into. The only part that might cause confusion (and with reason) is the box prompting you for your user password. Even if you supply this information, you'll still be prompted for your password when you connect to the terminal server.

The Display tab controls all session settings relating to display. The default settings shown in Figure 16.7 may not apply to the terminal session, since the maximum color depth on the terminal server will override the color depth you specify on this tab), but the full-screen mode will. The connection bar at the top of the terminal session window is useful for full-screen sessions, as it offers an easy way to minimize the session and reach the local Desktop. The resolution for the setting will depend on the local client settings—the settings for Remote Desktop size apply only to the window's size.

**FIGURE 16.6**

Use the General tab to supply user credentials and save connection settings to a file.

**FIGURE 16.7**

The Remote Desktop display settings are intended to mimic a user's local Desktop.

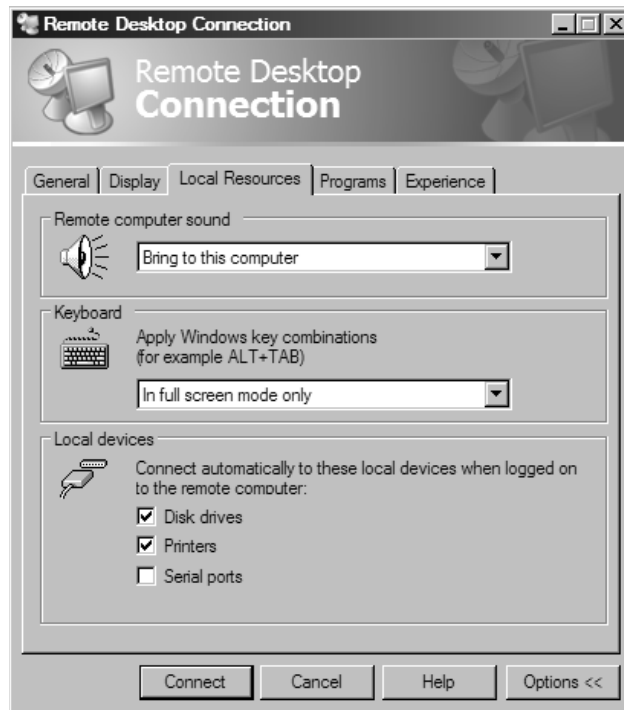

The Local Resources tab shown in Figure 16.8 is a little more in-depth containing some options that have not been previously available to people using RDP. Most of the settings are fairly self-explanatory, however. RDP's sound channel is enabled in Server 2003, so you can control where sound initiated in terminal sessions (perhaps from a training video) is played: on the user's computer, on the terminal server, or not played at all. In a terminal server environment, the two options that make sense are playing the sound on the client computer and not playing it; the option to play the sounds on the remote computer would really only apply to a Windows XP computer whose Desktop you were connecting to, and even then it seems like a bit of a stretch.

The key combinations settings specify whether standard Windows key combinations should apply to the remote session only in full-screen mode, all the time, or if they should always apply to the local session. This is something new, and I really like it. Previously, to use key combinations to navigate around the Desktop of a terminal session, you had to memorize a new set of key combinations—e.g., rather than pressing Ctrl+Esc to open the Start menu, you had to press Alt+Home. Now you have the option of using the standard key combinations in terminal sessions. I like the default option of sending the key combinations to the Desktop when it's in full-screen mode, as that way the key combinations always go to the most prominent work area. You can still use the nonstandard key combinations listed in Table 16.3 when a session is running in a window.

**FIGURE 16.8**

Edit local resource settings to determine how the local and remote sessions will work together.

**NOTE** One nonstandard keyboard combination still applies even if the session is in full-screen mode and you've chosen to send key combinations to the terminal session. To bring up the Task Manager in a terminal session, you must press Ctrl+Alt+End. Pressing Ctrl+Alt+Del still opens the Task Manager on the local computer.

**TABLE 16.3:** KEYBOARD SHORTCUTS IN TERMINAL SERVICES CLIENT SESSIONS

FUNCTION	LOCALLY USED COMBINATION	SESSION-SPECIFIC COMBINATION
Brings up application selector and moves selection to the right	Alt+Tab	Alt+PgUp
Brings up application selector and moves selection to the left	Alt+Shift+Tab	Alt+PgDn
Swaps between running applications	Alt+Esc	Alt+Insert
Opens the Start menu	Ctrl+Esc	Alt+Home
Right-clicks the active application's icon button in the upper left of the application window	Alt+spacebar	Alt+Del
Brings up the Windows NT Security window	Ctrl+Alt+Del	Ctrl+Alt+Esc

The Programs tab displayed in Figure 16.9 is pretty self-explanatory if you've used Terminal Services before. If you choose a program to run here, then that program will be the only one available—if the user closes it, then they'll end their session. The starting folder settings supply a working directory for the program if you don't want to use the default (often My Documents), but this is an optional setting.

**FIGURE 16.9**

Choose a single program for terminal sessions.

Finally, the Experience tab determines some features to enable based on Microsoft's guesses about what will work best on the selected connection speed (see Figure 16.10). Although you can

manually check or uncheck boxes to enable and disable features, for each network speed offered Remote Desktop will have some default settings.

***TIP** Although you can't control printer mapping from here, when creating a connection to work over a slow network, seriously consider disabling printer mapping.*

**FIGURE 16.10**

Enable or disable session features depending on the network speed the connection will be using.

**Troubleshooting Connection Problems**

When you set up a connection properly, it should work—but *should* is a nice word that doesn't always apply to reality. Table 16.4 lists a few error messages that users might encounter when trying to access a terminal server, either in Application Server mode or in Remote Administration mode.

**TABLE 16.4:** CONNECTION ERROR MESSAGES

**ERROR MESSAGE**

The local policy of this system does not allow you to log in interactively.

**PROBABLE MEANING**

The user attempting to log in does not have the “logon locally” permission available under Security Settings\Local Policies\User Rights Assignment\Log On Locally. Modify the appropriate GPO to grant the user or group this permission. This right is granted to ordinary users when you add the Application Server role, but normally only administrators are allowed to connect to a server via RDP when that server is not using that role.

*Continued on next page*

**TABLE 16.4:** CONNECTION ERROR MESSAGES (*continued*)

ERROR MESSAGE	PROBABLE MEANING
You do not have access to this session.	The user attempting to log in does not have sufficient permissions on the RDP-TCP connection. Modify the RDP-TCP permissions by using Terminal Services Configuration to grant the user or group the logon permission.
Your interactive logon privilege has been disabled. Please contact your system administrator.	The user attempting to log in does not have the Allow Logon to Terminal Server check box selected on the Terminal Services Profile tab of their account. Use Active Directory Users and Computers to modify this setting.
The terminal server has exceeded the maximum number of allowed connections. The system cannot log you on. Please try again or consult your system administrator.	The user is attempting to log in to a terminal server in Remote Administration mode, but the server has reached its connection limit. Terminal servers in Remote Administration mode allow a maximum of two concurrent administrative sessions, active or disconnected.
Terminal server sessions disabled. Remote logins are currently disabled.	The user is attempting to log in to a terminal server where an administrator has disabled additional logons by issuing the CHANGE LOGON /DISABLE command. To enable logon, issue the CHANGE LOGON /ENABLE command.
Because of a network error, the session will be disconnected. Please try to reconnect.	The user is attempting to log in to a terminal server where an administrator has specified a maximum connection limit, and the limit has been reached. To change this value, open the Terminal Services Configuration MMC snap-in, click Connections, double-click a connection—i.e., RDP-TCP—then select the Network Adapter tab. At the bottom of this tab are two options, Unlimited Connections and Maximum Connections.
The client could not connect to the terminal server. The server may be too busy. Please try connecting later.	<p>The user is attempting to log in to a terminal server where an administrator has disabled one or more connections. To check this, open the Terminal Services Configuration MMC snap-in, click Connections, right-click a connection—i.e., RDP-TCP—and select All Tasks. If Enable Connection is an option, the connection is currently disabled. There will also be a red X over the icon for the specified connection when disabled.</p> <p>This is also known as the World's Most Unhelpful Error Message because it may appear for any number of problems that don't have anything to do with the server being busy. For example, if your client can't find the subnet where your terminal server is, you'll see this error message. If the connection is enabled, start looking for network glitches.</p>

## Editing Client Account Settings

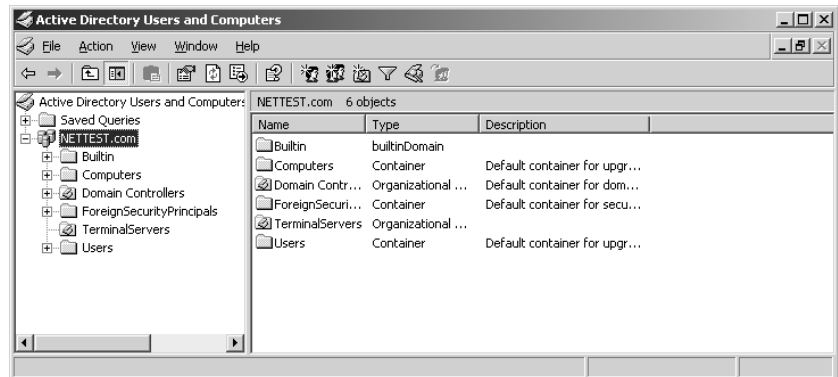

Everything's ready to go on the client side, but you may still have some work to do to get the server side configured. The following are optional—but useful—settings that allow you to define how long a session may last, whether someone can take remote control of a user's terminal session, how the RDP protocol is configured, and client path and profile information. The location of these settings

depends on whether you've set up the member accounts on the terminal server itself (as a member server) or are editing the main user database on a domain controller for the Active Directory—Windows 2000 or Server 2003. If the accounts are local to the server, the settings will be in the Local Users and Groups section of the Computer Management tool in the **Administrative Tools** folder. If the accounts are in the domain, the settings will be in the Active Directory Users and Computers tool in the **Administrative Tools** folder.

In this example, I'll use the Active Directory Users and Groups tool, shown in Figure 16.11. The settings for user accounts in the Local Users and Groups option are the same as the ones in the user accounts stored in the Active Directory, the only difference being that the Active Directory account properties have tabs related to user contact information.

**FIGURE 16.11**

Edit account properties from the **Users** folder in Active Directory Users and Computers.

Open the **Users** folder, find the user you want, then right-click it and choose the **Properties** item. This properties page controls all user settings, so I'll concentrate on the settings that apply to Terminal Services.

**NOTE** In previous versions of Windows, you had to edit all user (and server settings) on an individual basis, or apply settings to everyone using a protocol on a particular server. Not to mince words (or to mince them only a little) this was a pain in the tuchis for anyone with more than two servers or user accounts to edit. One excellent new feature of Server 2003 is its support for user and server management through group policies. To avoid rehashing the discussion of group policies that's in Chapter 9, I'll point out the relevant group policies where applicable and let that chapter show you how to apply them. I've noted each case where a GPO may be set for either user accounts or computer accounts. Although per-user accounts normally control if you configure settings from the user account properties, computer-based GPOs control if a policy may be set for both users and computers and is set for both.

## Remote Control

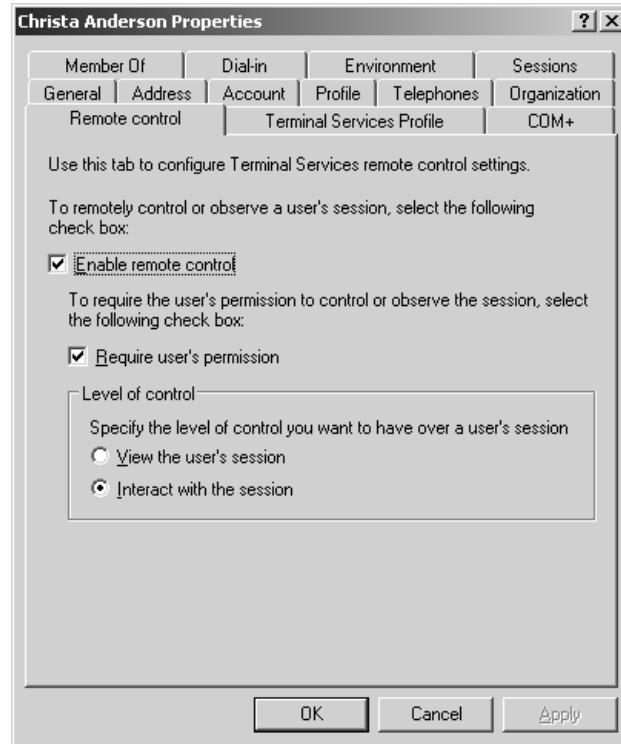

The ability to take remote control of a user's session comes in handy when troubleshooting time comes. Rather than trying to blindly talk someone through a series of commands ("Okay, find the **Programs** folder. Got it? Now look for the icon that says 'Microsoft Word'"), you can take over the session, manipulating it from your session while displaying it also for the user. The person whose session you're controlling will be able to see exactly how to complete the task and will have it done for them.

The settings for the kind of remote control that you can take are defined on the Remote Control tab of each user's properties pages, shown in Figure 16.12.

**FIGURE 16.12**

Setting remote control options for taking over user sessions

First, you must specify whether remote control is even permitted for the session (by default, you can take control of any session, no matter what rights the owner of the session has). Specify also whether the user whose session is being shadowed must permit the action before the remote control can begin. If you choose this option, the person who originated the session will see a message box telling them that such and such person of such and such domain is attempting to control their session, offering the chance to accept or refuse the control.

**NOTE** If permission is required, and a user refuses the remote control connection (or doesn't agree to it within the timeout period of about a minute), you can't control or view the session even from an account with Administrator privileges.

The final option on this tab determines what kind of control you can have over this user's session. For troubleshooting purposes, you'll find it most useful to be able to interact with the session, so you can actually show the user how to do something (or just do it for them). Choosing this option means that both the original user and the person with remote control over the session can send mouse clicks and keystrokes to the terminal server for interpretation. Graphical output is displayed on both the original session and the remote control view of the session.

If you're choosing the option to view the user's session, the person remotely controlling the session isn't really controlling it, but is only able to watch and see what the original user is doing. The person who set up remote control can't use the mouse or keyboard with the remotely controlled session. This could potentially be a troubleshooting tool if you're trying to find out exactly what someone's doing wrong and help them correct it, while making sure that you can't interfere. Most often, however, I find the option to take control of the session more useful than the ability to watch.

To control remote control settings via GPOs, turn to User Configuration\Administrative Templates\Windows Components\Terminal Services and enable Set Rules for Remote Control of Terminal Services User Sessions. When you do, you'll be able to choose options from the drop-down menu visible in Figure 16.13.

**FIGURE 16.13**

Remote control settings

Once you've permitted administrators to use remote control, the options here are divided into two main groups: full control, which lets the administrator interact with the user's session, and View Session, which lets the administrator only watch what the user is doing. Within those two main groups, you can specify whether the user must explicitly permit the administrator to take remote control of his session. All five options are listed in this drop-down list.

**NOTE** These settings are also available from the same path in the Computer Configuration section of the Group Policy Editor. If you set policies in both places, then the computer policies apply.

## Session Time-Outs

The status of a client session isn't a binary proposition. Rather than on/off, the state of a client session may be active, disconnected, or reset. An *active* session is what it sounds like: a session that's actively in use. In a *disconnected* session, the client has shut off the client interface to the session, but the session—and all its applications—is still running on the server. When a client *resets* or *terminates* a session with the Logoff command, the session ends and all applications in the session are shut down. Although the distinction may not sound significant at first, it's important. When clients disconnect from their sessions, all their data is still loaded into memory and their applications are running, exactly as they left them. This means that a client can disconnect while going to lunch, and thus secure the session without having to start over. The only catch to a disconnected session is that it still uses up processor cycles and some memory because the session thread still gets its crack at the processor and because all the user data is still active. However, as the data stops being accessed, the server will swap it out to the paging file on the hard disk and replace it in physical memory with more recent data; when the client reconnects to the session and tries to use the data, the data will be paged back in. The still-running client session also won't impact available network bandwidth much because the terminal server will detect that the session is idle and stop sending video updates to the client machine. You'll need to train users to make sure that they don't just close session windows and inadvertently disconnect when they mean to log off. If a user attempts to reconnect to the terminal server with more than one disconnected session running, a dialog box will display the disconnected sessions, their resolution, and the time that they've been disconnected. The user can then pick the session to reconnect. If the user doesn't pick a session in a minute or so, the highlighted session will be reestablished. The other session will remain on the terminal server, still in its inactive state.

You can control how long a session may stay active, how long it may stay disconnected without being terminated, how long active but idle sessions may stay active before they're disconnected—and even whether a particular user may connect to the server at all. These settings are controlled from the Sessions tab, shown in Figure 16.14.

You can control how long the setting may remain active before being disconnected or terminated. If you want to prevent people from forgetting to log out from their terminal session at the end of the day or at lunch, use this setting.

As I already discussed, a disconnected session is still using up terminal server resources—in the page file if nowhere else. This is by design, so that users can reconnect to a session and have all their applications and data still loaded, but if a session is permanently abandoned, there's no point in leaving it up. Choose a time-out period that reflects the amount of time you're willing to give a user to get back and use their connection before their applications are all closed.

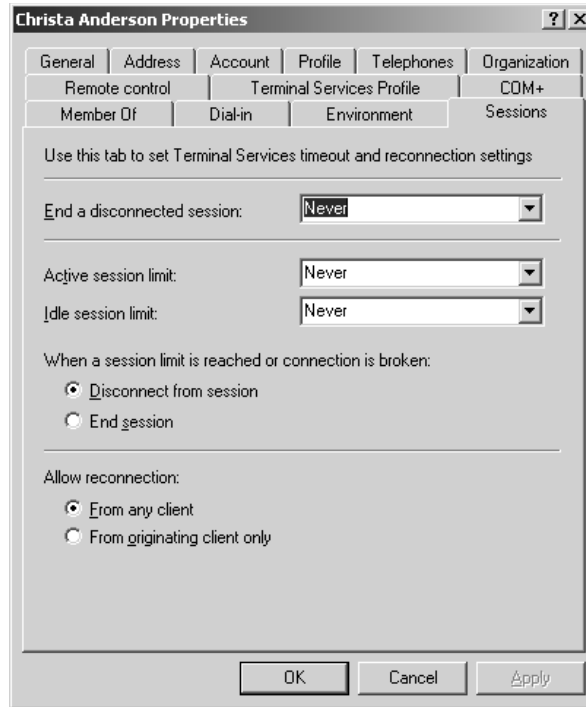

You can also determine how long a session can be idle before being disconnected or terminated. This isn't quite the same setting as the first one, which limits connection time whether or not the session is still getting input. Rather, this setting limits the amount of time that a session can be idle before being shut down. This setting is a little more useful in most cases, given that the session must be unused for a certain period before it is shut down.

The default for all three settings is Never, meaning there's no restriction on how long a session may be running, disconnected, or idle. The maximum time-out period is two days.

**TIP** *If you want to gather some statistics about how long people are staying logged in, or how long disconnected sessions are remaining idle on the server, you can get this information from the Terminal Services Manager. System Monitor can tell you how many active or inactive sessions are currently running on a given terminal server.*

**FIGURE 16.14**

Configuring session connection settings

The settings on the bottom of the tab determine how disconnected and reestablished connections should be handled. You may have noticed that two of the time-out options give you the choice of disconnecting or terminating the session at the end of the time-out session, but no option for specifying which it should be—disconnection or resetting the connection. The answer depends on whether you pick Disconnect from Session (the default) or End Session (which resets the connection) for broken or timed-out connections. The other option controls how users may reconnect to disconnected sessions. RDP sessions can reconnect to their client session from any client machine. Only ICA sessions can be forced to reestablish the connection from the same machine from which they started, and then only if you set up the ICA client to identify the computer it's running on. If a user has more than one disconnected session running on the same terminal server, when they reconnect they'll have a choice of which session they want to use. The session(s) not chosen will continue to run on the terminal server.

To configure these settings with GPOs, turn to User Configuration\Administrative Templates\Windows Components\Terminal Services\Sessions. You'll see the available policies in Figure 16.15.

The editing for each policy works the same way in all cases: enable a policy, and then pick the timeout period that you want, exactly as you would if configuring the setting on a per-user basis as described already in this section. The only policy in this area that might cause you difficulty is the one about only permitting people to reconnect from the same computer. Again, this setting is only available to those using properly configured ICA clients, but this isn't obvious unless you scroll down to the very bottom of the explanation.

**NOTE** These settings are also available from the same path in the Computer Configuration section of the Group Policy Editor. If you set policies in both places, then the computer policies apply.

**FIGURE 16.15**

accounts

## Setting Client Path Information

Unless you specify otherwise, user home directories are in subfolders of the terminal server's **Profiles** folder and are identified by username. Their temporary directories are subfolders of the terminal server's temporary directory and identified by Session ID. To keep all per-user information in a single place, you may want to specify a new home directory. This will give you a fighting chance of applying per-user system quotas and keeping all files in one place for easier recovery—not to mention keeping the home directories off the terminal server, which could ultimately take up a lot of room.

### PROFILE PATHS AND HOME DIRECTORIES

Roaming profiles are stored on a profile server instead of a local machine, so the user can log in with the same settings wherever she connects to the network. The other option is locally stored profiles, stored on the computer where they're displayed. When a profile is applied, it makes per-user changes to the Registry of the computer the person is logged in to that apply only to that user. So far, this is just like NT profiles have been for years.

Terminal Services still works more or less the same way. The profiles may still be stored either locally or on a profile server—but in this case *locally* means on the terminal server. As you probably know, you can't *not* use a profile—if you don't specify one, then you'll get the Default User profile.

You have a couple of options when it comes to profiles and Terminal Services. If you only provide a path for the user profile, then that path applies to both “normal” user settings and settings for terminal sessions that the user starts up. Filling in only the information the Profile tab in a user's profile will have this effect—the person will have the same profile path and home directory for terminal sessions as they do normally.

This may sound like a good plan, but in most cases it's not. First off, what works well for local use may not work well when logging onto a terminal session. For one example, the screensaver you might use on a Desktop without a second thought is a resource-draining vanity in a terminal session. For another, using the same profile for both ordinary sessions and terminal sessions leaves you exposed to lost profile changes. Consider how profiles work. When you open a profile and make changes to it, those changes are stored locally and don't get written back to the profile server until you log out. So what happens if you have two copies open, make a change in one and then log out, then make a change in the other copy and then log out? Right—you lose all the changes made to the first one because the copy you saved last to the profile server overwrote the copy you saved first. This can happen any time you open a profile more than once—it's not just a problem with Terminal Services—but you're not likely to log in two or more times when you're logging in to the domain from a fat client. Log in to both the fat client (since you needed to log in to the domain to get to a computer from which you could run the terminal session) and to the terminal server, and you immediately have two copies open. For these reasons, it's probably best to use different profiles for terminal sessions and fat client sessions.

How about roaming profiles for terminal sessions, if those profiles are different from the ordinary user profiles? This is still not a good idea because of the possibility that you'll have multiple copies of your profile open at once. Particularly if your terminal session is set up to only serve applications and you use more than one application, you're likely to open multiple copies of your profile at the same time.

So does this mean that local profiles are the way to go? Nope—not if you have many users to support and those users won't always log in to the same server. When you use local profiles, they're stored on the terminal server. If you have 60 users, each with his or her own profile, and you can't predict which of four servers those 60 users will connect to, then that means that you've got to store those 60 profiles on each server. That's a lot of room to munch up on the terminal server's system drive. It can also lead to inconsistency in the user environment if a user changes his profile on one server and not on another. It's especially important to not keep user profiles locally if you're using load balancing of any kind because doing so would mean that people would never know which profile they'd get.

For this reason, the best plan might be to use mandatory profiles, which are just ordinary profiles with a .man extension. Users can edit mandatory profiles to the degree their system policies allow them to, but those changes don't get saved to the server. Limiting to the user experience, perhaps, but if you use mandatory profiles with terminal sessions, then you avoid the problems of lost profile edits from multiple copies of the profile being opened. To specify a profile location, set the path location for the Terminal Services profile from each user's properties pages, as shown in Figure 16.16.

The Allow Logon to Terminal Server check box controls whether the person is permitted to log in to the terminal server at all. By default, anyone with an account on the domain or server may do so.

**FIGURE 16.16**

Specify the path to the user profile and home directory in the Terminal Services Profile tab.

The screenshot shows the 'Christa Anderson Properties' dialog box with the 'Terminal Services Profile' tab selected. The dialog has a title bar with a question mark and close button. Below the title bar are several tabs: General, Address, Account, Profile, Telephones, Organization, Member Of, Dial-in, Environment, Sessions, Remote control, Terminal Services Profile (selected), and COM+. A text box below the tabs reads: 'Use this tab to configure the Terminal Services user profile. Settings in this profile apply to Terminal Services.' The main content area is divided into two sections. The first section, 'Terminal Services User Profile', contains a 'Profile Path:' label followed by a text input field. The second section, 'Terminal Services Home Folder', contains two radio buttons: 'Local path' (selected) and 'Connect:'. The 'Local path' option is followed by a text input field. The 'Connect:' option is followed by a dropdown menu and a text input field labeled 'To:'. At the bottom of the dialog is a checked checkbox labeled 'Allow logon to terminal server'. The bottom of the dialog has three buttons: 'OK', 'Cancel', and 'Apply'.

User profile and home directory information are configured in computer group policies located in Computer Configuration\Administrative Templates\Windows Components\Terminal Services. The policies you're looking for are Set Path for TS Roaming Profiles and TS User Home Directory. Just include the computer name and path to the profile directory; the policy will fill in the username automatically. If the path you provide does not exist (or the server can't reach it) then it will use local profiles.

The same goes for setting up the home directory—type the UNC name for the network share, and assign a local drive letter if necessary (for applications that demand a drive letter), as I've done in Figure 16.17. I do not recommend putting the user home directory on the local terminal server unless you really have no other options, as doing so will give users separate home directories depending on which server they're connected to.

**FIGURE 16.17**

You can set home directory paths through group policies.

## PROGRAMMATIC UPDATES TO PROFILE INFORMATION

To change or set user profile information for one user account is no big deal: Open Active Directory Users and Computers, open the user account's properties sheet, turn to the Terminal Services Profile tab, and make the change. Multiply this procedure by 50, 500, or 5000 users, however, and it gets less easy. However, all is not lost: You can make these edits through ADSI (the profile path is now exposed as a property of the object representing the terminal server—this wasn't an option in previous versions of Terminal Services) or, if you're VBScript-challenged, with the `tsprof` command-line tool.

*Continued on next page*

**PROGRAMMATIC UPDATES TO PROFILE INFORMATION (*continued*)**

Tsprof supports three actions: You can update account profile information, you can copy it to another user account, or you can query a user account to make sure your changes took or see what the current profile settings are. The basic syntax for these commands looks like this:

```
TSPROF /UPDATE [/DOMAIN:domainname|/LOCAL] /PROFILE:<path> username
TSPROF /COPY [/DOMAIN:domainname|/LOCAL] [/PROFILE:<path>] sourceuser
destinationuser
TSPROF /Q [/DOMAIN:domainname|/LOCAL] username
```

Make sure you don't include extra spaces in the command, or you could accidentally query the domain name as though it were a username.

For example, say that my Terminal Services users don't have session-explicit user accounts; they're using the same accounts they typically use to log on to the domain. The profile settings that work well for a full-color session on a single-user computer might not translate well to a terminal session, so I want to edit that account information to C:\profiles. I can do so from the command line, like this:

```
tsprof /update /domain:redroom /profile:c:\profiles\profile.man christa
```

In this example, the user account is in the REDROOM domain, the profile path is C:\profiles, and the user account I'm editing is named Christa. This command will spit back the following information:

```
Terminal Services Profile Path for redroom\christa is { c:\profiles\profile.man }
```

If the curly brackets don't contain any information, you haven't set a Terminal Services profile for that user account. The /update argument doesn't tell you what the profile path information was *before* you changed it, so if you want to ensure that it needs to be updated, query the account. To perform the query, use the /q argument, like this:

```
tsprof /q /domain:labrynth christa
```

If you used tsprof with TSE, notice that the command now is /q, not /query. The command changed in Windows 2000 and retains that change in Server 2003.

Finally, you can copy profile-path information from one account to another. The /copy command works similar to /update, except you must provide the source and destination account names, in this case, Christa and Vera, respectively:

```
Tsprof /copy /domain:redroom christa vera
```

The system will now copy Christa's profile account information to Vera's user account; if I query Vera's account, the profile information will be there.

Be careful when you use these tools. Tsprof can't tell whether a profile path is valid any more than the graphical user account management tools can; tsprof will enter whatever information you give it. If the account name is invalid, tsprof will generate an error when it attempts to update the information—Failed Setting User Configuration, Error=1332 (0x534)—but won't show any problems when you perform a query.

### DEFINING THE SESSION ENVIRONMENT AND MAPPING CLIENT RESOURCES

The Environment tab in the properties pages (see Figure 16.18) sets the Terminal Services environment for the user, replacing any related settings (such as an application to run at logon) that might already appear in a user's client logon settings. If you want to automatically run an application at logon, type its path in the Program File Name box (sadly, there's no browse function). The working directory goes in the Start In box. Notice that supplying the name of an application does not limit the terminal server session to only running that application and then ending when the application is terminated. All this does is run the application when the session starts—the main Desktop still remains available. If you want to provide a terminal session running only a single application, and then closing when that application closes, you'll need to set that up when configuring the client connections, as described earlier in this chapter.

**FIGURE 16.18**

Tuning the user environment and mapping client resources

The settings in the Client Devices section at the bottom of this tab apply to clients using Remote Desktop Connection. The first one, Connect Client Drives at Logon, applies only to sessions where remapping client drives for use in terminal server sessions is enabled (and it may confuse users as to whether they're saving files to their local drives or to the terminal server, so this may be an option to give only to experienced users). Mapped drives will show up as "Other" drives in My Computer, retaining their original drive letters but without colons (that is, drive C: on your local computer will be drive C when mapped to a terminal session). The printing options, however, do apply to RDP

clients. Checking Connect Client Printers at Logon specifies that any printers mapped from the terminal server session should be reconnected. Default to Main Client Printer specifies that the client should use its own default printer, not the one defined for the terminal server.

To specify a program to run in the terminal session via group policies, go to Computer Configuration\Administrative Templates\Windows Components\Terminal Services and enable Start a Program on Connection. (You can also edit this setting in user GPOs, but if the policies conflict then the per-computer settings take control.) As when editing the setting for individual users, you'll need to know the path and working directory—you can't browse for it here.

All decisions about client resource mapping are set with policies in Computer Configuration\Administrative Templates\Windows Components\Terminal Services\Client/Server Data Redirection (see Figure 16.19).

**FIGURE 16.19**

Many policies control client resource mapping.

Most of these settings are easy to associate with their counterparts in the user account properties. One that you might not recognize (both because it's not on the Environment tab—it's a protocol configuration setting, not a user setting—and because it's new to Terminal Services in Server 2003) is Allow Time Zone Redirection. This policy pertains to how time zones work in terminal sessions. Prior to this, terminal sessions displayed the time zone of the terminal server, and if this time zone was different from that of the person connected to the terminal session it confused things like e-mail arrival times, that was just too darn bad. (Some third-party utilities fixed this problem, but Microsoft had no built-in fix for it.) Server 2003 allows time zone redirection, which is on by default. You must enable this setting to turn it off.

## Configuring Terminal Services for All Connections

You can configure general settings for all Terminal Services connections from the Terminal Services Configuration tool in the Administrative Tools folder. If you're running Terminal Services alone, you'll have only the RDP connection in this folder; if you have other multiuser Windows components added (like MetaFrame's ICA protocol or direct video support), they'll be in the folder as well.

What can you do here? The Server Settings folder contains settings that apply to all connections made to the server. The Connections folder shows all installed display protocols.

**NOTE** Server 2003 only supports one RDP connection per network adapter. If your terminal server has more than one NIC installed and you're using RDP with both of them, you can configure the RDP protocol for each adapter separately.

### THE SERVER SETTINGS FOLDER

The Server Settings folder (see Figure 16.20) contains options that control the creation and deletion of per-session temporary files and the types of access permitted to the terminal server. The options here are identical whether the server is set up to be an ordinary server with remote administration capabilities or an application server.

**FIGURE 16.20**

Server Settings folder for a terminal server in Application Server mode

### Licensing

On an application server, the licensing may be either Per Seat (the default) or Per Session. (On a server using RDP only for remote administration, the licensing information here will read Remote Administration.) Per Seat licensing is new in Server 2003.

### Temporary Folder Settings

Ordinarily, a terminal server stores temporary files for each session as a subfolder to each user's profile in `%userprofile%\Local Settings\Temp\sessionID` (the SessionID folders are necessary in case a user has more than one session open at a time). For applications that can't deal with per-user settings, you can force all temporary files to be written to the same folder on the server: `%userprofile%\Local Settings\Temp` on the server.

Deleting the temporary folders on exit means that when a user logs out of a terminal server session, the temporary folder they used—and all the TMP files in it—is deleted. This setting, set to Yes by default, keeps the terminal server from getting cluttered with TMP files, but ensures that those files are only deleted when they're no longer needed.

You can also apply these settings to temporary directories using GPOs, using the policies in Computer Configuration\Administrative Templates\Windows Components\Terminal Services\Temporary Folders. There are two policies here. Do Not Use Temp Folders Per Session and Do Not Delete Temp Folder Upon Exit, which you can enable or disable as appropriate. If you leave them unconfigured, then the default settings (to use temporary folders per session and delete those folders when the session ends) apply.

### Active Desktop Use

Another option lets you turn off the Active Desktop on the terminal server sessions. Unless you really need it for some reason, I'd turn it off and save the resources.

### **User Connection Restrictions**

This is something new to Windows Terminal Services—the ability to allow each person connecting to a particular server only one connection. If you have only one terminal server, then using this setting prevents the I-have-three-copies-of-my-profile-open problem. On multiple servers, this setting makes it easier for users to reconnect to disconnected sessions by giving them only one possible choice. The default setting limits users to one session per server.

To configure this setting using GPOs, you'll need the Restrict Terminal Services Users to a Single Remote Session setting, found in Computer Configuration\Administrative Templates\Windows Components\Terminal Services.

### **Security Settings**

Finally, you can choose the type of permissions you want to apply to this terminal server. Relaxed Security file access is compatible with all applications (but may leave some system folders vulnerable to changes from user applications) or Full Security file access may not work with all applications (because it denies permissions to some system folders) but does not allow applications to tamper with system folders. Always start out using Full Security, and only use Relaxed Security if a vital application simply won't run without it. Newer applications should work with Full Security.

### **THE CONNECTIONS FOLDER**

Use the Connections folder to configure protocol-wide settings. First, you can disable RDP so that no one can connect to the server, something you might want to do if you know you're going to be taking the server down for maintenance and don't want to have to bother with kicking new people off. Since you can't turn off the terminal server service, this is the easiest way to keep people off the server while still keeping it running. To do so, just right-click the protocol and choose Disable Connection from the All Tasks part of the pop-up menu. The command to re-enable the connection is in the same All Tasks section.

**NOTE** *This setting does not end existing sessions. To end all sessions—ungracefully and at once—you can reset a RDP listening session from Terminal Services Manager.*

For more detailed control of RDP, choose the Properties option from the pop-up menu. Most settings in the RDP-Tcp dialog box work the same way as their counterparts in the per-user connection settings, which normally take precedence. For a more uniform set of protocol configurations, you may edit the settings here and check the boxes that tell the protocol properties not to inherit their settings according to the user. The two settings that aren't configurable on a per-user basis control security are found on the General and Permissions tabs.

### **THE GENERAL TAB**

The General tab shown in Figure 16.21 controls the degree of encryption used with RDP. The encryption can protect both logins and the stream of text, but at a minimum protects the information passed during the login process.

By default, the client's level of encryption determines the level of encryption between client and server, which means that all communications between client and server are encrypted with the standard 40-bit algorithm (56-bit if the client is running Win2K Professional or XP Pro). High

encryption forces 128-bit encryption, which means that clients incapable of supporting this encryption level won't be able to connect to the terminal server.

**FIGURE 16.21**  
Configuring RDP  
access security

You don't have to worry about the Use Standard Windows Authentication check box unless you've installed a third-party authentication package on the server. In that case, checking this box tells the terminal server to use its native authentication scheme to validate terminal session user logons, rather than using the third-party package.

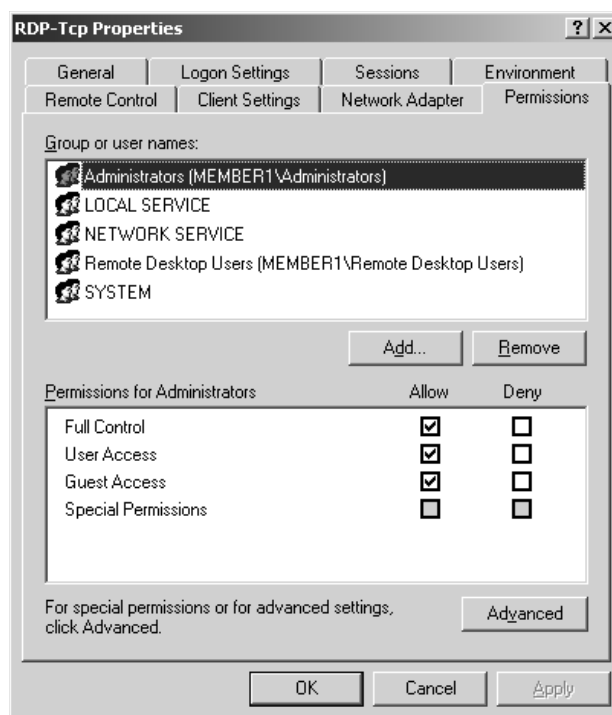

## PERMISSIONS

Those familiar with the NT security model will remember that you secure a network by defining user rights for what people can *do* on the network and setting permissions for the resources that people can *use*. Terminal Services security is controlled with permissions, on a per-group or per-user basis.

To set or edit the permissions assigned to terminal server sessions, turn to the Permissions tab. You'll see a dialog box like the one in Figure 16.22. From here, you can edit the basic permission sets of the groups for whom some kind of access to terminal server functions has been defined.

**TIP** If you turn to the Permissions tab and see a list of security IDs instead of user or group names, and the cursor changes to an hourglass when over the dialog box, don't panic. The terminal server is retrieving the names from the domain controller and will show the user and group names after a few seconds. If this doesn't happen—if the SIDs never resolve to user and group names—then there's something wrong with either the domain controller or the connection between the two servers.

**FIGURE 16.22**  
Default terminal  
server permissions

Not sure how to interpret the check boxes? If a permission is checked, then it's explicitly enabled or disabled, depending on which box is checked. If a permission is clear on both sides, then it's implicitly enabled. You can explicitly enable or disable the permission by checking the appropriate box.

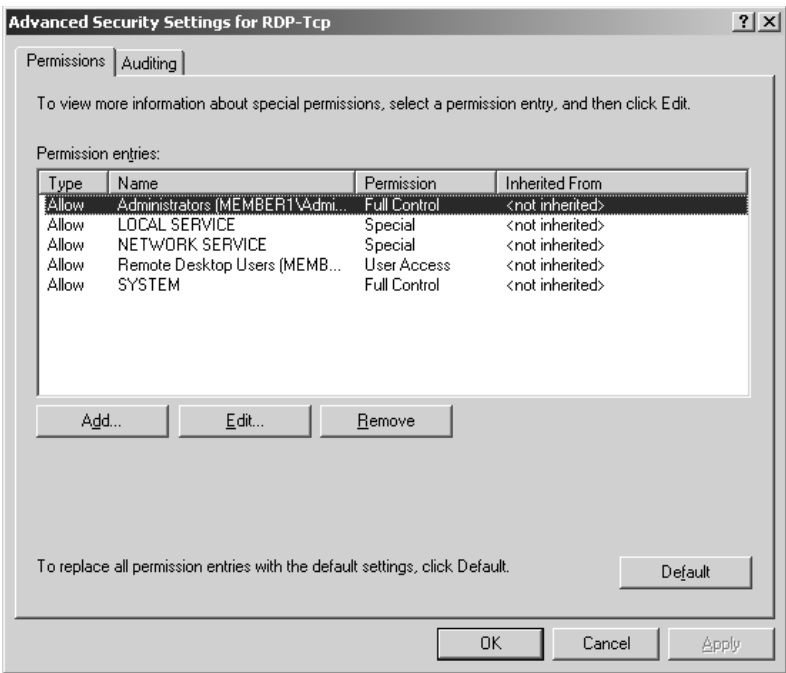

### ***Fine-Tuning Access to Terminal Server Functions***

The first page shows only the default groups and the basic permissions they've been assigned. For more control over the permission process, click the Advanced button to open the dialog box shown in Figure 16.23.

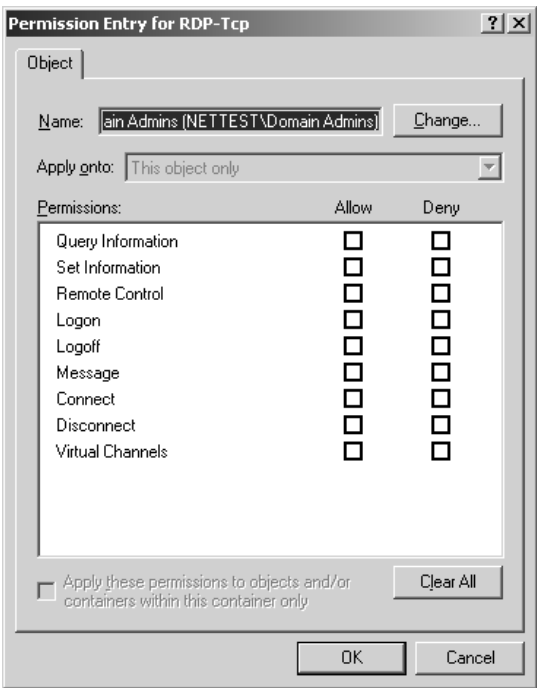

From here, you can see the state of the defined permissions. The Inherited From field indicates the level at which the permissions were set—here, or at a higher level.

You can adjust these permissions either by adding new users or groups to the list (getting them from the domain controller) or by editing the permissions of the groups already there. To define permissions for a new user or group, click the Add button. You'll open a dialog box where you can choose the name of the account to edit. Type the name of a user or group, then click the Check Names button to confirm that you got it right. When you've got the right user or group account name, click OK to open the dialog box in Figure 16.24.

**FIGURE 16.23**  
Setting advanced permissions

**FIGURE 16.24**  
Defining the permissions for a new user

By default, new users and groups (even domain administrators) have no permissions at all. You will need to specify the access you'd like to grant or deny to the groups and users you're adding to the list.

The permissions listed here have the characteristics outlined in Table 16.5. I'll talk more about how to *use* these functions in the later section "Managing Terminal Sessions."

**TABLE 16.5: TERMINAL SERVICES PERMISSIONS**

ACCESS TYPE	EFFECT	INCLUDED IN
Query Information	Allows users to gather information about people using the terminal server, processes running on the server, sessions, and so forth	Full Control, Service Permissions
Set Information	Allows users to set the level of control other users have over the session	Full Control
Reset	Allows users to reset other connections, ending them and logging the other user off the computer	Full Control
Remote Control	Allows users to take control of or view other user sessions	Full Control
Logon	Allows users to log on to the terminal server	Full Control, User Access, Guest
Logoff	Allows users to log off from the terminal server	Full Control, User Access, Guest
Message	Allows users to send messages to other terminal server clients	Full Control, Service Permissions, User Access
Connect	Allows users to connect to other terminal servers	Full Control, User Access
Disconnect	Allows users to disconnect from other terminal servers	Full Control
Virtual Channels	Enables virtual channels for that group	Full Control

**NOTE** Service Permissions are identified also as "Special". Same thing.

Changing permissions for an existing user or group works in much the same way as adding permissions for a newly defined group: Select a name, click the Edit button, and you'll see the same set of options to explicitly grant or deny permissions.

**TIP** If you want to cancel all permission changes for a user or group and start over, click the Cancel button. If you want to remove every granted or denied permission associated with a user or group, click Clear All, or just select them in the list on the Permissions tab of the RDP Properties sheet and click the Remove button—this will have the same effect.

## Terminal Services Licensing

Licensing single-user computers is complicated enough. Bring terminal servers into the equation, and the complications increase. Do you have to pay for only the operating system? Only the client sessions active at any given time? Only some client sessions? What about applications—an application is only loaded on one machine, so you should only have to pay for one license, right? And who's in charge of keeping track of all these licenses, anyway?

Licensing is never fun and it's not glamorous, but it's part of the cost of doing business. Read on to make some sense of the Terminal Services licensing model.

### The Terminal Services Licensing Model

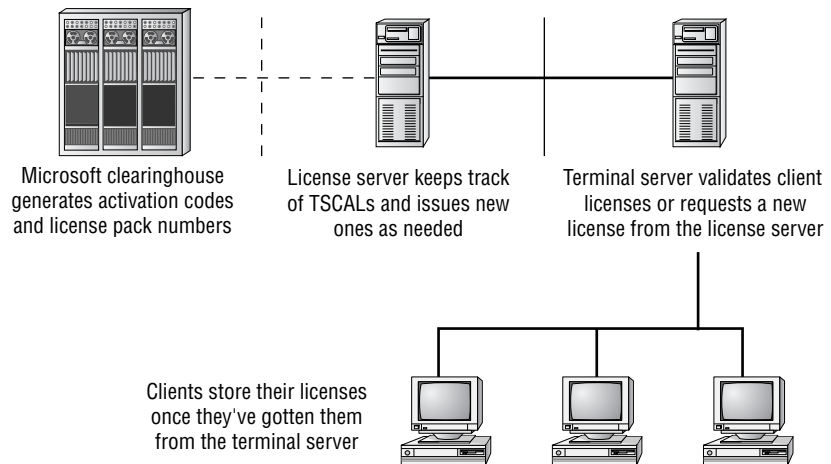

First, let's take a look at how the licensing model works in Win2K. In TSE, licensing was handled by a license manager service that came with TSE. You told the license manager how many Terminal Services licenses you had, and it kept track of how they were used. Windows 2000 added a license server, which might or might not be the terminal server—depended on the security model you were using. Beginning with Windows 2000, you also had to activate the licenses through Microsoft. You can't just tell the license server how many TS licenses you have, you must get official licenses from Microsoft and activate them.

As shown in Figure 16.25, several players cooperate to make Terminal Services licensing work in Server 2003:

- ◆ The terminal servers
- ◆ The license servers
- ◆ The Microsoft clearinghouse that enables the license servers and the access licenses

**FIGURE 16.25**

The Terminal Services licensing model

The first time a client connects to a terminal server, one of two things happens. When the user logs in, the terminal server will take the license the client proffers—I'll get to the question of just how a client would *have* such a license in a minute—or, if the client doesn't have a license, the terminal

server will find the license server by discovery (broadcasts in workgroups and NT 4 domains or by polling the domain controllers in Active Directory domains) and request a license from the license server. If the license server has a license to issue, it will give it to the terminal server, who will issue it to the client *computer* that's attempting to make the terminal connection. The client can then present its license to the terminal server. If the license server does not have an available license—even a temporary license—then the client cannot complete the connection and will be rejected. If the terminal server can't connect to the license server for some reason, then the terminal server will accept pre-existing licenses, but clients without valid temporary or permanent licenses will not be able to log in to the terminal server.

When a client disconnects from the terminal server, it retains its license—the license does not go back to a pool. Therefore, if I log in to the terminal server once from my office desk and once from my home office, I'll use up two separate licenses. You cannot give these licenses back to the license server; they're marked in the license server's database as given to a particular machine, identified by GUID.

## Understanding Session Licensing

When Microsoft first released Windows NT, Terminal Server Edition, it made a terrible marketing decision. Any client connecting to the terminal had to have a valid NT Workstation license. At \$400 a pop, NTW licenses weren't cheap, so a lot of people looked at TSE and said, "Nice, but not worth the money." This didn't do much to promote the use of Terminal Services by anyone not already using NTW. In an effort to win those people back, in February 1999 Microsoft revamped their licensing structure, giving NT Workstation clients a built-in license to access the terminal server but requiring you to purchase terminal server licenses (which cost approximately \$150 per seat instead of \$400) for computers running any other operating system. However, by default access to the server running Terminal Services is licensed on a per-seat basis, not per user—computers are licensed, not people.

The licensing structure includes four license types:

- ◆ Terminal Server Client Access Licenses (TSCALs)
- ◆ Built-in licenses
- ◆ Temporary licenses

**NOTE** *Not all Terminal Services functions use licenses. When you're running Terminal Services capabilities in Remote Administration mode you don't need TSCALs because Remote Administration mode comes with two administrator's licenses. You cannot use this licensing mode on a server configured with the Application Server role.*

### TERMINAL SERVER CLIENT ACCESS LICENSES

*Terminal Server Client Access Licenses* (TSCALs) are for named user accounts in the domain and issued on a per-seat basis. Anyone in a company who's using the terminal server must have a TSCAL, regardless of whether they're connecting to the terminal server via Microsoft's RDP display protocol or Citrix's ICA display protocol (which they will if you install MetaFrame). To access a terminal server at all, of course, a client also needs a Client Access License (CAL).

### **License Packaging**

The way you buy TSCALs determines how you pay for them and how much flexibility you have in the purchase. Most people who buy small volumes of Microsoft products will buy their TSCALs as part of a 5-CAL or 20-CAL Microsoft License Pak (MLP). Physically, an MLP is a thin cardboard envelope that contains the EULA denoting the number of CALs purchased. The MLP for TSCALs also includes a license code, a 25-character alphanumeric code that indicates what the license is for and how many TSCALs it purchases (so that you can't fudge the entries and say that you bought 20 TSCALs when you really only bought 5). You can only install an MLP once. Small to medium customers will get their licenses through a program called Microsoft Open License, which allows you to purchase a user-specified quantity of licenses, after which Microsoft issues you an Open License Authorization and license numbers for the licenses, which you can install as many times as you need to. Select and Enterprise Agreements for large customers work like open licenses, except that the customer provides their Enrollment Agreement number instead of the Open License numbers.

### **Reclaiming TSCALs**

Once allocated to a computer, a TSCAL belongs to that computer and is identified as such in the license server's database. You cannot manually reclaim TSCALs from a computer, so the visiting consultant who logs in to the terminal server once leaves with a TSCAL. Not only that, but if you wipe a computer's hard disk and reinstall, then there's no record of that TSCAL on the computer and it will have to request a second one. Unused TSCALs will eventually revert to the license pool on their own, but the process takes a while.

Rather than permanently assigning TSCALs to clients, the license server will give first-time requesters a TSCAL with a time-out period (a randomly assigned interval between 52 and 89 days). When the user logs onto the terminal server, the terminal server tells the license server that the license has been validated (used by someone with permission to log onto the terminal server). The TSCAL is then assigned to that machine. Every time someone connects to the terminal server from that machine, the terminal server will check the expiration date on the TSCAL. When the expiration date is less than 7 days, the terminal server renews the TSCAL assignment to that machine for another 52 to 89 days. Should the client machine not log into the terminal server before its TSCAL expires, its TSCAL will return to the pool of available licenses.

### **UNLIMITED AND TEMPORARY LICENSES**

Win2K and XP Professional computers can draw from the license server's pool of unlimited licenses, which effectively gives them a built-in license. Finally, the license server issues temporary licenses when a terminal server requests a license and the license server has none to give (perhaps because you haven't installed a license pack yet). The license server then tracks the issuance and expiration of the temporary licenses.

**NOTE** *Although the Unlimited license pool existed in RC1 of Server 2003, it will not exist in the final release of Server 2003. Windows XP OSes bought before April 2003 are grandfathered in, but all other OSes—and copies of Windows XP purchased after April—will need a TSCAL.*

Byzantine enough for you? Table 16.6 is a cheat sheet.

TABLE 16.6: TERMINAL SERVICES CLIENT ACCESS LICENSE TYPES

SITUATION	TERMINAL SERVICES LICENSE TYPE REQUIRED
Users connecting from Win2K Professional and XP Pro Desktops	Unlimited pool
Users connecting from any desktop not using Win2K or XP Professional	Terminal Server Client Access License (TSCAL)
Anonymous users connecting to the terminal server via the Internet	Terminal Services Internet Connector License (TSICL)

Server 2003 may offer Per Session licensing. Per session licensing allocates licenses to sessions, not to machines, so that the licenses are reclaimed when the session ends.

The Terminal Server Licensing Tool

The Terminal Server Licensing tool, found in the Administrative Tools program group of any Server with the Terminal Server Licensing service running on it, helps you keep track of license usage.

*TIP To add Terminal Services Licensing, open the Add/Remove Programs applet in the Control Panel and click the Add Windows Components icon. Follow the Windows Components Wizard and just pick the component from the list of available options. In a purely Active Directory domain, this license server must be on a domain controller. In a Mixed domain, the license server may be on a member server.*

When you first start the licensing tool, it will browse for license servers on the network and then report back with the ones it found, as shown in Figure 16.26.

FIGURE 16.26 Use the Terminal Server Licensing tool to manage license usage.

Creating a license server is a two-step process: you need to install the service, and you need to activate the license server. Although the temporary licenses will function for a limited time (120 days), to fully enable the terminal server licenses, you'll need to activate the server and download the license key.

Activation is essentially a way of making sure you've really paid for the licenses you're using. (According to Citrix, it also helps technical support keep track of you for better customer support, but I have a sneaking suspicion that the "let's make sure people are paying for what they use" issue is a little more important—not that it wouldn't be important to me, of course.) When you activate a license, you're providing your product number to Microsoft. Microsoft then runs an encryption algorithm on it and sends you back the results as your activation code. You then give Microsoft back

the activation code, they run another encrypting algorithm on it, and they send you a license code that corresponds to that activation code. This is an extra step, and that's annoying, but the procedure itself really isn't too arduous.

When you first open the Terminal Services Licensing tool, it looks like Figure 16.26. As you can see, the licensing server is present but not yet activated, as indicated by the red dot. To make the license server ready to monitor license usage and to issue TSCALs, you'll need to activate the server and install the license pack assigned to that server. To do so, connect the server to the Internet (easiest, as otherwise you'll need to recite license numbers and activation codes over the telephone) and follow these steps:

1. Right-click the server and choose **Activate Server** from the context menu. Click through the opening screen.
2. Choose a method of contacting Microsoft to get a license. You have three options for contacting Microsoft to give them your product number. Automatic Connection, the default option, gives you a direct connection to Microsoft but requires that the license server have an Internet connection. Other options include the Web (whether from the license server or another computer with an Internet connection) or telephone. For this example, choose the Automatic Connection (see Figure 16.27) and click **Next** to display the screen shown in Figure 16.28.

**FIGURE 16.27**

Choose a way of contacting the Microsoft clearinghouse to get an activation code and valid license packs.

**NOTE** If you choose to contact the licensing people via telephone, the next screen of the wizard will display a list of countries to choose from so that you've got a shot at making a toll-free call.

3. Next, fill out the form identifying yourself.

**FIGURE 16.28**

Fill in your name and company.

The screenshot shows a Windows-style dialog box titled "Terminal Server License Server Activation Wizard". The main heading is "Company Information" with the instruction "Provide the requested company information." Below this, it says "Enter your name, company name and country information below. This information is required to proceed." There are four input fields: "First name:" with the text "Christa", "Last name:" with "Anderson", "Company:" with "Acme Corporation", and "Country or Region:" with a dropdown menu showing "United States of America". At the bottom, there is a paragraph of text: "Name and company information is used only by Microsoft support professionals to help you if you need assistance. Country is required to comply with United States export restrictions. For more information, please see Microsoft's [privacy statement](#)." At the bottom right, there are three buttons: "< Back", "Next >", and "Cancel".

4. Next, the wizard will prompt you for some further contact information (see Figure 16.29).
5. The wizard will contact the Microsoft licensing clearinghouse and activate the server, then show you the confirmation screen in Figure 16.30.
6. You'll need client licenses, so you might as well continue. Click Next to move to the next screen of the licensing tool (see Figure 16.31), where you'll need to fill in the codes of all the license packs you have (the MLP number, or your Open License or Enrollment Agreement number, depending on what kind of customer you are). Again, confirm the information that you've entered and click Next to submit it.
7. In the next page of the wizard, you'll need to provide the license pack numbers. You can add more than one at a time—just click the Add button to add them to the list.

server activation

**Terminal Server License Server Activation Wizard**

**Completing the Terminal Server License Server Activation Wizard**

You have completed the Terminal Server License Server Activation Wizard.

Status:

Your license server has been successfully activated.

To install client licenses now, click Next.

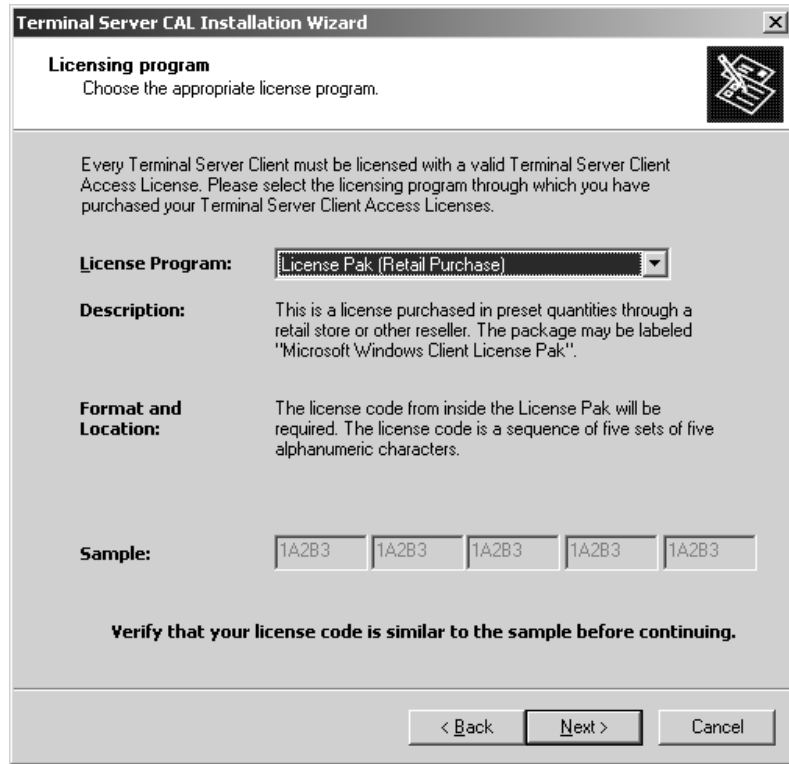

To postpone client license installation, clear the check box below, and then click Finish.

☒ Start Terminal Server Client Licensing Wizard now

< Back   Next >   Cancel

**FIGURE 16.31**

Installing a  
license pack

Once you install the license pack, the license server is ready to go.

**TIP** *If the license server won't accept a license pack and you're sure you typed it correctly, the database might be damaged. If it is, you can rebuild by uninstalling the licensing service, reinstalling it, and then reactivating the server.*

All that said, here's a warning: You have 120 days to activate a TSCAL license server. Use those 120 days to make sure you're running the licensing service on the computer that you want to take the job. The client licenses you create will only work on the server you've activated, and the activation code is based on the product ID.

## Application Licensing

Application licensing in a terminal server environment is simpler than you might think: Whatever licensing is applied to a product in a single-user environment applies to the terminal server environment. For example, Microsoft Office 2000 is licensed on a per-seat basis. If you install Microsoft Office onto the terminal server, then every computer that will ever run a Microsoft Office application will need to have an Office license, even if the application only runs once a year, because the application is *apparently* running on the client workstation. However, because Office is licensed on a per-seat basis, if you already have a licensed copy of Office installed on a PC client running terminal services,

that client may use Office in the terminal session (perhaps when dialing into the terminal server from home) without purchasing an additional Office license because that computer is already licensed to run the application suite. Be sure to get familiar with the licensing a given application requires so you can see how it will work in the multiuser environment.

## Configuring Applications for a Multiuser Environment

Not all applications work well in a thin client environment. Some use up too many processor cycles or too much memory; some can't tell the difference between a user and a computer; some store information in locations inappropriate to a multiuser operating system. Sometimes you're stuck with these problems, and if you really need to run those applications, you'll need to do it from the client Desktop. However, some problems are fixable, if you take a little time.

### Choosing Applications

First, which applications should you be trying to run at all? An application suitable for a terminal server environment fits the following profile:

- ◆ Undemanding of processor cycles and memory
- ◆ Modular in video output for better caching
- ◆ Stores user data in per-user spaces, not in per-machine spaces
- ◆ Identifies users by username, not computer name
- ◆ Stores global data in global locations, not local ones

**WARNING** *Poorly designed applications that can function in a single-user environment will bring a terminal server to a screeching halt. For example, the effect of memory leaks in an application is exponentially increased because multiple instances of the application—all leaking—may be running.*

In addition to these traits, consider the operating system for which the application was originally designed. Although some Win16 and DOS applications can work in a multiuser environment, Terminal Services works best for Win32 applications. The reason for this has to do with how the terminal server runs Win32 and Win16 applications. As a Win32 operating system, Windows 2000 can't run Win16 applications on its own. Instead, it creates a Virtual DOS Machine (VDM), which is a 32-bit application, and runs the Win16 application within the context of that VDM. Whereas Win32 applications running normally on the server can share files and structures among themselves, so long as they're not changing those files or structures, applications running within VDMs can't "see" each other to share files. The practical upshot of this, combined with the fact that translating 16-bit calls to the operating system into 32-bit calls takes some overhead, means that Win16 applications perform less well in this environment than Win32 applications. They'll work—a good thing because you may not have a choice about running them if that's what you're using—but they'll use more memory than Win32 apps.

DOS applications present another kind of problem. Actually, they present two other kinds of problems. First, DOS applications were written for a single-user, single-tasking environment. To be as responsive as possible, some DOS applications constantly poll the keyboard buffer, looking for

input that's meant for them. This means that a DOS application in the foreground, even when not doing anything, is using up an astounding amount of processor time. This is acceptable in a single-user environment, but won't work when that processor time has to be shared with a dozen people.

### TAMING DOS APPLICATIONS

Windows NT, Terminal Server Edition (TSE), included a utility called DOSKBD that modifies a program's keyboard polling to improve system performance when you run DOS-based programs. Essentially, DOSKBD puts a program to sleep when it polls the keyboard buffer too often and negatively affects server performance. Server 2003 doesn't include a copy of DOSKBD, and the TSE version doesn't work with later versions of Terminal Services. However, there's another option. Go to <http://www.tamedos.com> and check out Tame, a tool for tuning DOS applications in an NT environment. That's the advice you'll get from Microsoft Support if you ask about tuning DOS applications.

Also, DOS applications with a graphical UI don't use Windows graphics rendering instructions, but bitmaps. Bitmaps take much longer to download to the client than GDI rendering instructions, so session responsiveness will suffer. Bitmap-displaying applications are jerky at best in a terminal server environment and more often are completely unusable, particularly on slower connections. Another problem with DOS applications in a multiuser environment is that you can't run them in full-screen mode. Because full-screen mode requires loading a different font set from the Windows one used for DOS applications running in a window (and thus increased memory overhead), Microsoft decided not to permit this.

You *can* run DOS and Win16 applications in a terminal server environment. They just won't cooperate with other applications as well as Win32 applications will. DOS applications in particular probably won't look as good as they would running locally.

However, you can often tweak an application to make it work better in a multiuser environment than it would if left to its own fell devices. Installing applications in a multiuser environment takes a little more care than does installing them for a single-user environment, but that's part of the price of thin client networking.

### Making Your Applications Play Well with Others

Even if an application doesn't need any massaging to make it work right when shared among multiple people, you can't install it in the same way you would if installing it for a single person's use.

To work properly in a multiuser environment, applications should edit the HKCU branch of the Registry to add user-specific information, rather than HKLM. Otherwise, those settings apply to the machine, not to the user. This means that not only are per-user settings available to everyone using that particular machine, but the settings will only be available at that machine—if the user logs in to another machine, the settings won't be available. If you've only got one terminal server in your network, it won't matter for this reason if application settings are machine specific, but a single terminal server will generally only serve a couple of dozen people, tops, and maybe fewer than that if client demands are high. Even if you do only have one terminal server, you've still got the problem of trying to keep user-specific information limited to the people who set it up. For example, say that Web browser bookmarks are stored in a machine-specific area. In a terminal server environment, that means everyone will have the same bookmarks—and will overwrite each other's settings at will.

Point being: User-specific settings should go into HKCU, not HKLM. However, you can't *install* applications into HKCU. HKCU applies only to the current user, not all users, and the identity of the current user will change depending on who's logged in—the contents of HKCU are different for each terminal server session. To get around this dilemma you need some user-specific settings, but you need to keep them someplace all users can get to, at least at first. The terminal server manages this by providing a global installation mode that exploits the machine-wide settings of HKLM.

### INSTALLING APPLICATIONS FOR MULTIPLE USERS

Each Terminal Services session has two operating modes: Execute and Install. The names are descriptive of what the modes are for: Execute mode is for running applications or installing for single users, and Install mode is for installing applications to be available to multiple users. The mechanics of installing an application depend on which mode you're in when running the application's Setup program.

If you install an application while in Execute mode, it installs and edits the Registry as it would if you installed it for use on a single-user computer. When a session is in Install mode, all Registry entries created during that session are shadowed under HKLM\Software\Microsoft\Windows NT\CurrentVersion\Terminal Server\Install. Any edits that an application makes to HKCU or HKLM are copied to HKLM\Software\Microsoft\Windows NT\CurrentVersion\Terminal Server\Install\Machine. You don't have to know all this to install applications. What you *do* have to know is that when the session is in Execute mode, if an application attempts to read an HKCU Registry entry that doesn't exist, Terminal Services will look in HKLM\Software\Microsoft\Windows NT\CurrentVersion\Terminal Server\Install for the missing key. If the key is there, Terminal Services will copy it and its subkeys to the appropriate location under HKCU and copy any INI files or user-specific DLLs to the user's home directory. For users without home directories, the files go to their profile folder. In short, the server makes the basic settings for each application machine specific, then copies these base settings into the user Registry entries so that the user can customize the application. Notice that this doesn't mean the application keeps returning to its pristine state every time the user runs it—the keys are only copied from their Install mode location to their user location if the keys don't already exist under HKCU.

**NOTE** Unfortunately, there's no way to spoof a user's identity to install an application for an individual while logged in with another account (if you logged in as Administrator and wanted to install an application for a particular user, for example). Nor can you specify a subset of users who should have access to a particular application. If you only want some people to use an application stored on a terminal server, the easiest way to manage that is to limit the people allowed to use that server.

So how do you put the server into Install mode? On a terminal server, it's easy: If you attempt to install an application from its Setup program (named `Setup.exe`) without using the Add/Remove Programs applet, the installation will fail, and the server will nag you to run the Add/Remove Programs applet to install applications on a terminal server. You cannot install an application for a single user if you've set up the server to be an application server.

**NOTE** Some applications allow you to bypass Add/Remove Programs because the Setup program isn't named `Setup.exe`. For these applications, you'll need to make sure that you put the server into Install Mode manually, either by running Add/Remove Programs or by using the `change user` command (discussed below).

When the application's Setup program finishes running, you'll go back to the wizard, which will prompt you to click the Next button. Finally, you'll see a dire-looking dialog box (see Figure 16.32) telling you to click the Finish or Cancel buttons when the installation process is complete, but warning you in capital letters not to do so *until* the installation is complete. Clicking Finish or Cancel returns the session to Execute mode.

**FIGURE 16.32**

Don't click the Finish button until the application is completely installed, or all the settings won't get copied.

Install mode's usefulness isn't limited to the installation process. Using application compatibility scripts or hand tuning, you can use Install mode to configure an application with general settings to apply to all users. Outside of Add/Remove Programs, you can put a session into Install mode with the `change user` command-line utility. `change user` has three options:

- ◆ `/execute`, the default, in which applications install in single-user mode
- ◆ `/install`, used to put the session into Install mode so that applications will be available to all users
- ◆ `/query`, which reports the mode that the session is in, like this:  
Application EXECUTE mode is enabled.

So, before running a setup program, open a command prompt and type **`change user /install`**. This will cause the server to shadow new Registry entries, as I described earlier, so that they'll be copied to each user's personal Registry settings as the user runs the application for the first time. Just bear in mind that *any* changes you make to an application while in Install mode will be copied to that Registry key and therefore apply to all users using the application for the first time.

#### USING APPLICATION COMPATIBILITY SCRIPTS

Given that just about all of the applications the terminal server users will be running were originally designed for a single-user environment, many applications require a little manipulation to get them

optimized for a multiuser system. Server 2003 includes application compatibility scripts for some applications. You can find the scripts for the applications in `%systemroot%\Application Compatibility Scripts\Install`. Server 2003 comes with three of them: one for Eudora 4, one for Outlook 98, and one for Visual Studio 6.

These scripts are designed to customize the application's setup to be appropriate for terminal server users, first setting up the command environment, then making sure that the session is in Install mode, checking the Registry for evidence of the application to be configured, and finally editing the Registry as needed. The contents of the scripts vary based on the application, but generally speaking, they do things like turn off processor-intensive features, add multiuser support to the application, or set user-specific application directories for applications that need them.

To use the scripts, just run them right after you install the application they customize, before anyone has had a chance to use the application. For example, when you run the script for Outlook 98, Notepad will open and display the `RootDrv2.cmd` file, prompting you to pick a drive letter for the customized installation to use. Provide a drive letter, save the file, and close Notepad, and the script will run. Log out and log back in, and the new settings will be applied.

**TIP** To make sure that no one tries to use the application before you've run the compatibility script, disable the RDP connection while finalizing the application setup.

You're not limited to using the default settings included in these scripts. To edit one of them, right-click the script's icon and choose Edit from the context menu to open the file in Notepad. You'll need to be familiar with the NT command-line tools to do this.

What if your application doesn't have a script made for it? The `Templates` folder in the `Install` directory includes KEY files (you can open these in Notepad as well) that show you where each Registry entry for application settings is located and what the values should be. Based on this information and using an existing CMD file for a template, you can use the Windows scripting language to create a new script. Alternatively, you can manually edit the user settings from the application interface while the session is in Install mode, as described in the later section "Hand-Tuning Applications."

## INSTALLING MULTIUSER-ENABLED APPLICATIONS

As Terminal Services becomes more widespread, it's probable that more applications will come with multiuser installation packages. Microsoft Office 2000 is one that presently does. If you try to run the normal installation program on a terminal server, you'll see a nag screen telling you that you can't do that and prompting you to use the installation files provided with the Office 2000 Resource Kit:

1. First, get the terminal server transform file, `TermSrvr.mst`, and place it in an accessible location for the installation. You can obtain the transform file from the `\ORK\PFFiles\ORKTools\Toolbox\Tools\TermSrvr` folder of the Office 2000 Resource Kit CD, or in `\Program Files\ORKtools\Toolbox\Terminal Server Tools` if you installed the Resource Kit.
2. Install Office Disc 1 on the Terminal Server computer.
3. In the Control Panel, double-click Add/Remove Programs, click Add New Programs, and then click CD or Floppy. Click Next, then click Browse, and then move to the root folder of the installation CD and select `Setup.exe`. Click Open to add `Setup.exe` to the Run Installation Program box.

4. Don't run it yet. On the command line, append the following command after `Setup.exe`, separated by a space: `TRANSFORMS=path\TermSrvr.mst`, where *path* is the location where you copied `TermSrvr.mst`.
5. From here, all goes as expected. In successive windows of the installation wizard, provide your customer information and accept the EULA, then choose Install Now. When you see a message telling you that the installation completed successfully, click OK, click Next, and then click Finish.

### HAND-TUNING APPLICATIONS

If you don't need to edit many per-application settings, it might be simpler to make the changes from the user interface while in Install mode, rather than trying to create a new compatibility script. You can also manually edit applications that *have* compatibility scripts but don't include some settings that you need to configure.

#### Turn Off Processor- and Bandwidth-Stressing Features

Terminal servers are designed to squeeze every last bit of juice out of system resources so that nothing is wasted. Therefore, they're often stressed—they're *supposed* to be stressed. Given that, don't waste processor cycles on producing effects that don't necessarily add any real content to the end product, and don't waste network bandwidth on sending those useless effects to the client.

#### Provide Path Information

Many applications have settings for file locations—places to save files to, places to open files from, template locations, and so forth. However, those locations will often be different for different users. To make sure that file locations for each user are correct, enter a drive letter—and then map that drive letter to different locations for each user. For example, the Save As location for all Word users could be H:, but H: would direct each user to their private home directory.

### USING THE REGISTRY TO TUNE APPLICATIONS

Of course, if an application doesn't have a setting in its interface, you can't use Install mode to tune that setting. However, all is not necessarily lost. You can edit some application settings directly within the Registry, in `HKLM\Software\Microsoft\Windows NT\CurrentVersion\Terminal Server\Compatibility\Applications`. (Obligatory warning follows.)

**WARNING** *Be careful when editing the Registry. The Registry Editor has no Undo feature, and will not tell you if you give a meaningless value to an entry. Back up the Registry before you edit it, and remember that a mistyped entry in the wrong place can wipe out needed information or render the server unbootable.*

More specifically, keep the following in mind:

- ◆ When editing value data, notice whether the values are shown in hex, decimal, or binary. When you're editing string values, you can choose to display them in any of those formats. Just be sure that you're entering the data in the chosen format. 15 decimal is F hex, but 15 hex is 21 decimal. You can guess how mixing up hex and decimal could get very ugly very quickly.

- ◆ If you're replacing a key (and, if you try out these hacks, you will be), be sure that the key that's selected is the one you want to replace. Restoring a key deletes all the present information in the key and replaces it with what's in the restored key. For example, say that you want to replace the contents of the **MSOFFICE** key that's a subkey of **Applications**. If you have **Applications** selected when you restore the saved REG file, you will wipe out every subkey of **Applications** and replace it with the information that should have gone into **MSOFFICE**.
- ◆ Never run a REG file unless you know exactly what it contains and what it will do. Executing a REG file imports the contents of that file into the Registry—permanently. There is no Undo feature.

Now that you're thoroughly intimidated, read on to see how to make your applications play well with others and call you by your name.

### ***Bad! Bad Application! Go to Sleep! Reducing Demands of Windows Applications***

Even if you turn off processor-hogging effects, some applications are just more cycle-hungry than others. In a terminal server environment, this is a Bad Thing. Not only do processor-sucking applications themselves under perform in a multiuser environment because they're contending with other applications, but they hurt other applications' performance by denying them cycles. You can edit the Registry to make the server keep a closer eye on Windows application management, denying processor cycles to applications that use too many, known internally as Bad Applications. Doing so will give more cycles to the other applications that the processor-sucker was starving, but will also make the errant application less responsive itself.

To make the edit, open the Registry Editor and turn to the key **HKLM\Software\Microsoft\Windows NT\CurrentVersion\Terminal Server\Compatibility\Applications**. As you can see in Figure 16.33, within the **Applications** key, you'll see a long list of keys for available applications.

**FIGURE 16.33**

The contents of the **Applications** subkey

First, check to see whether the application you want to configure is already listed; if it is, then a key with the name of the application will be present. If the key exists, then open it and look at the values within it, which are described in Table 16.7.

TABLE 16.7: BAD APPLICATION REGISTRY VALUES		
VALUE NAME	DESCRIPTION	DEFAULT VALUE
FirstCountMsgQPeeks-SleepBadApp	Number of times that the application will query the message queue before the server decides the application is a Bad Application. The lower this value, the sooner the server will decide that the application is bad, and the more quickly the other two values will apply.	0xf (15 decimal)
MsgQBadAppSleepTime-InMillisec	The number of milliseconds that a suspended application will be denied processor cycles. The higher this value is, the longer the application will sleep.	0
NthCountMsgQPeeks-SleepBadApp	The number of times that a Bad Application can query the message queue before the server will put it to sleep again. The lower this number, the more often the misbehaving application will go to sleep.	0x5 (5 decimal)
Flags	Describes the type of application to which these settings apply. Your options are 0x4 for Win16 applications, 0x8 for Win32 applications, or 0xc for both types.	0x8 (Win32 only)

To make your edits in the dialog box shown in Figure 16.34, double-click the value data to edit the values, bearing in mind the information I gave you about what those edits will do. Make sure you’ve set the flags properly according to whether the application you’re editing is a 16-bit or 32-bit application, and don’t forget to notice whether you’re making changes in hex or decimal.

**FIGURE 16.34**  
Edit string values to set the Bad Application parameters you want.

The settings will take effect when you next open the application. Because you edited a key in HKLM, the changes will apply to all instances of the application running on this terminal server.

### ***Making Applications Reference Usernames***

Windows Terminal Server, and terminal sessions running on early betas of Win2K Server, had a little problem when it came to running WinChat, the graphical chat application that comes with Windows. Because WinChat referenced computers, not users, you couldn't use it from a terminal server session to talk to someone running another terminal session. Try to connect to someone, and you'd see a list of computers to choose from. Chat sessions with yourself get dull, so that made WinChat pretty well useless from terminal sessions.

The intrepid user of Terminal Services is not foiled by such petty machinations, however. You could use to make the application reference usernames instead of computer names. In `HKLM\Software\Microsoft\Windows NT\CurrentVersion\Terminal Server\Compatibility\Applications`, where you just edited the Bad Application settings, there's a value for Flags, which in the previous section was 8 or c, signifying that the settings applied either to a Win32 application or to both Win16 and Win32 applications.

**TIP** *To apply more than one flag to an application, add together the value of all the flags you want to use and make that the value of the Flags entry.*

You can apply several other compatibility flags to Flags with varying results. One flag tells the server to make the application return the version number; another tells it to make the application use the system root directory instead of the user's system directory. For our purposes, the important value is 0x10 (that is, 10 hex), which tells an application to look for users by their usernames, not their computer names. So, you could edit the value of Flags for the WINCHAT key to 18, telling the server, "Not only is this a Win32 application, but it should reference usernames, not computer names." No reboot is necessary; just restart WinChat. It wouldn't display usernames—that would have been handy, but no dice—but if you plug a username into the browse function, it would find that user and place the call.

You're probably thinking that I'm going to tell you that Microsoft fixed this problem. In a way, you would be correct: You will no longer have problems running WinChat in a terminal server session and only being able to reference computers. This is because Microsoft decided there was no point in having a messaging application that "didn't work" from terminal server sessions available to those sessions. Now, if you attempt to run WinChat from a terminal session on a server running Windows 2000 or Server 2003, you get an error message telling you that that application can't be used from a terminal server remote session. Well, that's *one* way to cut down on support calls, I suppose.

The good news is that this hack will still work if you have any other applications that reference computer names instead of usernames—just edit that application's key as I described here. You just can't use it any longer to fix WinChat.

## **Managing Terminal Sessions**

Thus far, you've configured client settings and set up applications. Everyone's happily typing away in their sessions. But what if they're not so happy? Terminal Services management capabilities allow you to keep tabs on what's happening on the terminal server. These capabilities work both from the GUI and from the command line.

## Introducing Command-Line Tools

Terminal Services has some excellent GUI tools that make it easy to quickly get used to working with the service. That GUI can't do everything, however, and what it can do it can't always do *quickly*. Thus, the command-line tools that allow you to manage terminal sessions come in handy when it's time to make batch files—or just to do something quickly without taking the time to hunt down the right tool or part of the MMC.

There are far too many options to go into complete detail about every one of the command-line tools listed in Table 16.8, but the following sections should help you get an idea of how you can manipulate Terminal Services from the command line and the graphical administration tool. I already discussed some of these—`flattemp` and `tsprof`, for two—earlier in this chapter.

***TIP** To see a complete list of all options for a command, type its name and `/?` at the command line.*

TABLE 16.8: SUPPORTED TERMINAL SERVICES UTILITIES	
COMMAND	FUNCTION
change logon	Temporarily disables logons to a terminal server.
change port	Changes or displays COM port mappings for MS-DOS program compatibility. For example, you could use this utility to map one port to another one so that data sent to the first would actually go to the second.
change user	Flips between Execute mode and Install mode.
cprofile	Removes unnecessary files from a user profile. You can only run this tool on profiles not currently being used.
dbgtrace	Enables or disables debug tracing.
flattemp	Enables or disables redirected temporary directories, which you can use to send TMP files to a location other than the default.
logoff	Ends a client session specified by session name or Session ID, either on the local terminal server or on one specified.
msg	Sends a message to one or more clients.
query process	Displays information about processes.
query session	Displays information about a terminal server session.
query termserver	Lists the available application terminal servers on the network.
query user	Displays information about users logged on to the system.
register	Registers applications to execute in a system or user global context on the computer.
reset	Resets (ends) the specified terminal session.

*Continued on next page*

**TABLE 16.8:** SUPPORTED TERMINAL SERVICES UTILITIES (*continued*)

COMMAND	FUNCTION
shadow	Monitors another user's session. Cannot be executed from the console and cannot shadow the console. Equivalent to the graphical remote control tools.
tscon	Connects to another existing terminal server session.
tsdiscon	Disconnects from a terminal server session.
tskill	Terminates a process, identified by name or by Process ID.
tsprof	Copies the user configuration and changes the profile path.
tsshutdown	Shuts down a terminal server.

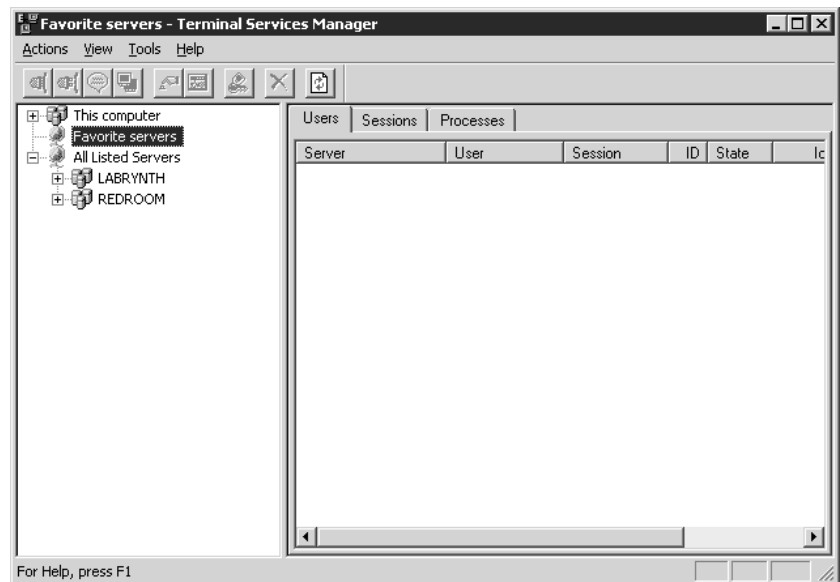

Those who went straight from TSE to Server 2003 will notice that their tools are here, but many of the command names have changed. The utilities still provide the same functions as the commands in TSE, but you'll have to learn new names for most of them.

## Using the Terminal Services Manager

To help you keep track of who's using the terminal server, what processes they're running, and the status of their connections, you'll use the Terminal Services Manager, found in the Administrative Tools program group and shown in Figure 16.35.

**FIGURE 16.35**

The Terminal Services Manager tool

The left pane shows all domains in the network and all terminal servers within those domains. (You can use this tool to manage any terminal server that's listed; you don't need to be physically at that console.) The right pane's content depends on what's selected: If it's the domain or the entire network, then all current connections to that server (active or disconnected) and the name of the server hosting them are displayed; if it's a terminal server, then all current connections to that server are displayed; if it's a username, then all the processes running in that user's context, or information about the user session, are displayed. Notice also that the right pane is tabbed, with the contents of the tabs depending on whether you've got a domain, server, or user selected on the left. Broadly speaking, you use the administration tool to get information about:

- ◆ Users, including what their Session IDs are, what applications they're running, and what server they're using
- ◆ Sessions, including what the ID of that session is, what's running in that session, what the status of the session is, how long the client has been logged in, and information about the computer the client is logged in from (IP address, RDP version, and so forth)
- ◆ Processes, including the Process IDs and the executable files (*images*) with which these processes are associated

**NOTE** *It's not hard to figure out what information you're looking at—a short period of poking around will teach you where everything is. More important is the question of what you can do with this tool. In the following example, I'll show you how to use the management tools to see what's running on the server, send messages to people on the server, terminate remote processes, and close user sessions. For this example, I'll refer to a fictional game called TSQUAKE, a Terminal Services-compliant version of Quake.*

### GATHERING INFORMATION

Who's playing TSQUAKE again?

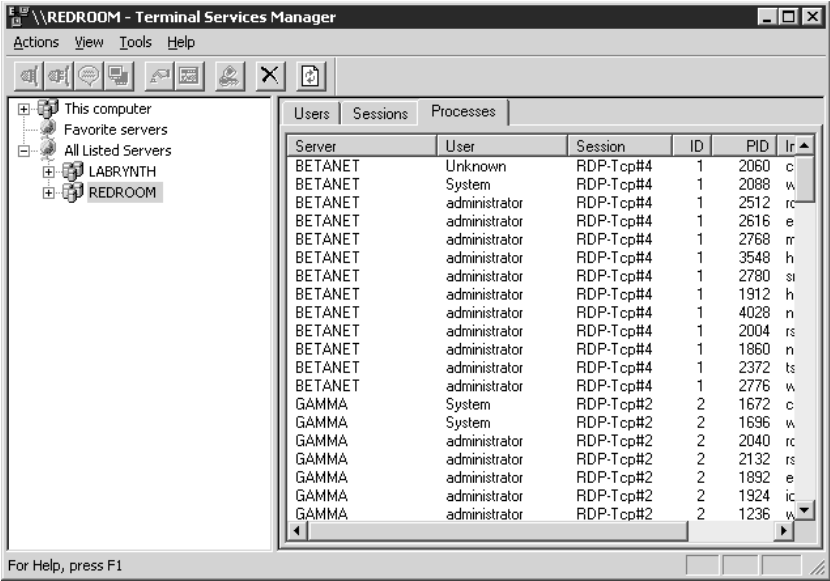

To find out, you'll need to know who's logged in to the server or servers and what processes are running in their sessions. You can use both the Terminal Services Manager and the command line to get this data.

From the GUI, select the terminal server or domain for which you want information. In the right pane, three tabs will become visible: one listing users currently logged in to the terminal server, one showing the current active and disconnected sessions, and one showing the processes currently running on the terminal server.

Flip to the Processes tab associated with the domain (see Figure 16.36) to see a complete list of all processes running in the domain, the server they're running on, the session they're in, and the name of the user who owns that session. This screen will also show the Process ID (PID), which will come in handy when it comes time to terminate processes.

You can get more than just process information from this screen. Select a terminal server in the left pane. From the tabs that appear on the right, you can find the information described in Table 16.9.

**FIGURE 16.36**  
Viewing processes  
running on a  
terminal server

**TABLE 16.9:** FINDING INFORMATION IN THE TERMINAL SERVICES MANAGER

DATA TYPE	TAB
Client computer name or IP address	Sessions
Image names for processes	Processes
Process IDs	Processes
Protocol used for each session	Sessions
Session idle time	Users
Session IDs associated with processes	Processes
Session status	Users, Sessions
User logon time	Users, Sessions
Username associated with processes	Processes
User Session IDs	Users, Sessions

Everything you need to find out—which user and which PID is associated with which session, and how busy that session is—is here. If you use the command-line `query` utility, you can get much the same information that you can from the Terminal Services Manager tool, but you have to do it a piece

at a time. From the command line, there's no way to retrieve a list of all processes running in a domain or across all domains, so first you'll have to isolate the terminal server. For example, to see a complete list of all terminal servers in the current domain, type **query termserv**. The server will return a complete list of all terminal servers in the domain, like this:

```
Known Terminal servers
```

```
-----  
BETANET  
GAMMA  
TERMSERV  
-----
```

Need the list from another domain? Add the domain name you're retrieving the list from to the command, like this:

```
query termserv /domain:domainname
```

You'll get the same output, customized for the domain you specified.

Once you've got the name of the server you need to check out, look for TSQUAKE by querying for processes, like this:

```
query process
```

The server will return a list of all user-launched processes running in the current session (even if that session is the console), as shown:

USERNAME	SESSIONNAME	ID	PID	IMAGE
>administrator	console	0	1152	explorer.exe
>administrator	console	0	1348	osa.exe
>administrator	console	0	1360	findfast.exe
>administrator	console	0	532	infoview.exe
>administrator	console	0	2052	depends.exe
>administrator	console	0	2172	cmd.exe
>administrator	console	0	764	taskmgr.exe
>administrator	console	0	1256	tsadmin.exe
>administrator	console	0	1636	mmc.exe
>administrator	console	0	1500	winword.exe
>administrator	console	0	2092	regedit.exe
>administrator	console	0	1776	query.exe
>administrator	console	0	1652	qprocess.exe

To query the process list for a different user, add that person's username to the command, like this:

```
query process gertrude
```

**TIP** You can also list processes associated with a particular session name or Session ID, although for most purposes I find it easier to reference usernames. You'll use the Session ID to determine if a user has more than one session open.

Okay, but what you really want is a list of everyone who's goofing off and using up processor cycles. Although you can't get a list of all processes running in a single domain or across domains,

you can retrieve a list of all users with a particular process running in their sessions, like this:

```
C:\>query process winword.exe
USERNAME      SESSIONNAME    ID  PID IMAGE
>administrator console      0  1500 winword.exe
christa        rdp-tcp#1      1  1400 winword.exe
```

Use this command to track down those TSQUAKE users.

### SENDING MESSAGES

Once you've got your list of people running TSQUAKE, you can let them know that they're caught. From both the GUI and the command line, you can send messages to a single person, to multiple people, and even across domains.

From the left pane of the Terminal Services Manager tool, select the terminal server the people are using. In the right, select the people to whom you want to send a message (Ctrl+click to select multiple usernames). From the Actions menu, choose Send Message to open the dialog box shown in Figure 16.37. Click OK, and the message will instantly pop up on the screen of everyone you included on the recipient list.

**FIGURE 16.37**

Sending a message  
to users

You can also send messages from the command line with the `msg` utility. This works much like `msg` did in single-user Windows, with one exception: messages sent to a username will be sent to all instances of that name, not just one. This is so that a person running multiple sessions will be sure to get their message.

`msg` has lots of options. Its basic syntax looks like this:

```
msg {identifier} [/SERVER:servername] [/TIME:sec] [/v] [/w] [message]
```

The *identifier* can be a username, Session ID, session name, or a filename containing an ASCII list of all users to whom the message should go. The `/TIME` parameter doesn't delay the message; rather, it's a time-out period that cooperates with the `/w` switch that waits for user response before giving control of the command prompt back to the message's sender.

**NOTE** Like the other command-line utilities, `msg` operates on the server you're connected to unless you specify otherwise.

To send a message to a single user, run `msg` like this:

```
msg gertrude Gertrude, please close TSQUAKE. You're wasting processor time.
```

If you want some kind of record that Gertrude saw the message—or at least clicked OK—use the `/v` (for “verbose”) switch as follows:

```
msg gertrude /v Gertrude, I mean it. Close the game.
```

You’ll see output like the following:

```
Sending message to session RDP-Tcp#1, display time 60
Timeout on message to session RDP-Tcp#1 before user response
```

To send a message to everyone logged in to that terminal server, use an asterisk, like so:

```
msg * Hey, everyone—Gertrude's got enough free time to play TSQUAKE. Anyone got anything for her to do?
```

Alternatively, send a message to a preset group by typing all recipient names into a Notepad file and saving it, then referencing the file like this:

```
msg @users Hey, everyone—Gertrude has enough free time to play TSQUAKE. Anyone got anything for her to do?
```

The only catch to sending messages to multiple users is that if you add the `/w` option, `msg` works sequentially. That is, it will send the message to the first person in the list (going in order of Session ID) and wait for either a response or a time-out before sending the message to the second person in the list.

### TERMINATING APPLICATIONS

Gertrude and the other TSQUAKE players aren’t paying attention to your pleas. Time to get tough and terminate the application. Every instance of TSQUAKE that you close will exit immediately, with no warning to the user and no chance to save data.

**NOTE** Before I get into this, let me distinguish again between terminating and resetting. Both options close applications with no warning, but single processes are terminated and entire sessions are reset.

To kill a single application from the GUI, select the server or domain in the left pane and turn to the Processes tab in the right. All running processes will appear here, identified by the name of the server they’re running on, who’s got them open, the PIDs of the processes, and other relevant information. As elsewhere, you can Ctrl+click to select multiple processes. When every process to be terminated is selected, right-click and choose End Process from the context menu (it’s the only option). The selected applications will close instantly.

You can also terminate applications from the command line. Just be careful. This procedure is open to error, and you will not make people happy if you accidentally close the wrong process and lose all their data.

The command to kill terminal server applications is `tskill`, related to the `kill` command that appeared for the first time in NT 3.5’s Resource Kit and which stops an application by killing its process. Like the Terminate menu command, `tskill` will stop an application as soon as it’s executed, with no time allowed for saving data or other tasks. It’s very intrusive, so you should only use it when there’s simply no other way of getting an application to stop.

The syntax of `tskill` is as follows:

```
tskill processid | processname [/SERVER:servername] [/ID:sessionid | /a] [/v]
```

Notice that you can reference a process either by its name or its Process ID. The former is easier and necessary if you're using the `/a` switch to close all instances of an application on the terminal server. The latter is necessary if you're only trying to close specific instances of the application, perhaps leaving untouched the instance of TSQUAKE that your boss has open.

So, to kill all instances of TSQUAKE running on the currently selected server, you type:

```
tskill tsquake.exe /a
```

To kill only selected instances, get the PID by running `query process` or `query user` and plug it in, like this:

```
tskill 1875
```

Sadly, you can't list several PIDs at once to kill, so if you need to pick and choose processes without killing all instances, you'll need to terminate instances of a process one at a time.

**TIP** Although you need to supply the executable extension with `query process`, the command won't work if you supply the extension with `tskill`. So, it's **query process tsquake.exe**, but **tskill tsquake**.

### TAKING CONTROL OF USER SESSIONS

Sometimes, the best plan isn't to just shut down applications from the terminal server. Instead, you can take control of a user session and see what they're doing (as opposed to listing processes, which just tells you what processes are active in the context of a given session). This can be especially helpful for troubleshooting purposes, such as if Gertrude says she didn't mean to run TSQUAKE but couldn't figure out how to shut it down once she had it running. Taking remote control of the session gives you the same degree of control that you'd have if logged on as that user.

You can remotely control a user's session in one of two ways: from the Terminal Services Manager or from the command line.

**TIP** You can only take remote control of a terminal server session from another terminal server session, not from the console. The remote control option in the Terminal Services Manager and the `shadow` command-line utility won't work from the console.

To use the GUI, start a terminal server session, logging in with an account with Administrator privileges. From within the session, start the Terminal Services Manager. Select a terminal server in the left pane and switch to the Users tab so that user sessions are showing. Find the session you want to shadow, and choose Remote Control from the Actions menu. A dialog box like the one shown in Figure 16.38 will prompt you for the hotkey combination you want to use to end remote control of your own session (so you can get back to the original session).

If the user session is configured to require user permission for control, then a dialog box will appear on the screen, letting the user know that someone has requested permission to control their session. If they permit the control, then you're in charge of their session without further ado. If they don't permit the control, then you'll see an error message telling you that you couldn't get permission to control the session.

**FIGURE 16.38**

Choose a hot key combination to toggle back to your original session.

**NOTE** The degree of control you have over a user's session that you're remotely controlling depends on the settings in the user's account settings.

The command-line utility for taking remote control of a user session is called **shadow**, after the WinFrame and MetaFrame name for remote control. Its syntax is as follows:

```
shadow {sessionname | sessionid} [/SERVER:servername] [/v]
```

To use it, start a terminal services session with administrative privileges. Open the command prompt and run **query user username** or **query session username** to find the Session ID or session name of the user whose session you want to shadow. You can't shadow based on *username*, so you'll need this information even if you know the account name of the person whose session you're shadowing.

If shadowing a session on the same terminal server that you're logged in to, the command syntax for shadowing Session ID 1 is as follows:

```
shadow 1
```

If that session requires user permission to be remotely controlled, then you'll see the following message while your session waits for permission to take over the remote one:

```
Your session may appear frozen while the remote control approval is being negotiated.
Please wait...
```

Once you have permission, you're in, just as you would be when using the GUI remote control option. The session must have someone logged in at the time—you cannot shadow a disconnected session.

The only tricky part to shadowing from the command prompt is that you had best do it at least once from the GUI before trying the command-line utility. The **shadow** command does not prompt you for a hotkey combination to end remote control and return to your session. It will use the one defined for the GUI, so if you know what that hotkey combination is, you can use it. Just make sure you know how to return to your own session from the remote control.

#### ENDING—OR PREVENTING—USER SESSIONS

That's it—Gertrude's kicked off the server until she can learn to stop using it incorrectly.

If you want to stop an entire terminal session, not just a single process within it, you can either disconnect or reset the connection. Disconnecting, you recall, cuts the user off from the session (although there's normally nothing to keep a user from reconnecting), but leaves all applications running and data in memory. When the user reconnects to a session they were disconnected from, then they're right back where they left off. A reset connection, in contrast, closes all applications the person had open and ends the session without saving any changes to the user profile. Disconnected sessions still use some system resources, albeit not much because their data will eventually be paged to disk and they won't have new user input to process. Reset sessions use no resources.

To disconnect or reset a session from the Terminal Services Manager tool, select it in the left pane and choose Reset or Disconnect from the Action menu. You'll see a dialog box warning you that the session will be disconnected or reset; click OK, and the selected session or sessions will be ended.

You can also end user sessions from the command line with the `tsdiscon` and `reset session` commands. The syntax for `tsdiscon` is as follows:

```
tsdiscon [sessionid | sessionname] [/SERVER:servername] [/v]
```

Once again, you can choose to identify sessions to close by session name or Session ID. To find out both, run `query session` to get output like the following:

SESSIONNAME	USERNAME	ID	STATE	TYPE	DEVICE
>console	Administrator	0	active	wdcon	
rdp-tcp	65537		listen	rdpwd	
rdp-tcp#2	Christa	2	active	rdpwd	
		1	idle		
		3	idle		

Find the session name or ID you want, and plug it into the `tsdiscon` command like this: **`tsdiscon 2`**. Once you've pressed the Enter key, the user of the selected session sees a message, "Terminal Server has ended the connection," and is given a Close button to push.

**TIP** *I find it easiest to reference Session IDs. You always have to use a number—you can't choose to disconnect a session attached to a particular username—so you might as well choose the shortest identifier you can get away with.*

The syntax for resetting a session is similar to that used for disconnecting it:

```
reset session {sessionname | sessionid} [/SERVER:servername] [/v]
```

Once again, the user will see a dialog box telling them that Terminal Server ended the connection and prompting them to close.

What if you'd like to keep people off the terminal server altogether, perhaps while you're installing new applications on it? If no one's yet connected, you can disable the RDP protocol from the Terminal Services Configuration tool located in the Administrative Tools program group. Right-click the RDP protocol, and from the pop-up menu that appears, choose All Tasks/Disable Connection.

**WARNING** *If you disable the connection from the Terminal Services Configuration tool, you'll reset any existing sessions.*

If you've reset all connections in preparation for shutting down the server, you can also shut down the server without going to the console. `tsshutdn`'s syntax is as follows:

```
tsshutdn [wait_time] [/SERVER:servername] [/REBOOT] [/POWERDOWN]
[/DELAY:logoffdelay] [/v]
```

Most of these options are what they appear to be. `wait_time` specifies the amount of time (in seconds) until the server is shut down, and `servername` specifies a server if you don't want to shut down the one you're currently logged in to. `/REBOOT` reboots the server, and `/POWERDOWN` shuts it down if the server has Advanced Power Management drivers (if not, the server shuts down all server processes and displays the Click to Restart message).

**TIP** Use `tsshutdn` to circumvent the nag screen asking you why you want to shut down a perfectly good server. This works on any Server 2003, not just terminal servers.

So, for example, you could combine `tsshutdn` and `msg` to tell everyone that the server's going to be rebooted in five minutes. First, send the following message:

```
Msg * The server will go down in 5 minutes for maintenance. Please log out.
```

Second, run the `tshutdn` command with the following parameters:

```
tshutdn 300 /reboot
```

**NOTE** Any dialog boxes that require user response (for example, one asking you if you want to save changes to a MMC snap-in that you edited) will want your response—they won't just go away without a response. Therefore, if using `tsshutdn` you must respond to those dialog boxes before the `tshutdn` timeout period. Otherwise, `tsshutdn` will respond that the shutdown operation completed successfully, but the server will still be running.

Say, however, that you don't want to shut down the server. You just want to keep any new sessions from starting. To disable the protocol for new sessions without disturbing the ones already in place, you'll need to use the `change logon` command utility. Its syntax is as follows:

```
change logon {/QUERY | /ENABLE | /DISABLE}
/QUERY    Query current terminal session login mode.
/ENABLE   Enable user login from terminal sessions.
/DISABLE  Disable user login from terminal sessions.
```

Typing `change logon /disable` prevents any further connections from being made until you reenables the protocol. Anyone who tries to connect will see an error message telling them that remote logins are currently disabled. Disabling RDP does not, obviously, affect the console session as it's not dependent on RDP. As I mentioned earlier, you'll need to disable logins if you want to keep people off the terminal server, as the service itself does not shut off.

## Using Remote Administration Mode

This chapter is generally about how to use Terminal Services to create application servers, but as I've said, Terminal Services gives you a handy way of accessing *any* server that can accept incoming RDP connections. If you've never used Terminal Services for remote management and you've just read this

chapter about how to set up an application server, you may have some questions about how Remote Administration mode works and what you can do with it, so let's address those now.

## Enabling Remote Administration

Although Terminal Services is installed by default, for security reasons the server will not accept incoming connections by default. To enable them, open the Control Panel and turn to the Remote tab of the System applet (see Figure 16.39).

**FIGURE 16.39**

You must enable Remote Desktop to permit incoming connections.

**NOTE** If using a firewall to secure servers, you'll need to open port 3389. If you're using Server 2003's Internet Connection Firewall, this means opening the Remote Connection port (available from the Settings button on the Advanced tab of the connection's properties sheet).

Once you've done that and ensured that the RDP port is open for the network connection, the server can accept incoming connections.

## Connecting to Remote Servers Using the Remote Desktops Tool

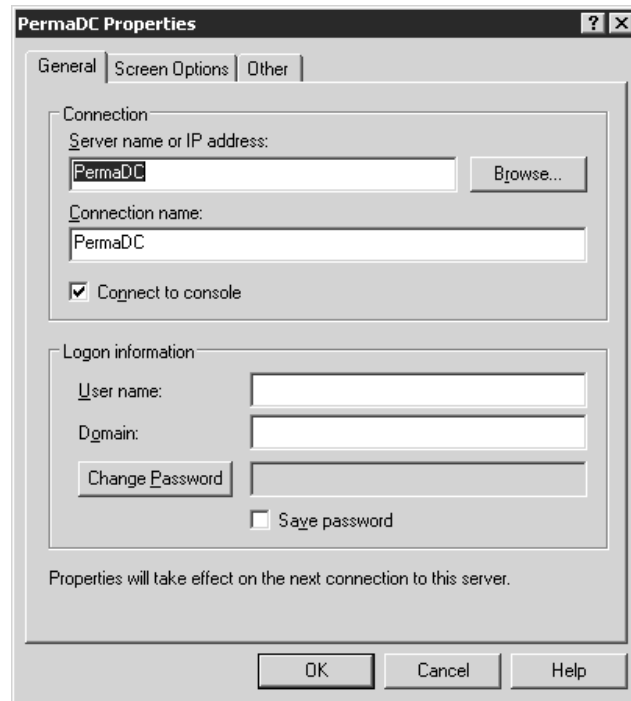

The Remote Desktop Connection client comes preinstalled on Server 2003, but this isn't the best tool for server administration unless you normally only interact with one server at a time. Instead, try the Remote Desktops tool in the Administrative Tools section of the Start menu. Using this tool, you

can connect to multiple servers and flip back and forth between them without having to maximize and minimize session windows. This tool works for both Windows 2000 and Server 2003 servers—the servers just have to have Terminal Services installed and be accepting incoming connections.

When you first open Remote Desktops, it won't have any servers in it—just a Remote Desktops icon. To create a connection, right-click this icon and choose Add New Connection from the context menu. You'll open the dialog box in Figure 16.40.

**FIGURE 16.40**

Adding a new Remote Desktops connection

There's an annoying bug here (or feature—I suppose it depends on your outlook). See that Browse button in Figure 16.40? It looks like you can browse for servers to connect to, doesn't it? Well, you can... but the only servers that it will return are application servers (and Windows 2000 servers in remote administration mode, if you have any). Server 2003 computers using Remote Administration will not appear. However, you can connect to them by typing their names or IP addresses—you just can't browse for them.

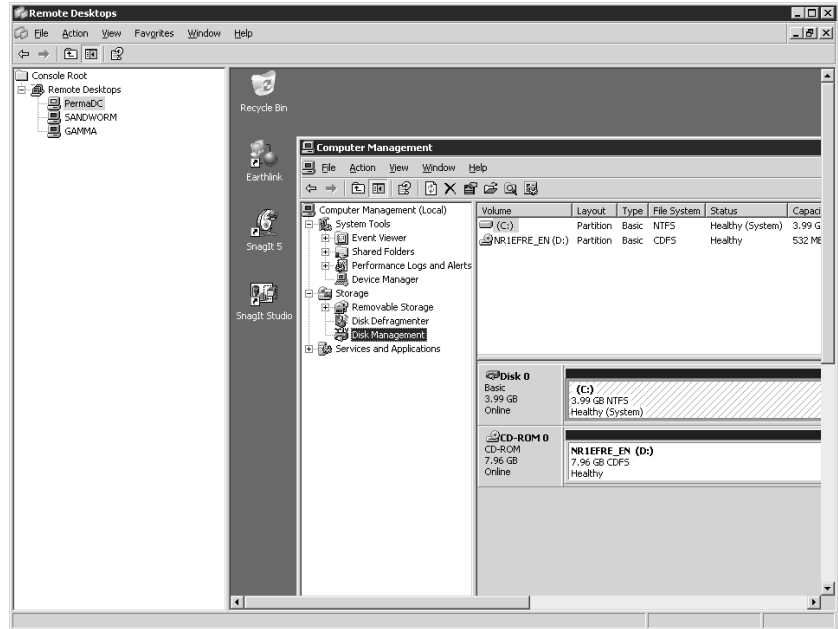

Notice that you can connect to the console of the server, both for Server 2003 computers and Windows 2000 computers. This is helpful if you're doing something that requires interacting with the console directly—for example, running software that sends messages to the console, not to sessions. If you connect to a server's console session, you'll lock the local console session so that two people aren't interacting with it at once.

Finally, notice that you can provide a name and password to use when connecting to the remote computer. When you're finished setting up the connection, click OK to save the connection. The new connection will appear in Remote Desktops as in Figure 16.41. (I've added a couple of additional

connections to show you what they look like.) To launch the connection, right-click a server's icon in the left pane and choose Connect. To toggle between multiple open sessions, just click the appropriate server's icon in the left pane.

**FIGURE 16.41**

You can manage several servers at once using the Remote Desktops tool.

**TIP** The display for Remote Desktops is currently a little buggy and does not resize the terminal session window when you resize the display pane or adjust its resolution to fit the display window. I find that I get the best display if I maximize the Remote Desktops tool and the right display pane before launching a connection.

To end a session, either disconnect or log out as you would if using Remote Desktop Connection, or right-click a server's icon and choose Disconnect. Disconnecting, once again, does not completely close a terminal session. Disconnected sessions count toward the two concurrent administrative logins permitted.

## Questions about Using Remote Administration

You've connected... but how does this work? Read on.

### HOW MUCH WILL REMOTE ADMINISTRATION MODE AFFECT SERVER PERFORMANCE?

You're probably aware that a terminal server requires a lot of horsepower to support all those clients and may be wondering whether Remote Administration mode is going to require you to seriously beef up your ordinary servers. Nope. Application servers require so much memory because many people are using them at once, not because the service itself is particularly power-hungry. The total memory requirements for running Terminal Services in Remote Administration mode are a little less than 2.5MB of RAM. In other words, if the server can do what it's supposed to do, unless it's very stressed, remote administration shouldn't faze it.

**HOW MANY PEOPLE CAN LOG IN TO THE SERVER?**

When you install Terminal Services into this mode, you're permitting up to two simultaneous administrative connections to the terminal server. (Anyone whose account does not have administrative privileges on the domain will be denied access to the server, so you don't have to worry about Joe User logging into the Web server if he doesn't have an administrative account.) The licenses for these connections are built in, so you don't need additional licenses for server management—or a Terminal Services license manager—if you're only using Terminal Services for this purpose.

**CAN I RUN ANY MANAGEMENT TOOL FROM A TERMINAL SESSION?**

Sort of. Microsoft notes several tools that won't work in a terminal session and that you must operate from the console. Microsoft SQL Server 6.5 and 7 PerfMon counters cannot be accessed from a remote session (this is fine; you really don't want to be running System Monitor from an RDP session anyway—too many graphical updates) and must be viewed from the console. Also, Pervasive SQL v7 has a namespace problem that prevents the tool from installing properly from a terminal session. Otherwise, though, most tools will work in a remote session. With the faster RDP connections available today, even fairly graphically intense management tools are working pretty well.

## Chapter 17

# TCP/IP Server Services (IIS, NNTP, Telnet, SMTP, POP3, and FTP)

UNLESS YOU'VE BEEN LIVING in a cave somewhere for the past five years, you're undoubtedly aware that the Internet is becoming a major part of the way that the world works. Notice I said world, not just companies. With each passing day, the Internet is having more and more of an impact on the daily lives of countless people. The amount of information available to anyone, anywhere, at any time is simply mind boggling, and this trend is only going to continue to grow in the future.

Not one to miss out on such a significant part of people's lives, Microsoft is doing everything that they can to be a part of this revolution. While some of their tactics might be questionable—such as tying their Internet Explorer browser directly in with their most recent operating systems—other approaches are quite beneficial. The most significant benefit is the inclusion of the latest version of Internet Information Services (IIS) with the base Windows Server 2003 operating system.

Internet Information Services is a full-featured platform capable of servicing HTTP (Web), FTP (file transfers), NNTP (news), and SMTP (e-mail) tasks for an organization. Due to its integration with the Windows operating system, it is relatively easy to set up, configure, and manage. IIS is capable of scaling to meet even the most demanding of environments—Microsoft runs their own Web site on IIS, and their site receives millions of hits per day. Currently, Internet Information Services is enjoying second-place title as the most widely implemented Web server around, according to Web server statistics available at Netcraft ([www.netcraft.com/survey/](http://www.netcraft.com/survey/)). According to the December 2002 statistics, Internet Information Services (in its various versions) accounted for 27.58 percent of 35,543,105 Web sites that were queried. So what was the first-place Web server? A package known as Apache, an open-source version of the original NCSA HTTP Web server. In the same survey, Apache (and its different versions, including some commercial implementations) accounted for 62.02 percent of the servers sampled and was still increasing in market share.

Despite its second-place title (or perhaps because of it) IIS 5 was plagued with security holes and exploits. IIS administrators spent the last three years patching software, disabling the very open default configuration, and biting their nails while scanning the latest security bulletins. However, Microsoft has really stepped up to the plate with IIS 6, implementing a complete reversal of attitude about security and default configurations. In keeping with their new “locked down” philosophy for

the Windows Server 2003 operating system, IIS 6 is not installed with the operating system, and a default installation of IIS 6 is so locked down that it will only serve static content. If that were the only change in IIS, it would be a great improvement, but the fun doesn't stop there. The biggest changes are "under the hood" and a full explanation would require quite a long discussion, but here's a short list of new features and improvements:

- ◆ The code for IIS has been completely revamped to achieve greater stability and performance. The new processing model, called *worker process isolation mode*, permits one or more sites or applications to run in designated application pools. Since sites and applications can run on separate worker processes, a bug or security exploit that brings down one site doesn't have to affect any other sites on the system. For backward compatibility with IIS 5–dependent applications, IIS 6 also supports *IIS 5 isolation mode*.
- ◆ A set of command-line administration scripts are now included in the `\Windows\system32` directory. These VBScripts can perform most common administration tasks.
- ◆ Configuration information is now stored in two XML files instead of a binary file. These XML files can be viewed and modified with a common text editor like Notepad. Administrators can now read and edit the IIS configuration directly (and while IIS is running!) instead of using scripts or code.
- ◆ IIS 6 supports importing and exporting configuration information at any level (site, server, or directory). This makes it easy to duplicate settings across servers.
- ◆ IIS 6 permits server-independent backups. You can now back up a configuration and restore it to another system, using an encrypted password.
- ◆ If an IPv6 protocol stack is installed on the IIS Server, IIS 6 will support HTTP requests over IPv6.
- ◆ An improved method of response compression permits dynamic content to be compressed on-the-fly while static content is stored in a disk cache.
- ◆ FTP now supports *user isolation*, which means that individual FTP clients can be restricted to their own home directories without the ability to view or modify content in other users' directories.
- ◆ Technically it's not part of IIS, but the inclusion of a POP3 Server in Windows Server 2003 means that the system can act as a real mail server, not just a mail forwarder, without installing any third-party software.

## Overview of IIS and Other Web Server Applications

Internet Information Services (IIS) is really a suite of TCP/IP-based services all running on the same system. Although some of the services rely on shared components, they are functionally independent from one another. Just as an electrician has different tools for different jobs, IIS has different Internet capabilities to help meet different needs. With the release of Windows Server 2003, Microsoft has reached version 6 for Internet Information Services. The following sections will briefly discuss some of the web application server functionality included with IIS 6.

### World Wide Web (HTTP) Server

If you're reading this book, and this chapter specifically, I'll assume that the World Wide Web is nothing new to you. IIS includes an HTTP server so that you can publish data to the World Wide Web

quickly and easily. IIS's Web service is easily configurable and reliable, and it supports security and encryption to protect sensitive data.

You can use IIS's Web service to host a Web site for your own domain or multiple domains, an intranet, and the Internet, and even allow users to pass through your IIS Web server to access HTML documents on machines within your organization.

If you worked with Windows 2000 Server and IIS 5, you know that the default Windows 2000 Server installation also installed IIS 5 automatically, including almost any optional component you could conceivably need. Windows Server 2003, however, emphasizes security over convenience. IIS 6 is not installed on Windows Server 2003 by default; furthermore, a default installation of IIS 6 will only serve static content, meaning that the default service configuration will not process any scripts or code embedded in the Web pages. Components that support Active Server Pages, Server Side Includes, and FrontPage server extensions (which allow clients to publish and manage Web sites using Microsoft FrontPage), are not installed by default. Basically, everything that could be considered a security issue must be specifically installed or enabled.

### **File Transfer (FTP) Server**

Although the use of File Transfer Protocol is not the only way to send a file from one location to another, it is by far the most widely supported as far as the Internet is concerned. FTP was one of the original means of copying files from one location to another on the Internet, long before the days of graphical browsers, HTTP, and Web sites. Since the protocol has been around for so long, support is available on almost any platform, including midrange and mainframe systems that might not typically support HTTP.

In IIS 6, the FTP service now includes support for individual user directories. This feature can be used to permit access to private directories while preventing users from seeing or writing to directories other than their own.

### **Network News (NNTP) Server**

Sometimes referred to as Usenet, Network News Transport Protocol (NNTP) is something that I hope to see start taking off in the near future, simply due to the great functionality it provides. By using Internet standards (RFC 977), the NNTP service can be used as a means of maintaining a threaded conversation database on an IIS server, just like in Usenet groups on the Internet. Users with properly configured newsreader programs can navigate through and participate in these conversation databases.

Although services like Google Groups (<http://groups.google.com>) have made Usenet better known, it still isn't as widely used as something like HTTP. That's unfortunate; NNTP represents a great cross-platform protocol for managing threaded conversation databases. Let's hope the inclusion of NNTP with IIS will increase the use of this capability.

### **E-Mail Services**

Microsoft included an SMTP service with IIS version 5; however, it was not sufficient to act as a full-blown e-mail server for an organization. The SMTP service included with IIS 5 was only meant to support the other services within IIS—namely HTTP and NNTP. You see, the SMTP service included with IIS 5 was missing an important component—a POP3 or IMAP service. POP3 or IMAP is the means by which clients retrieve their specific messages from their mailbox on a mail server. SMTP provides a “store-and-forward” service for mail but does not support individual user

mailboxes or a method to retrieve mail. If you wanted a Windows 2000–based mail server, you had to use a commercial product that included POP3 or IMAP, or use the free EMWACS SMTP/POP3 server product.

Windows Server 2003 now includes a POP3 service that can work with the SMTP service to provide a very simple but functional mail server platform. Although it's not technically part of the IIS services and must be installed separately, it does offer a more simple (and cheaper) alternative to Exchange or other expensive commercial products for organizations with simple e-mail requirements.

## Installing Internet Information Services

The only real requirement to install IIS is that the TCP/IP protocol be installed on the system. The system should also have a static IP address (instead of a DHCP-assigned address), although this is not required for IIS services to run on the server. If you want clients to be able to use friendly names instead of IP addresses to connect to the server, you'll also need some method of name resolution. If you are deploying an intranet Web server, you'll want to have a DNS server running on your network, although it's also possible to use HOSTS files on individual systems. The dynamic DNS that runs on Windows 2000 and Windows Server 2003 makes it possible to have an intranet server with a dynamically assigned IP address (although personally, I would not use that strategy on my intranet). If the server will be accessible from the Internet, you must register your domain name for your site and either maintain two DNS servers on the Internet or work with an ISP to maintain your DNS records. Finally, for maximum security configuration capabilities on an Internet-accessible IIS server, format your drives with the NTFS file system.

It is possible to use the Manage Your Server application to install IIS; however, I recommend using the Add/Remove Programs applet in the Control Panel for finer control of installed components.

To install Internet Information Services, open the Control Panel and launch Add/Remove Programs, then click the Add/Remove Windows Components button. This will launch the Windows Components Wizard, from which you can add or remove any parts of the operating system. In the list of components, check the option for Web Application Server, as shown in Figure 17.1.

**FIGURE 17.1**

Installing Web  
Application  
Services

Selecting this option will install several Web application components on your system, including IIS, which is installed in “locked down” mode by default; only HTTP, NNTP, and SMTP are enabled. To install FTP and FrontPage server extensions, click the Details button for Web Application Server and highlight Internet Information Services (IIS) from the list of subcomponents. Click the Details button for IIS to see a list of components that includes FTP and FrontPage 2002 server extensions (shown in Figure 17.2). Select the options that you want to install.

**FIGURE 17.2**

Subcomponents of Internet Information Services

To enable active content and install HTML-based remote administration, highlight World Wide Web Service from the list of IIS components and click the Details button for that selection. From the list of WWW service subcomponents shown in Figure 17.3, check the corresponding option boxes to enable active content or install Remote Administration support. It's not strictly necessary to enable the active content options at this point, though. You can enable them later, using the Internet Information Services console. However, FrontPage extensions, FTP, and the Web interface for Remote Administration cannot be enabled from the management console; you must install them using the Windows Components Wizard.

**FIGURE 17.3**

Subcomponents of the World Wide Web Service

**TIP** You can also install the Remote Administration Tool (HTML) by running `sasetup.msi` from the Run dialog box.

When you've selected the options you want to install, click OK to close all the open details windows and return to the Windows Components Wizard. Click Next and Setup will begin installing the selected components. You may also be prompted to insert the Windows Server 2003 CD-ROM at this point. Once the components are successfully installed, click Finish to close the wizard.

**Default Configuration**

If you accept the defaults and do not choose to install any optional components, you should end up with a default configuration similar to the following:

- ◆ Default (empty) Web site without FrontPage extensions, responding on TCP/IP port 80 on all configured IP addresses. The home directory for the default Web site is `c:\inetpub\wwwroot`
- ◆ Default SMTP virtual server, responding on TCP/IP port 25 on all configured IP addresses
- ◆ Default NNTP virtual server, responding on TCP/IP port 119 on all configured IP addresses

Looking at these services through the Internet Information Services console (`iis.msc`), you should see a screen similar to the one in Figure 17.4.

**FIGURE 17.4**  
IIS.MSC with  
default settings

If you install FrontPage server extension, FTP, or Remote Administration (HTML) components, additional sites will be created as follows:

- ◆ If you install the FTP server, Setup will create a default FTP site responding on TCP/IP port 21 on all configured IP addresses.
- ◆ Installation of the Web Interface for Remote Administration will create an Administrative Web site, responding on TCP/IP port number 8098 using SSL on all configured IP addresses.
- ◆ Installation of FrontPage server extensions will create a Web site named Microsoft SharePoint Administration, responding on a randomly assigned TCP/IP port on all configured IP addresses.

The `iis.msc` tool shown in Figure 17.4 is a bit different from the administration tool for IIS 5. Sites are listed by category now, and there are two new nodes in the console tree: Application Pools and Web Service Extensions. The Application Pools node is only available when running IIS in worker process isolation mode (which is the default mode). This new feature of IIS 6 allows individual applications or sites to be isolated from other sites or applications by assigning them to run on separate processes. You'll use the Web Service Extensions node to enable and disable handlers for dynamic content, including Active Server pages and Server Side Includes.

## Global IIS Configuration Options

IIS is a suite of services with a diverse set of configuration parameters, but there are a few settings that are common to all IIS services. To see these, select your server name at the top of the console tree in `iis.msc`, right-click and choose Properties (shown in Figure 17.5). From here you can enable Direct Metabase Edits while IIS is running, use UTF-8 encoding in log files to support international and non-ASCII characters, or configure MIME types.

**FIGURE 17.5**

Configuring global server properties for IIS

The third option you can set globally for IIS services is the MIME (Multipurpose Internet Mail Extensions) mappings that the IIS Web service will send to client browsers when a file is requested. Web servers use MIME mappings to send file type information to browsers or mail applications. The browser or mail application needs to know whether the information it is receiving is text, graphics, an audio file, executable code, or an embedded file that requires another application for viewing, such as an Excel spreadsheet.

MIME type settings specified here in the master properties will be used by all sites on the system. Mappings may also be customized at the All Web Sites level or for individual sites. However, if you change a MIME type in the master properties after modifying the same MIME type at a lower level, the master properties configuration will override the modified mapping at the site or directory level. To avoid confusion, you may want to leave the default MIME mappings untouched at the global level and modify them only for individual sites as necessary. The default mappings should be sufficient for most situations anyway. The exception would be if you wish to remove certain mappings at the global level to prevent the system from serving certain types of content completely. IIS will only serve files that have defined MIME types unless you create a wildcard entry for undefined files in the mappings.

If you need to add, remove, or change MIME mappings on your system, click the Mime Types button in the global server properties page to open the dialog box shown in Figure 17.6. From here you can view, add, remove, or edit file extension mappings for all Web sites and directories.

**FIGURE 17.6**

Configuring MIME types for all IIS services and sites

## Configuring Web Services

Once you have the global settings configured correctly on your server, it's time to start publishing content. In the following sections, I will discuss setting up Web and FTP sites on your system and the configuration items associated with each. For the purposes of our discussions throughout the remainder of this chapter, I'll assume that you are configuring new sites or virtual servers in each case.

### Master Properties for Web Sites

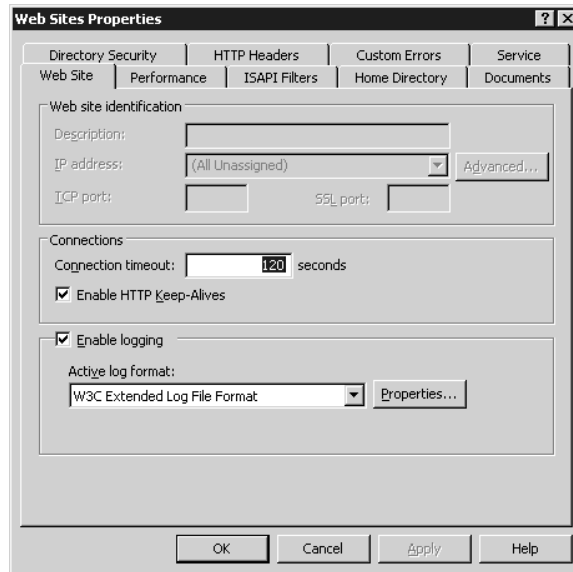

To set defaults and parameters for all Web sites on your system, select your IIS server in the console of `iis.msc`, expand the list of nodes, select Web Sites, and then choose Properties from the Action menu. You should see a property page with a set of tabs similar to those shown in Figure 17.7. Properties that are unique to individual sites, such as the Web site identification information shown in Figure 17.7, are grayed out in the master properties page.

The Service tab shown in Figure 17.8 is not available in the property page for individual Web sites. This tab presents options for two new features of the Web server. By default, the Web service runs in *worker process isolation mode*, which is a new process model for IIS 6. In worker process isolation mode, applications can be assigned to individual worker processes, offering enhanced security and reliability over the IIS 5 process model. However, you can choose to run the Web service in IIS 5 isolation mode if you have applications that rely on the IIS 5 process model and encounter compatibility issues. Choosing this option will require IIS to restart.

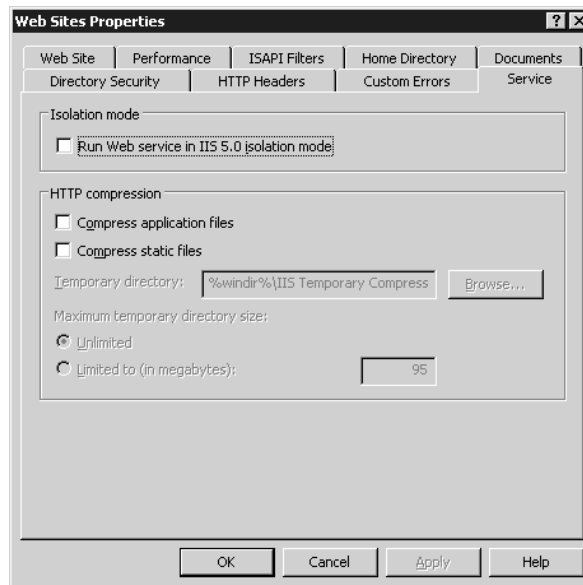

**FIGURE 17.7**

Configuring properties for all Web sites on a server

**FIGURE 17.8**

The Service tab in the Web Sites properties page

The ability to compress responses to HTTP requests isn't entirely new, but under IIS 5 it was implemented as an ISAPI filter. In IIS 6, compression is implemented as a feature of the service and can be enabled separately for static files or dynamically created content (application files). If compression is enabled for static content, compressed files are stored in a temporary file directory, found in `\Windows\IIS Temporary Compressed Files` by default. Compressed application files are not stored in

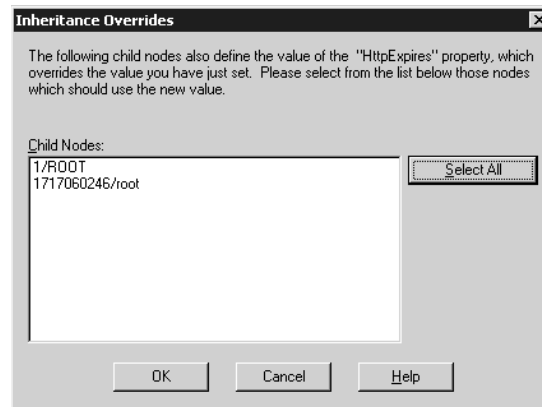

the temporary directory; they are compressed as they are created. You can use the HTTP Compression options in the Service tab to specify a different temporary directory and to set a size limit on the directory.

In general, you will use the other master property page tabs to configure settings that apply to all of your Web sites. Individual sites inherit these master configuration settings, but configuration settings at the site level can override those specified at the higher level. For example, if you choose to limit the total network bandwidth available for all sites on the server to 64KB per second, and then limit bandwidth for an individual Web site to 16KB per second, the individual Web site throttles according to its own settings and the IIS service throttles connections to all other unthrottled sites as a whole (more on throttling in a moment). Similarly, anonymous access is enabled globally, but specifically disabled for the Administration site. With this configuration in place, anonymous access is automatically permitted for any new sites that are created, but individual sites can be configured to require one of the other modes of authentication.

The other settings in the Web Sites property pages are covered in the “Modifying Web Site Properties” section later in this chapter. If you already have sites running and configured on your system and change the master parameters for the Web sites, IIS will also give you the option to apply these changes to the individual Web or FTP sites on that system. For example, in Figure 17.9, I have specified that Web site content should expire immediately for each Web site on my server. IIS is indicating that this conflicts with settings for two of the Web sites on the system.

**FIGURE 17.9**

Setting global properties that override individual site properties

Two existing Web sites already have different content expiration policies in place, so the system is asking if I would like to apply the new global default to the individual Web sites in question. The child node reference numbers shown in the figure correspond to the identifier field for the Web sites. The identifier field is shown in the details pane of the console when the Web sites are listed. I guess it was too hard to use the human-friendly description of the Web site, eh? By selecting the site(s) to change and then clicking OK, the operating system will apply the global defaults to the individual site(s). If you plan on hosting multiple Web sites on your server, this is a great way to make across-the-board changes to your system.

In addition to setting defaults for all Web sites, you can also use a feature called bandwidth throttling to control how much bandwidth IIS uses on your network. This option is a great feature for several reasons. First, if you have other Internet-based services on your network that require a set amount of bandwidth, setting this parameter will ensure that IIS doesn't consume all of your

available bandwidth. This is good for making sure that there is enough bandwidth left on your Internet connection for e-mail and other services.

For example, let's say that you have a T1 connected to your organization's network, but you don't want the IIS process to ever consume more than one-quarter of the bandwidth on this connection. By using the figures in Table 17.1, you can see that a full T1 (1,544,000 bits per second) represents approximately 193KBps, so to limit IIS to one-quarter of your T1, you would enter a value of 48 here.

**TABLE 17.1: COMMON BANDWIDTH CONVERSIONS**

CONNECTION TYPE	BANDWIDTH, IN BITS/SEC	BANDWIDTH, IN KILOBYTES/SEC
56K	56,000	7
64K	64,000	8
128K	128,000	16
256K	256,000	32
512K	512,000	64
T1	1,544,000	193
10Base-T	10,000,000	1250
T3	44,736,000	5592
100Base-T	100,000,000	12,500

Bandwidth throttling is also a great feature for testing how well a Web site will perform over a slow link. Want to see how a Web site is going to look and perform for someone dialing in over a 56K connection? Try setting the bandwidth throttle down to 7 or 6KBps. It is also useful in benchmarking and scaling systems.

## Setting Up a New Web Site

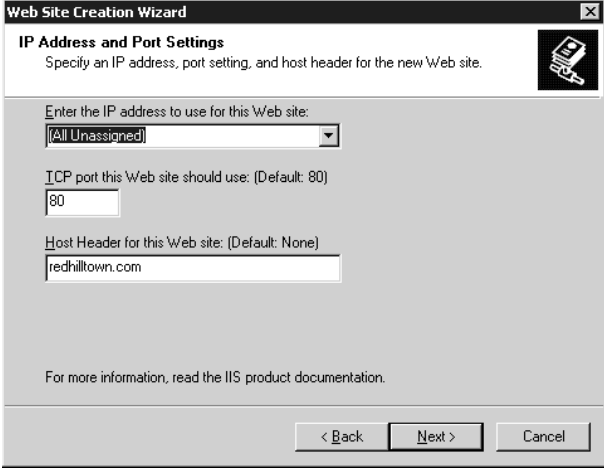

When you are ready to start building a Web site, the steps you must follow are quite easy. First, you will need to have the following information available:

- ◆ What IP address you want this Web server to live on (or if it should respond on all available IP addresses).
- ◆ What TCP/IP port number this Web server should listen to on the previously specified IP address(es). Typically, this is port 80.
- ◆ What TCP/IP port number this Web server should listen to for secure communications on the previously specified IP address(es). Typically, this is port 443.
- ◆ What *host header name* your Web site will respond to if you will be configuring multiple Web sites on a single IP address. Host header names are common Web site names, such as [www.microsoft.com](http://www.microsoft.com). (I'll explain host header records soon.)
- ◆ What directory on your system will house your Web site content (HTML, scripts, etc.)?

Begin creating your Web site by highlighting the Web Sites node in `iis.msc` and then choosing New/Web Site from the Action pull-down menu. This will launch the Web Site Creation Wizard, which will walk you through the process to create a Web site. The first question the wizard will ask is for a descriptive name for your site. Enter an appropriate name, and then click Next to proceed to the step shown in Figure 17.10.

**FIGURE 17.10**

Web Site Creation Wizard, IP Address and Port Settings and Port Settings section

In this second step of the Web Site Creation Wizard, you will need to enter information about how your Web site can be reached. This is defined by three items: the IP address used, the port used, and any host header strings sent to your server. IIS will use any and/or all of these items to determine which Web site on your system to direct users to. If you are only hosting one Web site, the defaults should be acceptable. However, if you will be hosting multiple Web sites (for example, a private, internal Web site and a public, external Web site), the correct configuration here is important.

### SERVER IP ADDRESS

The first piece of information the Web Site Creation Wizard wants to know about is which IP address to use for this Web site. This is primarily for servers with more than one network adapter or with multiple IP addresses assigned to a single network adapter. For systems with more than one network adapter, you can host a different site on each adapter by choosing the appropriate IP address in this field. If you have a network adapter with multiple IP addresses assigned to it (see Chapter 6), you can assign a different Web site to each address. Although the latter configuration is primarily seen in larger Web-hosting type arrangements, it can still be useful. If you'd prefer to have IIS simply display the same site to any IP address configured on the server, leave the default All Unassigned value in place; otherwise, select the appropriate IP address from the pull-down list.

**TIP** If you are going to have an internal, private Web site published on your internal network adapter and an external, public Web site published on your external Internet network adapter, make sure that the IP address for your internal adapter is unreachable from the outside world. You can test this by trying to ping—from the public Internet—your internal IP address, or by trying to connect to it via a browser.

### HTTP PORT FOR WEB SITE

The second thing the Web Site Creation Wizard needs to know is which port to use for your Web site. By default, port 80 is the standard port assigned to the HTTP protocol. If you will be hosting a public Web site, accessible to anyone, leave the selection at port 80. Browsers will try to connect to Web sites on this port when a user types in a URL. However, if you have custom needs or want to secure your Web site a bit, you can change this port to any number from 1 to 65535. To connect to your Web server with a customized port, users will need to know the port number and append it to the URL string as follows: `http://www.redhilltown.com:9000/`. This would direct a user's browser to attempt to open up an HTTP session on port 9000 instead of the default port 80. So, for example, you could access my Web site as `http://www.minasi.com/` or `http://www.minasi.com:80/` and either would work.

### HOST HEADER RECORDS

Unique IP addresses were once the way that multiple Web sites were hosted on the same physical box. However, since IP addresses are becoming more and more of a commodity, there is a means of assigning multiple Web sites to the same IP address and port number through the use of something called host header names. A host header name is a way to include the host name a browser is requesting (e.g., `www.microsoft.com`) into the HTTP header transmitted to the HTTP server. Modern (post-1997) browsers not only say to Web sites, "Please give me your Web pages," they also say, "Please give me your Web pages—and by the way, *I think I'm talking to* `www.bigfirm.biz`." That's important because just one Web site can have several names; for example, if you type `www.minasi.com`, `www.learnwindows.biz`, or `www.windownetworking.info`, you'll still end up at my Web site. It doesn't matter which URL you use to get to my site in this case. But that same Web server also runs a completely different site, `www.softwareconspiracy.com`. The IP addresses and port numbers are the same for the two Web sites, so how does IIS know which site you want? It listens to that host header record that your Web browser sent along with its HTTP request.

More specifically, when a client browser begins to open a Web site, it will (by default) look up the IP address for the host name in the URL and open a TCP connection on port number 80. Once that connection is established, it will transmit its request for a page to the server and include the host header name information in with the request. IIS will look at the host header name information, compare the name to those in its list of servers, and then respond accordingly by returning the correct pages for the corresponding site. This is a quick and easy way to host multiple sites on a single server, but clients must be using at least Microsoft Internet Explorer 3 or Netscape Navigator 2 for this to work correctly. Anyone using an earlier browser will be directed to the default Web site instead.

### SSL AND HOST HEADER CONFLICTS

SSL is the means by which Web servers and browsers can maintain secure communications between each other. You have probably used SSL if you have ever purchased anything over the Internet.

SSL and host header names don't mix. If you are planning on using SSL, you can only assign one host header name to your site, since the domain name is encoded in the certificate. If you need to host multiple SSL sites on the same box, use multiple IP addresses.

---

Once you have all the information entered correctly, click Next to move on to the next step of the wizard, shown in Figure 17.11.

**FIGURE 17.11**

Specifying  
anonymous access  
and the path to files  
for a site

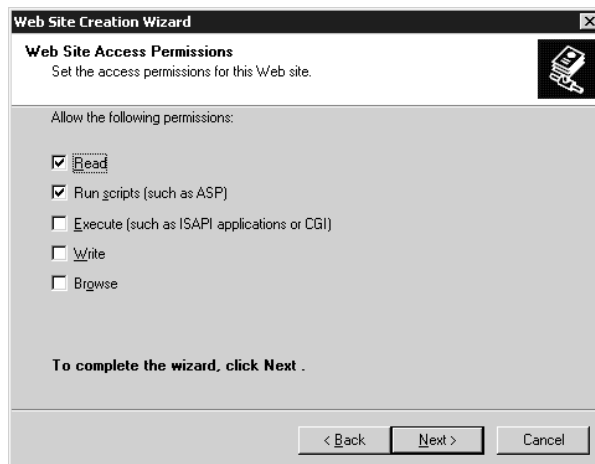

Now you will define a location for your files for this Web site, and whether to allow anonymous access to the site. The path is pretty much straightforward: enter the local path that IIS should use for files when someone connects to this site. Or, if you intend on hosting your content on another machine within your organization, you can enter a UNC path in the form of `\\servername\sharename`. If you choose the UNC option, the wizard will prompt you for an appropriate username and password combination to use when retrieving content from the target system.

If you will be making this a publicly accessible Web site, leave the Allow Anonymous Access to This Web Site box checked. This will allow any user to connect to the Web site without providing any form of authentication. However, if you want this to be a private, secured site, uncheck the box to remove anonymous access. Specific security settings that you can apply are discussed in the “Modifying Web Site Properties” section later in this chapter. Click Next to move on to the final step in the wizard, shown in Figure 17.12.

**FIGURE 17.12**

Setting Web site  
access permissions

The last step in the Web Site Creation Wizard is to define access permissions to be used for this site. The permissions applied here will start at the root of the site and automatically be applied to any subdirectories below this site. Of course, you can always change the site settings later, or implement custom settings for any subdirectories below the site. Briefly, each of these access settings controls the following:

**Read** Allows users to read files from your Web server. In most instances, you will want this option set for the root of a new site. The primary reason for disabling this option is for directories that contain CGI (Common Gateway Interface) or ISAPI (Internet Server Application Program Interface) applications, which will usually be set on a subdirectory level.

**Run Scripts (Such as ASP)** If you need to allow the execution of Active Server Pages (ASP) scripts on your site, enable this option.

**Execute (Such as ISAPI Applications or CGI)** If you need to allow the execution of ISAPI or CGI applications on your site, enable this option. When you enable this option, it is inclusive of the Run Scripts option as well.

**Write** If client browsers either will need to upload files on your Web server or will be writing data to a file (maybe filling out a registration form or something like that), you will need to have write permissions enabled. Personally, I prefer to only enable write permissions in subdirectories of a Web site, not the main directory itself.

**Browse** If a user does not send a request for a specific file on your Web server (for example, `default.html`) and there is no default document defined on your system, IIS will return an HTML representation of the files and subdirectories in the root of your site. Except in special circumstances, this option should be left disabled.

Once you have defined the necessary security for your site, click Next to finish the wizard, and your Web site will be created. If you have HTML content to publish, you can start by putting the necessary files in the directory you defined for this site. By default, all new Web sites (unless you changed the master properties for this option) will look for a file named `default.htm`, `default.asp`, `index.htm`, or `Default.aspx` (in that order) to use as the default home page, so make sure that the file you want presented to users when they first connect to your site is named appropriately. Using a client workstation with a browser, test your site to make sure that it is operating correctly.

And don't forget the NTFS permissions! When an anonymous Web user tries to access content such as an HTML file, a JPEG, or the like, NTFS thinks that person is the user named `IUSR_computername`. If you have denied that user access, then people on the Internet won't be able to get to your Web site—IIS will pop up a box requiring them to log in.

**TIP** You can also use the command-line script `iisWeb.vbs` to create or delete Web sites and to stop, start, or pause individual sites. To create a site called Web Pizza, for example, with a home directory at `F:\PizzaSite` and a host header name `www.Webpizza.com`, you would use the following syntax: `iisWeb /create F:\PizzaSite "Web Pizza" /d www.Webpizza.com`. If you don't want IIS to start the site right away, add the switch `/dontstart` to the end of the line.

## SETTING UP MULTIPLE VIRTUAL WEB SITES

With that background out of the way, let's look at how to set up more than one separate and distinct Web site on an IIS server.

In early versions of IIS, hosting multiple Web sites (sometimes referred to as “virtual sites”) on the same physical system was often a tricky operation, sometimes requiring modifications to the system Registry. Fortunately, this process has been made much easier in IIS 5 and 6. To host two different Web sites on your server, one for `www.redhiltown.com` and one for `www.hawkmoon.org`, you’d follow these steps:

1. Create DNS records for each of your Web sites, each pointing to the same IP address or to unique IP addresses. (For more information on creating DNS records, please see Chapter 7).
2. Choose how you want to determine which site on your server visitors are trying to reach, via one of the following options:

**Host header records** The easiest of all three choices, host header records allow you to specifically enter the site name—for example, `redhiltown.com`—in your definition of a Web site. As you’ve just read, modern browsers (IE 3 or Netscape 2 or later) will transmit the name of the site to the server, and the server will return the pages for the appropriate sites.

**Multiple IP addresses** Whether you have multiple NIC cards installed in your server or you have programmed multiple IP addresses for a single NIC card, assigning a unique IP address to each unique Web site is one of the more common ways to host multiple Web sites on the same system. In the IP address, enter an appropriate, unique IP address for each site that matches the DNS records you defined.

**Unique port numbers** Although less common than the other two methods of hosting multiple sites, using a unique TCP port number for each site can also allow you to host multiple sites on the same system. This is more commonly seen with sites that don’t need to be publicly accessible, since browsers will use port 80 by default. You can enter a custom port number in the TCP port field; however, client browsers will have to append the port number to their URL to be able to access the site (e.g., `http://www.redhiltown.com:200` for accessing port 200).

3. Using the Web Site Creation Wizard, create the new Web sites on your system. Define each site with a unique host header name, IP address, or TCP port—depending on how you want to control virtual sites on your system. If you accidentally create a conflict with a Web site using the same IP address and TCP/IP port, or if DNS can’t resolve the specified host header name, you’ll see an error message and the site will not start. Once you correct the problem, start the Web site by right-clicking it and choosing Start from the Context menu.
4. Place the necessary Web content for each site in the directory defined for the site. Now go test it with a browser, or select the site in the IIS MMC, right-click and choose Browse from the context menu to open the home page in the results pane of the console.

#### A MULTISITE EXAMPLE, STEP-BY-STEP

Let’s wrap up this section with an example of how you’d put a site named `www.joeslabs.com` and another named `www.janesmarket.com` on a single server—say, on a machine named `spider.acme.com` at 210.10.20.40:

1. Create a folder for the Joeslabs content on the `spider.acme.com` machine; for example’s sake, let’s say that you put it on `E:\joeslabs`. Put the files relevant to the Joeslabs site—`default.htm`, the JPEGs, any other HTML or script files—in `E:\joeslabs`.

2. Similarly, create a folder for the `www.janesmarket.com` content, perhaps on `E:\janesmarket`. Put the Janesmarket content in `E:\janesmarket`.
3. Ensure that DNS points to 210.10.20.40 for both `www.janesmarket.com` and `www.joeslabs.com`. In each zone, you'd probably just create a CNAME record pointing to `spider.acme.com`.
4. Install IIS on `spider.acme.com`.
5. Create the Joeslabs site: From the `iis.msc`, right-click the icon representing `spider.acme.com` and choose New/Web Site, which starts up the Web Site Creation Wizard. Click Next to get past the opening screen, then type in some descriptive text for the Joeslabs Web site: **Joeslabs Web site** will do fine, although the actual text is pretty irrelevant; it's mainly to remind you as the Web administrator which of your sites does what. Then click Next to get to the IP Address and Port Settings page.
6. In the IP Address and Port Settings page (see Figure 17.10 earlier in this chapter), you'll see the three alternative methods that you can use to distinguish this site from others running on this server: you can use a different IP address, a different port, or a different host header record. Of the three, the third option—different host header record—is by far the easiest and least costly. (Who wants to burn up an IP address for each Web site? Well, you'd have to if you were still using IIS 4!) In the field labeled Host Header for This Web Site (Default: None), fill in the URL that you want people to use when referring to this site—**www.joeslabs.com**.
7. Click Next and then fill in the home directory for this site, which means point the server to the folder with the content. Fill in `E:\joeslabs` and click Next.
8. Set the access permissions on this directory. In most cases, you can just take the defaults and only allow users to read files and run scripts. Click Next and then Finish, and `www.joeslabs.com` is done.
9. Repeat Steps 5 through 8 to create the `janesmarket.com` site, but choose a different IP address, port, or host header name to distinguish this Web site from the Joeslabs Web site.

## Modifying Web Site Properties

Once you are sure that your site is functioning correctly, you might find a need to fine-tune some of the parameters of the site. To change any of the settings for your site, return to `iis.msc` and select your site in the scope pane. From the Action pull-down menu, select Properties to edit the properties pages for this site.

### WEB SITE PROPERTIES

The Web Site properties tab shown in Figure 17.13 contains some general parameters for your Web site:

**Web Site Identification** Here, you can change the description, IP address, TCP port number, or SSL port number assigned to your Web site. Obviously, changing any of these options will change the way clients access your site, so plan your changes accordingly. If you want to change the host header record for your Web site, click the Advanced button to get to the advanced identification properties for this site. As you can see from the example in Figure 17.14, it's possible to have the same Web site associated with several different identities (defined by different IP addresses, TCP/IP port numbers, or host headers). For example, if you want clients to see the same Web site

whether they point their browsers to `www.salome.com` or to `www.hawkmoon.org`, add an additional identity for the Web site by clicking the Add button and specifying a different IP address or host header name to associate with this site. From the dialog box that appears (see Figure 17.15), you can change the host header name for this Web site either by adding a new identity (IP address, port, or host header name) or by modifying the existing record.

**FIGURE 17.13**  
Web site properties  
for an IIS Web site

**FIGURE 17.14**  
Advanced Web Site  
configuration  
properties

**FIGURE 17.15**  
Advanced Web  
site identification  
properties

**Connections** Returning to the properties page shown in Figure 17.13, the next group of options you can modify is how IIS will manage incoming connections. You can enter a time-out value for IIS to close out idle connections, and you can enable HTTP keep-alives. Enabling HTTP keep-alives allows client browsers to maintain an open connection in between individual requests to a Web server. Since Web pages are often made up of several elements (text, graphics, etc.) that must be opened individually, this option increases performance on servers. Disabling this option could cause browsers to open a separate connection for each Web page element.

**Enable Logging** You can enable or disable logging for this Web site by checking or unchecking the Enable Logging box. Since log files take up space on your system, you might consider disabling this option for an internal Web site. If you enable logging, you have format options to choose from in the Active Log Format pull-down box, including W3C Extended Log File Format, ODBC Logging, NCSA Common Log File Format, and Microsoft IIS Log File Format. Depending on which option you choose, you can edit properties for that format by clicking the Properties button. For example, choosing the ODBC Logging option and clicking Properties will take you to a dialog box where you can define the ODBC data source name, table, etc. The W3C Extended Log File Format properties will allow you to define how often new logs are created, where they are stored, and which data items to log.

## PERFORMANCE PROPERTIES

The next options you can configure for your Web site are performance related, and can be found under the Performance properties page shown in Figure 17.16.

Depending on the size of your Web site and the amount of traffic you expect you will be handling, you can modify these parameters to adjust the behavior of your site:

**Enable bandwidth throttling** As I discussed back in the “Master Properties for Web Sites” section, you can control the amount of bandwidth that the overall server or an individual site can consume. Settings defined here will override the master settings. Refer back to Table 17.1 for a listing of common bandwidth sizes and their translations into kilobytes/second.

**Limit Web site connections** You can limit the number of simultaneous client connections to your Web site, or use the master properties pages to limit the total number of simultaneous client connections to all sites. This is useful if your server is a busy Web server but also runs a mail server or performs other important tasks. Setting a limit can ensure that the system has enough memory and CPU resources to spare for its other tasks. The default setting for unlimited connections will permit as many connections as the system and network bandwidth can handle. Limiting the number of simultaneous connections can also protect your system against attacks aimed at overloading the server with thousands of client requests.

**FIGURE 17.16**  
Performance  
properties for an  
IIS Web site

**ISAPI FILTERS**

The next properties page—ISAPI Filters (shown in Figure 17.17)—lets you set options for which ISAPI filters are installed for a specific Web site and the order they execute in.

**FIGURE 17.17**  
ISAPI filters  
properties for an  
IIS Web site

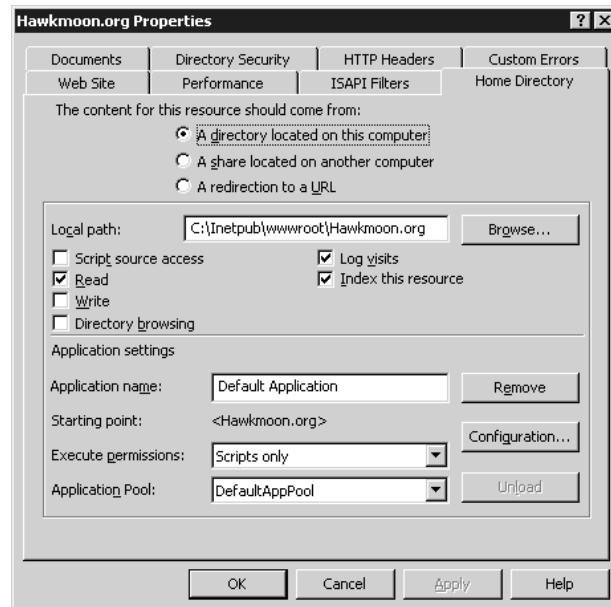

ISAPI filters are programs that respond to events that occur on the server during the processing of an HTTP request. The ISAPI filters displayed in this property page are active for this Web site only, although filters may also be defined globally for the Web server. In that case, both sets of filters apply for the Web site. If two or more filters are registered for the same event, filters with a higher priority are executed first. Filters can be added, removed, modified, or disabled from this list by using the buttons on the right side of this properties page. To change the order of execution for filters, adjust them with the Move Up and Move Down buttons.

### HOME DIRECTORY PROPERTIES

The next tab in the Web Site properties pages is the Home Directory page, shown in Figure 17.18. This group of settings lets you control where IIS will look for Web content, and what security permissions to use while handling it.

**FIGURE 17.18**

Home directory properties for an IIS Web site

By selecting the appropriate radio button on the top of this properties page, you can control where IIS will go to look for the content for this site, or if it will send users to another Web site. Based on the selection you make, the lower portion of this properties page will change accordingly. If you select the option for a directory located on this computer, you will need to enter the local path in the middle section (as in Figure 17.18) of the dialog box.

If you select the option for a share located on another computer, the Local Path field will change to a Network Directory field, where you will need to enter the correct \\servername\sharename UNC path. When you choose to use a share located on another computer for your files, you might need to use the Connect As button that appears to enter logon credentials for the IIS service to use when it is accessing the other system. The IIS service will actually log in to the other system, retrieve the files, and present them to the user just as if the files were local. This is a great way to distribute

an entire Web site throughout an organization. If individual departments are responsible for maintaining different sections of a site, you can use this feature to direct requests for their content to their servers, instead of requiring all your departments to publish their data to one system.

Lastly, if you choose to redirect users to another URL, IIS will create an HTML redirection page pointing users to the URL you specify. The Local Path field will change to a Redirect To field, where you can enter a full URL to send users to. Redirecting users to a URL can be configured through three different options: redirect users to an exact URL, redirect users to a lower subdirectory, or permanently redirect users to an exact URL. Redirecting users to an exact URL is pretty straightforward; users are sent to the exact URL you enter, just as if you typed it into their browser for them. Redirecting users to a lower subdirectory will let you create an alternate directory in your Web site structure. The last option, for permanently redirecting users to a URL, is very similar to the first option, with the exception that a permanent redirection will send a “301 Permanent Redirect” message to the browser, instead of the usual “302 Temporary Redirect.” The net result of this is that some browsers will modify any bookmarks or favorites on file if they receive a permanent redirection.

If you chose either of the first two options for your content location—a directory on your IIS computer or a share on another server—several security settings will be displayed under the Local Path field. These settings can be used to control what can and can’t be done on your site:

**Script Source Access** This option is only available when read or write access is enabled. This option allows access to source code, including scripts in ASP applications.

**Read** Allows users to read files from your Web server. In most instances, you will want this option set for the root of a new site. The primary reason for disabling this option is for directories that contain CGI or ISAPI applications, which will usually be set on a subdirectory level.

**Write** If client browsers either will need to upload files on your Web server or will be writing data to a file (filling out a registration form, etc.), you will need to have write permissions enabled. It’s safer to enable write permissions only in subdirectories of a Web site and not in the main directory itself.

**Directory Browsing** If a user does not send a request for a specific file on your Web server (for example, `default.html`), and there is no default document defined on your system (see the next section), IIS will return an HTML representation of the files and subdirectories in the root of your site. Except in special circumstances, this option should be left disabled.

**Log Visits** Depending on whether or not you want logging information stored about visitors to your site, check or uncheck this box. Logs will be stored in the format defined in the Web Site properties page described earlier in this section.

**Index This Resource** To speed searching for text data, select Index This Resource, which will cause the Indexing Service to index all the content of this site.

**Application Name** If your site is going to be the starting point for an application, this is where to enter the name of the application.

**Execute Permissions** This pull-down box will let you define whether or not to allow the execution of scripts, the execution of scripts and executable files (`.exe` and `.dll`), or nothing at all.

**Application Pool** To prevent errant applications from taking out other processes on your system, you can assign applications to be run by one or more dedicated worker processes. The set of one

or more applications and one or more dedicated worker processes is called an application pool. Applications can run alone, in a dedicated application pool, or together in a pool with other applications. This feature is only available when the server is running in worker process isolation mode. If you must run the Web server in IIS 5 isolation mode for compatibility with applications designed for IIS 5, this option will be named Application Protection and you can choose between Low, Medium, or High protection levels. Low protection will allow applications to execute in the same memory space as the IIS process itself; medium protection will pool applications for this site together; and high protection will isolate each application from any others.

## DOCUMENTS PROPERTIES

Continuing with our Web site configuration, the next settings tab in the Web Site properties pages is the Documents tab, shown in Figure 17.19

**FIGURE 17.19**

Documents properties for an IIS Web site

Unless a visitor has clicked a link to a specific page on a Web site, it's much more likely that they will try to connect to a Web site using the name `http://www.redhilltown.com`, for instance, than with the address `http://zooropa.redhilltown.com/default.htm`. When users attempt to connect to your Web server without specifying a specific document to retrieve, IIS will look through the list of default documents (if enabled) to return to the user. By default, the IIS installation process will add `default.htm`, `default.asp`, `index.htm`, and `default.aspx` to this setting in the master properties, which are then inherited by each Web site. If for some reason you would prefer to use another name, you can add the name to the list of default documents by clicking the Add button. IIS will look through this list, in order, and return the first matching document it finds. If you would prefer to adjust the order, use the arrows to the left of the document list to place the documents you want to look for first at the top of the list.

If you want to have every Web page within your site sent out with a common footer (for example, copyright and disclaimer information), you can have IIS do this by selecting the Enable Document Footer option. The document footer is an HTML file that IIS will merge in at the bottom of each page it displays. The footer file should not be a complete HTML file in and of itself (with `<HTML>` `</HTML>` tags, for example). Instead, it should just contain the basic HTML code you want displayed, for example:

```
<h2>This is a footer</h2>
```

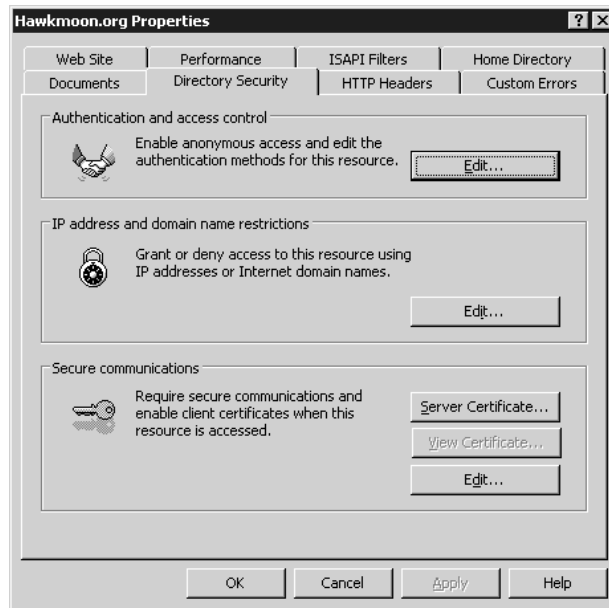

This is all that would be necessary for a footer file to display the text shown as a heading type 2.

### DIRECTORY SECURITY PROPERTIES

The next section of the Web Site properties pages—Directory Security—allows you to control access to your Web site based on authentication, client IP addresses, or ACL settings on files, and gives you the ability to secure communications when clients connect to this Web site. The Directory Security properties page is shown in Figure 17.20.

**FIGURE 17.20**

Directory security properties for an IIS Web site

One method for securing a Web site is to define an authentication method to validate users. Since browsers—by default—will try to access a site anonymously, one option available is to remove anonymous access from your site. Click the Edit button in the Authentication and Access Control box to edit the authentication properties of your system. The Authentication Methods dialog box is shown in Figure 17.21.

By default, IIS will allow anonymous access for Web sites and directories, unless you have overridden this option in the master settings. There are two primary means of securing your Web site—or certain areas of your Web site. The first is to remove the check mark from the Enable Anonymous Access box. This will effectively make your entire site a secured site and require an authentication

before a user is allowed to connect at all, even to the default home page. If you choose this option, then the Authenticated Access area in the lower half of the figure becomes important in determining just how clients will authenticate themselves. If you remove anonymous access from your site, you must have some authentication option selected, or else you will effectively disable all access to your site.

**FIGURE 17.21**

The Authentication Methods dialog box

The options under Authenticated Access control what level of authentication users must negotiate to get connected to your protected site. The details of each type are as follows:

**Integrated Windows Authentication** If both the client and server are using Active Directory Services, Kerberos 5 authentication will be used. Otherwise, the method used will be NT Challenge/Response Authentication (also known as NTLM). In this process, the user is not initially prompted for a password. The browser passes the current username and password information to the server transparently. If the transparent authentication attempt fails, the browser will prompt the user for a Windows username and password. You guessed it; integrated Windows authentication requires users to use Internet Explorer for their Web browser. Instead of the actual passwords, Internet Explorer sends a password hash. User accounts are checked against the accounts in the domain of the IIS server. Any version of Internet Explorer after version 2 can support this method of authentication. Since this type of authentication does not work with HTTP proxies or with firewalls that use HTTP proxies, it's best suited for use on intranets. Windows authentication, like anonymous authentication, is enabled by default.

**Digest Authentication** Digest authentication securely transmits an MD5 hash value over the Internet instead of a password, thus keeping system passwords confidential. There are a few requirements for using this type of authentication, however. Namely, client workstations must be using Internet Explorer version 5 or later, users must have a valid account in the Active Directory, and user passwords in the Active Directory must also be stored as cleartext.

**TIP** *If the IIS server is a Windows Server 2003 domain controller, you can edit a metabase key called `UseDigestSSP` to enable Advanced Digest Authentication, which will store the MD5 hash for passwords in the Active Directory instead of cleartext passwords.*

**Basic Authentication** This is the most basic level of authentication (and therefore the most widely supported) for validating a user accessing a Web resource. Practically all Web browsers, including Microsoft's and Netscape's, support this type of authentication. Using this authentication method, usernames and passwords are transmitted in cleartext and checked against the accounts in the domain of the IIS server (if you would like to use accounts on another domain for validation, click the Select button next to Default Domain). If you expect to be running a public Web site, accessed by users on various platforms and browsers, this is probably the best option for requiring authentication on your site; however, it is the least secure of all the authentication types unless you use it in combination with SSL. Not only are passwords transmitted in an unencrypted form, but the user accounts also need the Log On Locally right. If your IIS server is a Windows Server 2003 domain controller (and this is not necessarily recommended), you will have to explicitly grant user accounts on the server the right to log on locally.

**.NET Passport Authentication** The Windows .NET Passport online authentication system is designed to benefit e-commerce Web sites by making it easier and faster to sign in and to make online purchases. Selecting this authentication method tells your server to validate accounts with a .NET Passport Server instead of using a local accounts database or the Active Directory. Since .NET Passport uses standard Web technologies like cookies, SSL, and JavaScript, it is compatible with Internet Explorer 4 and later, Netscape Navigator 4 and later, and even some Unix browsers. On the down side, though, the licensing fees to use .NET Passport can be steep. For more information, check out the .NET Services information at Microsoft's Web site.

## USING NTFS PERMISSIONS TO CONTROL ACCESS TO WEB SITES

If you want to make some areas in your Web site open to the public while leaving other areas protected, permit anonymous authentication but also set permissions on the specific files and directories you want to protect. This will only work on NTFS volumes (you can't define permissions on FAT volumes).

When anonymous authentication is enabled, IIS will use the anonymous user account first to try to read a file and pass it back to the user requesting it. For publicly accessible Web content, without any permission settings restricting access, the IIS process should be able to access that content via the anonymous user account (`IUSR_servername`). However, if IIS fails in accessing that file due to a security restriction, it will look to the authentication options defined previously to determine whether it should request an authentication from the user. If an authentication option is set, IIS will prompt the user for a username and password combination (or retrieve that information transparently, depending on the authentication method), and then attempt access using those credentials. Therefore, if you want to restrict access to specific files or directories to certain users, simply add the users or groups to the permissions applied to those files or directories, and exclude or deny access for the anonymous user account. (For more information on placing security rights on files in NTFS, see Chapter 10.)

Another means of securing a Web site is to restrict who can access the site based on an IP address, a range of IP addresses, or a domain name. This requires knowing in advance who should be connecting

to your site and from where, but it is particularly useful when setting up Web sites designed to interface with clients or suppliers. Click the Edit button in the IP Address and Domain Name Restrictions area shown in Figure 17.20 to see a screen similar to the one in Figure 17.22.

**FIGURE 17.22**

The IP Address and Domain Name Restrictions dialog box

Select the appropriate radio button option to either grant access or deny access to everyone, and then enter the exception list by selecting Add. Exception list entries can be defined by individual IP addresses, network addresses, or by domain name. Individual IP address restrictions can be useful for home users, provided that they have a static IP address assigned by their service provider. However, it is more common for home PCs and laptops on the road to use dynamically assigned IP addresses. Sometimes a business will use a firewall or proxy server that hides all internal IP addresses and uses a single address as the source for all internally generated requests. In that case, you could permit connections from that business and refuse all other connections by entering the IP address of the firewall or proxy server. Groups of computers with static addresses or with dynamic addresses that will always fall within certain network numbers can be defined by entering a network address and subnet mask. Domain name restrictions are only useful as a last resort when you don't know the IP addresses of client systems that will be accessing your Web server. Since IIS only identifies connections by a source IP address, the server must do a reverse-DNS lookup, which can slow down server response time significantly. Unless your situation requires using domain names, it's probably worthwhile to find out the exact IP address ranges to allow into your site and configure them accordingly.

**NOTE** Many hosts out on the Internet don't actually have reverse-DNS records assigned to them, and some hosts have incorrect reverse-DNS records assigned to them. Therefore, if you were to put in a restriction based on a host/domain name, it might not work quite as well as you expect.

Although source IP addresses can be faked, and should not be used as the sole means of protecting sensitive content, IP address restrictions can be combined with authentication restrictions, allowing for some very secure Web site access. For example, if you have users who frequently work from home—on a computer with a fixed IP address—you could secure your site (or a portion of it) by allowing connections only from specific IP addresses, and also require a secure user authentication before allowing access.

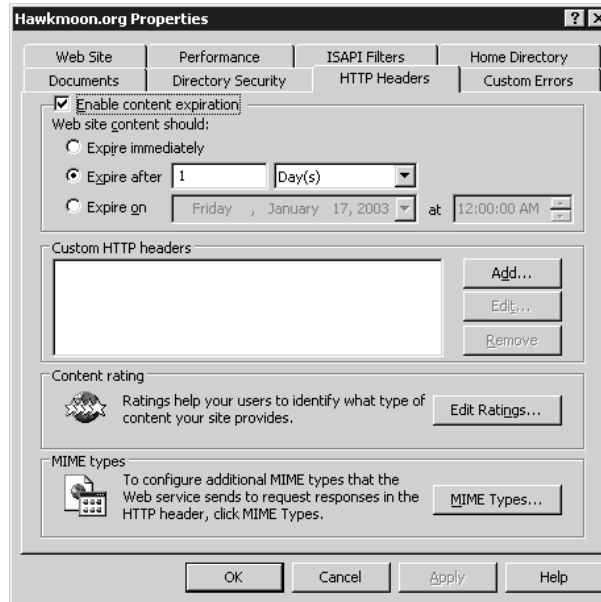

The last option for securing a Web site is to require encrypted communications between the client browser and the server, preventing anyone from intercepting data as it travels across the Internet. This is done with SSL (Secure Sockets Layer) encryption, discussed later in this chapter in the “Communicating Securely with SSL” section.

### HTTP HEADER PROPERTIES

The next group of settings you can control for your IIS Web site are what headers the IIS service should include with HTTP pages it transmits. These parameters are adjusted under the HTTP Headers tab, pictured in Figure 17.23.

**FIGURE 17.23**

HTTP header properties for an IIS Web site

HTTP headers let you control several things that your Web server will transmit to Web browsers along with the HTML pages on your site. The primary things most administrators want to control are content expiration, content ratings, and MIME file types. However, custom headers can be added as necessary for new HTML standards that haven't been implemented in IIS yet.

By checking the Enable Content Expiration box, you can effectively control how browsers will handle their cached pages when communicating with your site. If a user has visited your site before, the pages may still be in the cache of their machine; however, you may only want pages to be valid for a day or two, depending on the type of material being presented. By selecting an expiration option (to expire immediately, expire after a certain number of days, or expire on a set date) you can force browsers to request a new page from your server after the expiration interval has been reached.

If your Web site will be hosting material that contains content some people might find objectionable, you can enable content ratings for your site or for areas of your site as needed. In the Content Rating area, click the Edit Ratings button to open the Content Ratings properties page. From there, you can learn about the Platform for Internet Content Selection (PICS) system that was developed by the Recreational Software Advisory Council (RSAC) and is used to determine a "rating" for a Web site's content. There is also a questionnaire that you can walk through to determine an appropriate rating for your Web site. Once you have a set of ratings you want to apply to your site, click the Ratings tab in the Content Ratings properties page to begin entering those ratings (see Figure 17.24).

**FIGURE 17.24**  
Implementing  
content ratings

As you can see from the screen, there are four primary categories for rating a Web site—violence, sex, nudity, and language. For each of these categories, there are five levels—0 through 4—that dictate how strongly offensive the content of your site is in each category. For example, level 0 for language is defined as “inoffensive slang,” while level 4 is defined as “explicit or crude language.” The settings you apply here will have a direct correlation to the content settings available in Internet Explorer or Netscape Navigator, and will effectively block visitors from reaching your site if your content ratings exceed their browser settings. Set your ratings accordingly and enter an e-mail address and an expiration date for your content settings. Once the content ratings are set, IIS will transmit them out with every page on the corresponding Web site or subdirectories of the site.

If you have a need to add or remove MIME types for this site, go back to the HTTP Headers tab and click the MIME Types button. Use the MIME Types dialog box to add additional MIME file types by clicking the New button and entering the appropriate associated extension and content type as prompted. The content type should be in the format of *MIME type/filename extension*. To remove a MIME file type, highlight the file, type in the list of registered file types, and then click the Remove button. The file extensions defined in the properties pages of an individual site will apply only to that site. The master properties pages for the Web server (accessed by right-clicking Web Sites in the *iis.msc* console) define mappings for all Web sites.

If there are custom HTTP headers you would like transmitted to browsers along with each page, enter them in the Custom HTTP Headers box by clicking the Add button. One thing custom headers are useful for is for HTML standards that have been developed but have not made their way into IIS yet.

#### **CUSTOM ERRORS PROPERTIES**

When building your Web server and Web sites, there may be occasions when you want to control how and what is displayed to users who receive an error. For example, you might want to have a custom HTML page displayed when a user reaches a 404 error (file not found). To customize the

error messages on your site, click the Custom Errors tab on the Web site properties pages. The page for custom errors is shown in Figure 17.25.

**FIGURE 17.25**  
The Custom Errors  
properties page

Through this dialog box, you can choose from having a default error message, file, or URL displayed for any type of HTTP 1.1 error. The HTTP error types (along with their subtypes) are listed in the left column, the types of response are in the middle column, and the details of those responses are in the right column. In a default installation of IIS, some messages will contain default responses (just one line of text), and other errors will be defined by HTML files. Windows Server 2003 stores its default IIS error message files in the %systemroot%\help\iisHelp\common directory; you can use these as templates to define your own error messages. To change an error message on your system, find the HTTP error number you want to change in the list (along with the subtype if necessary) and click the Edit button to modify the properties of that error message. From the Error Mapping Properties dialog box, you can change the message type and the location of the file or URL to display (if you've chosen that type of response).

**FRONTPAGE SERVER EXTENSIONS**

Microsoft FrontPage server extensions are server-side components that permit Web developers to open and author a Web site using the FrontPage client. Before this is possible, FrontPage server extensions must be installed on the server (they are not installed by default), a virtual server must be created for each Web site that will be available to FrontPage, and the Web site must be *extended*, which is just a fancy way of saying that server extensions must be explicitly enabled for the site.

Once you install FrontPage server extensions using the Windows Component Wizard in Add/Remove Programs, each Web site's properties pages will include a tab called Server Extensions 2002. If you've just created a new site, you won't see anything under this tab (except for instructions on how

to enable the extensions) until you extend the Web site. By the way, don't think that you must enable FrontPage extensions at all—unless your organization has standardized on FrontPage Web development, there are easier ways to manage content and content development. Simple FTP or Web Distributed Authoring and Versioning (WebDAV) are two alternatives that come to mind.

Installing FrontPage extensions on the server creates a Web site named Microsoft SharePoint Administration. This is the administrative Web site for FrontPage server extensions and replaces the wizard and property pages used to configure FrontPage extensions in IIS 5.

### Enabling FrontPage Server Extensions

To enable server extensions to a site, highlight the site in `iis.msc`, and select the Configure Server Extensions 2002 option from the All Tasks item in the Action pull-down menu. Or right-click your site and select the same option, as shown in Figure 17.26.

**FIGURE 17.26**

Adding server extensions to a site

This will open an HTML-based form (shown in Figure 17.27) for extending the site. The form confirms the name of the Web site to extend and asks you to confirm the administrator account for this virtual server. If the default information is correct, you need only to click the Submit button to enable the server extensions.

Once you've enabled server extensions for the Web site, the Server Extensions 2002 tab in the site's properties pages will contain a Settings button, which takes you to the general server extensions configuration pages. Use the Microsoft SharePoint Administrator Web pages to manage server extensions. When you install FrontPage server extensions on the system, a link to the Microsoft SharePoint Administrator is created in the Administrative Tools group.

**FIGURE 17.27**

Extend a virtual server with FrontPage extensions

## Virtual Directories

As I discussed in the previous section, a Web site's content is stored initially in a home directory. This home directory is considered the root directory (/) for the Web site and may point to a directory on the local system or a share on another system, or it can be a redirection to another URL. A bare-bones Web site may store all of its files together in the root directory. But as Web sites begin to grow there is often a need to organize levels of content into subdirectories off of the main root of the site. There are two ways to do this for a Web site. The first is to actually create a subdirectory in the root directory and place content into that directory. For example, let's say you have a site that is stored in `C:\Inetpub\wwwroot` and is accessed by a URL of `www.companyname.com`. If you decide you want to move all of your graphics files to a separate subdirectory, you could create a subdirectory called `C:\Inetpub\wwwroot\images` and then move all of your graphical content into that directory. To access files in that directory, client browsers would access the URL `www.companyname.com/images`.

However, what if you want to have content available as a subdirectory in your site, but you don't want to move the content to a normal subdirectory within your site's structure? Virtual directories are a means of adding a subdirectory off of the root of your site (or even a lower level of your site) and then creating an alias, or a pointer to a directory somewhere else on your system or on another computer on your network. By using virtual directories, you are not forced to move all of your Web content to one system and then place it in an orderly structure for visiting users. Instead, you can have content stored anywhere on your machine or on any system within your network, and users can access it through a simple directory structure.

For example, imagine that you want to visit a Web site named `www.redhilltown.com`. You click a link you found in a search engine, or type the address `www.redhilltown.com` into your browser. The IIS 6 server that answers to `www.redhilltown.com` receives the request, checks its configuration, and sees that the home directory for that Web site is `c:\inetpub\wwwroot\redhilltown`. Since you haven't requested a particular page, it returns the file `default.htm` from that directory. Now you are looking at the home page for the `redhilltown.com` site. You find several interesting links on the page; one is to a selection of images you might like to download (`www.redhilltown.com/images/default.htm`), another is to a "members only" private area (`www.redhilltown.com/private/login.asp`). You click the Images link. Although it's transparent to you the user, the Images directory is actually an alias

to the directory `d:\webdirs\redhilltown\newimages` on the IIS 6 server, and the private directory is an alias for a shared folder on another system completely. These three different directories could be stored on different machines and different physical hard drives, yet to the browsing user they all seem to be in one logical structure.

Virtual directories are useful for several reasons:

- ◆ They simplify the Web site structure from the user's point of view. A virtual directory can appear to be right off of the root of the Web server, whether it refers to a location that is ten levels deep in the directory structure or is stored on a separate physical drive or a separate system completely.
- ◆ They permit greater flexibility in organizing content. A corporate intranet may include virtual directories for several different departments that are actually stored and maintained on departmental servers instead of on the IIS server. If an administrator needs to move directories around, she only needs to modify the alias mapping instead of fixing every link on every darn Web page.
- ◆ They can provide another layer of security because a) users can't tell where the content is actually stored, and b) even if the root directory of a site is on a FAT partition and accessible to any anonymous user, you can still create a virtual directory pointing to a folder on an NTFS partition and limit access to authenticated users with file and directory permissions.

### CREATING A VIRTUAL DIRECTORY

To launch the Virtual Directory Creation Wizard, return to the Internet Information Services tool and highlight the Web site you want to work with in the Scope pane of the window. Select New/Virtual Directory from the Action pull-down menu, and the wizard will start walking you through the configuration process. The first step of the wizard is shown in Figure 17.28.

**FIGURE 17.28**

Defining an alias for a virtual directory

The first thing you will need to specify for your virtual directory is the alias that refers to it. The alias is the directory name that client browsers will need to use to access the directory. For example,

if a user were accessing the URL `www.companyname.com/documents` on your Web server, `documents` would be the alias. The alias does not need to match the name of the directory where the files are actually coming from, so you can use whatever name works best in this field. Click **Next** to proceed to the next step of the wizard, shown in Figure 17.29.

**FIGURE 17.29**

Defining a content directory for a virtual directory

If you want to define a virtual directory that points to another directory on the same computer, enter the path name here (such as `D:\documents`). IIS will define the virtual directory as pointing to another directory on the same server. However, if you want this virtual directory to point to data located on a share on another server, enter the UNC path to that system here. When you click **Next**, the Virtual Directory Creation Wizard will take you to another dialog box, shown in Figure 17.30, for entering user credentials.

**FIGURE 17.30**

Entering a username and password to access shared content via a virtual directory

When IIS needs to contact another server for Web content, it will need to do so with a specific username and password combination. Enter an appropriate set of credentials here, one that would have appropriate access rights to the content you are trying to reach. Click Next to move to the last step of the wizard—defining access permissions—shown in Figure 17.31.

**FIGURE 17.31**

Defining access permissions for a virtual directory

This step in the wizard is identical to the one mentioned earlier in this chapter and shown in Figure 17.12. Return to “Setting Up a New Web Site” for a description of these permissions.

Once you have entered all of the required information, you should have a new virtual directory item listed below your Web site. A virtual directory appears with a gear icon in the IIS Manager tool. You can make sure that the virtual directory is configured properly by launching a browser and then navigating to your virtual directory. To verify your virtual directory from the IIS Manager, just highlight the virtual directory, right-click, and choose Browse from the context menu. If everything has gone according to plan, IIS should return content from the appropriate location.

You can modify properties for a virtual directory in exactly the same manner that you would for a Web site—by editing the properties pages for the directory itself. You can edit the following properties pages for a virtual directory: Virtual Directory (equivalent to Home Directory for a site), Documents, Directory Security, HTTP Headers, and Custom Errors. These pages are functionally identical to the pages defined earlier in this section for modifying the properties for an entire site.

**NOTE** The `iisvdir.vbs` script can create and delete Web virtual directories from a command line. As an example, to create a virtual directory called `PizzaIngredients` for the Web Pizza Site at `f:\ingredients`, use the following syntax: `iisvdir /create "Web Pizza" pizzaingredients f:\ingredients`. If the physical path to the virtual directory doesn't exist, `iisvdir` will create it.

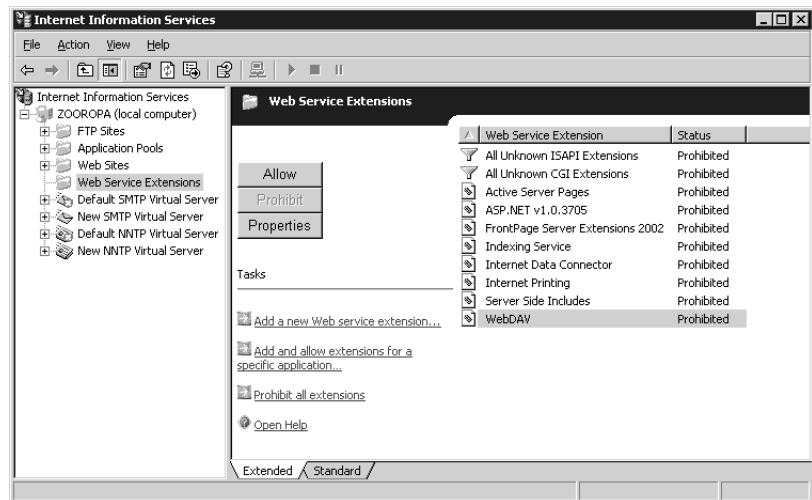

## Enabling Dynamic Content

A default installation of IIS 6 will only serve static Web pages. ISAPI and CGI extensions, Active Server Pages, Server Side Includes, and all of the handlers that generate dynamic context are disabled.

In other words, the Web server will not run the required DLL (or sometimes EXE) files required to support that type of dynamic content. If you need to host applications or just permit Indexing Service queries on your Web site, use the Web Service Extensions node in the IIS Management console to enable specific request handlers. From the IIS console, select the Web Service Extensions node. A custom taskpad will be displayed in the results pane, as shown in Figure 17.32. All Web Service extensions are prohibited by default. These extensions are simply one or more DLL files grouped together under a user-friendly name. For example, FrontPage server extensions use about six different DLL files. These library files may also be enabled or disabled individually to prohibit certain operations. To enable a specific extension such as the Indexing Service, highlight it in the results pane and click the Allow button. To disable all extension in one move, click the Prohibit All Extensions link. If you need to permit extensions that are not listed in the console, you may create and permit new extensions by clicking the Add a New Web Service Extension link. You will need to supply a friendly name for the new extension and a list of files that are required by the extension.

**FIGURE 17.32**

The Web Service Extensions taskpad

**NOTE** You may also use the `iisecnfg.vbs` script to enable or disable Web service extensions. To enable the extensions for WebDAV, for example, type the following single line at a command prompt: `iisecnfg /enapp webdav`.

## Using WebDAV

Web Distributed Authoring and Versioning (WebDAV) is a great way to manage Web site content; it's more user-friendly to Windows users than FTP file transfers and much simpler to use than FrontPage and its associated server extensions. You set up a WebDAV directory as a virtual directory on a Web site. Users with permission to access it can then use an integrated Web client component on Windows 2000 and XP Professional client systems to access the folder using Windows Explorer. In fact, the remote folder looks very much like a shared folder to the client, although the HTTP protocol is actually being used instead of the Windows file mounting service. WebDAV is particularly useful when an author needs to connect to a Web server through a firewall and upload content (it's not safe to permit file server connections through a firewall). Since WebDAV is designed

particularly for managing Web content, only one user can modify a file at a time. Authorized users can also move and copy files, search the directory structure, and modify attributes.

Before you can set up WebDAV publishing on your IIS server, enable the Web service extension for WebDAV, using the IIS MMC or `iiscnfg.vbs`. The procedure to enable a Web service extension is described in the previous section.

First, create a publishing directory anywhere on your Web server and set appropriate permissions on the resource. For convenience, this directory may be the same directory as the root of the Web site, or it may be the same path as another virtual directory in the Web site. If you must put the directory under `\wwwroot`, you'll need to change the default permissions, which only permit read access.

Next, create a virtual directory on your Web site and give it the alias WebDAV. Specify the path to the publishing directory and grant Read, Write, and Browse permission to the virtual directory. Once the virtual directory is created, open the Virtual Directory properties pages in the IIS MMC and go to the Directory Security tab. Edit the Authentication and Access Control settings to disable anonymous access and require integrated Windows authentication (this process has been described previously in the section on configuring virtual directories). You must use Windows integrated authentication and put your publishing directory on an NTFS partition, or user-level security cannot be enforced.

Now you are ready to have users connect to the WebDAV publishing directory. The simplest way for clients to do this is using the Add Network Place wizard on a Windows 2000 or XP Professional client system. You can access WebDAV folders with Internet Explorer version 5 or later. In our first example, we'll use the Add Network Place wizard.

From a Windows 2000 or XP Professional system, open My Network Places and click Add a Network Place. When the wizard asks you for an address or location, type the full URL of the publishing folder, including the virtual directory (`http://www.redhiltown.com/WebDAV`, for example). Give that sucker a friendly name, and you're done. A shortcut to the publishing folder will appear in the list of network places. If you specified that users must do Windows integrated authentication and you set appropriate NTFS permissions on the directory structure, users should not even be prompted for a username or password. The existing user context will be used to access the publishing folders.

To access the publishing directory from Internet Explorer, choose File/Open and type in the full URL including the WebDAV virtual directory, as you did in the Add a Network Place Wizard. Before you click OK, though, select the check box labeled Open as Web Folder. This tells IE that you want to be able to make changes in the folder; otherwise IE will just serve up the content like any other Web page. Since users will have Browse permission, they may see a list of files and folders, but access will be read-only.

## Working with Application Pools

IIS 6 has redesigned its Web service to support separate processes and memory space for Web sites, virtual directories, and applications. Because each site or application on the Web server can be assigned to one or more dedicated processes, problems, bugs, and failed processes are isolated and won't bring down the entire Web server or affect other sites. There are also a whole slew of configuration options that allow the Web service to monitor itself and implement safeguards against failures.

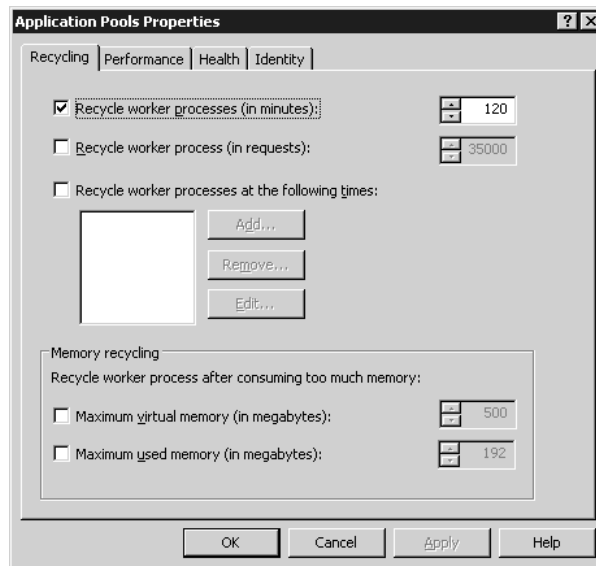

Application pools are only available when the HTTP service is running in the default mode, worker process isolation mode. If the Web server is running in IIS 5 isolation mode, the Application Pools node in the IIS MMC is not visible.

### CONFIGURING APPLICATION POOL PROPERTIES

Before you create any new application pools, let's take a look at the default settings. Select the Application Pools node in the IIS MMC, right-click and choose Properties from the context menu to view and modify the master properties for all application pools (shown in Figure 17.33). Like the master properties for Web sites, any new pools will inherit these global settings that you create, and properties set for individual pools will override the global settings. These properties pages are identical to the properties pages for new pools and for the existing default pool (DefaultAppPool).

**FIGURE 17.33**

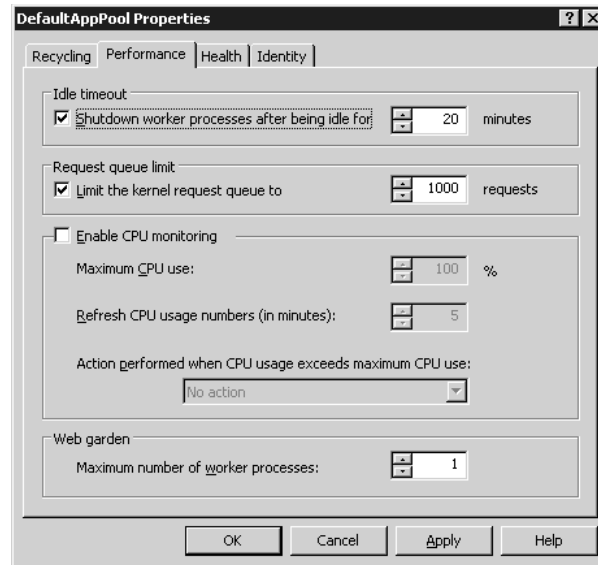

Recycling settings for application pools

The Recycling tab specifies parameters for process and memory recycling. Process recycling occurs when new worker processes (instances of `w3wp.exe`) start up periodically and old ones are killed off as they take care of any pending requests. This can be configured to happen at certain intervals, after a certain number of requests are processed, or at a particular time during a 24-hour period. If an application is suffering from a memory leak of some sort, you can also configure the worker process recycling options based on memory usage thresholds.

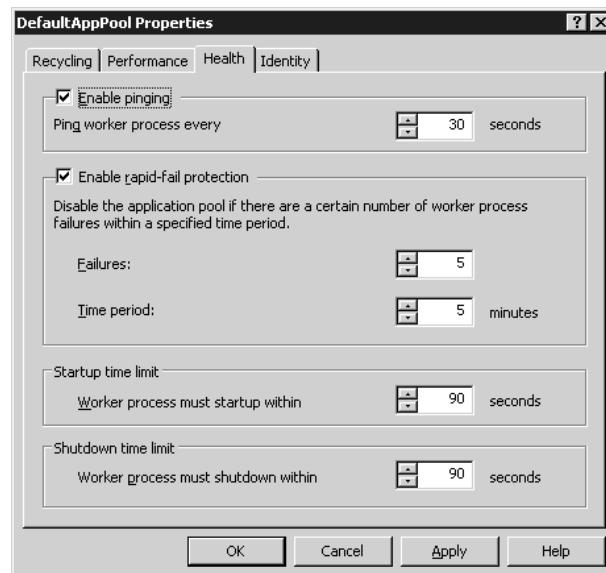

The Performance tab, shown in Figure 17.34, displays options to protect the server from becoming overloaded. The idle timeout interval permits a worker process to be killed after standing idle for 20 minutes. The request queue limit prevents overloading by monitoring the number of queued requests to the pool. When the number of requests exceeds the limit, new requests are rejected and a 503: Service Unavailable error is returned to the client. Enable CPU monitoring to prevent an application pool from consuming too much of the processor's resources. And finally, a Web garden is a fancy name for an application pool that can run more than one worker process. If you plan to take a lot of hits on a particular application, increase the maximum number of worker processes to distribute the workload.

**FIGURE 17.34**  
Performance  
Settings for  
Application Pools

The Health tab settings shown in Figure 17.35 can be used to monitor the, well, the health of your worker processes. By default, a worker process will be pinged every 30 seconds to confirm that it's still running. If the worker process does not respond in a timely fashion, the monitoring process (called the Web Administration Server, or WAS) will terminate the worker process and start another one.

**FIGURE 17.35**  
Health settings for  
application pools

By default, if the WAS detects a worker process failure (because of a failed ping or a dropped connection to the WAS control process), it restarts the worker process and sends a message to the

Event log. The rapid-fail protection function tells WAS that if it detects 5 failures within 5 minutes from the same worker process, it should immediately take the pool offline. If this happens, the Web server will start returning 503 messages to requests for the application.

The startup and shutdown time limits ensure that worker processes don't hang while starting up or shutting down. If they do hang, WAS orphans or kills them.

Use the Identity tab (shown in Figure 17.36) to specify a security account for the application pool. By default, application pools run as the Network Service account, which is a pretty powerless account. However, if you want to use another account, perhaps even a more powerless one, it needs to be a member of the IIS\_WPG group on the server. This group (IIS\_WPG is short for IIS Worker Process Group) already has the rights and permissions needed to run a worker process. The IWAM\_*computername* account is already a member of the IIS\_WPG group.

**FIGURE 17.36**

Identity configuration for application pools

If you aren't grappling with a buggy application, there's probably no need to modify any of these defaults. Still, when problems arise, it's nice to know they are available.

### CREATING NEW APPLICATION POOLS

By default, all Web sites and applications run in the DefaultAppPool. That is, they all share the same worker process. If you host multiple Web sites on the same system, or have a test version of a site running alongside a production version (not that I'm recommending this!), you may want to configure a separate application pool for each Web site. In the example that follows, we'll create two application pools, one for our [www.redhilltown.com](http://www.redhilltown.com) site and another for the [www.hawkmoon.org](http://www.hawkmoon.org) site. Then we will modify the properties for each site to associate it with the new application pool.

To create a new application pool, highlight the Application Pools node in the IIS MMC, right-click, and choose New/Application Pool from either the context menu or the Action menu. The Add New Application Pool dialog box, shown in Figure 17.37, prompts you for a pool ID and asks

whether to use the default properties (Performance, Health, Recycling, and Identity settings) for application pools or to use the settings from an existing pool as a template. Type in a pool ID name or accept the default settings, select an option for configuration defaults, and choose OK. Now repeat the process to create a second application pool for the second Web site. I named the two new pools AppPool #1 and AppPool #2 after the defaults, but you can give them friendlier names if you prefer. Now assign the `www.redhilltown.com` site to run in AppPool #1 and the `www.hawkmoon.org` site to run in AppPool #2.

**FIGURE 17.37**

Adding a new application pool to IIS

Now that the pools are created, let's assign our Web sites to run in their own memory space on dedicated worker processes. In the IIS MMC, select the first site to be reassigned (`www.redhilltown.com`), right-click, and open the properties pages. Select the Home Directory tab and pull down the Application Pool list box to see a list of pools (shown in Figure 17.38). Select the appropriate pool (AppPool #1) from the list and click OK. There's no need to stop and start the site; IIS will handle the transition to a separate application pool automatically. Now repeat the process for `www.hawkmoon.org` and assign it to AppPool #2.

**FIGURE 17.38**

Assigning a Web site to an application pool

That's it! Now our two Web sites are completely isolated from each other, running in separate memory spaces on separate worker processes. To see this in action, open a couple of browser windows to your Web sites and then open the Windows Task Manager on the server. You should see multiple instances of `w3wp.exe` running in the list of processes, one for each Web site. Which brings me to a final point: when I checked, each instance of `w3wp.exe` on my system was using about 4MB of RAM. So application pools are pretty neat, but if you have a bunch of them on the Web server, they are going to increase your memory and CPU overhead.

By the way, you can use the `iisapp.vbs` script to see what process IDs (PIDs) are assigned to what Application Pool ID. Just type `iisapp` from a command prompt without switches to see output similar to this:

```
W3WP.exe PID: 3420    AppPoolId: AppPool #1
W3WP.exe PID: 2264    AppPoolId: AppPool #2
```

This information tells you that the `www.redhilltown.com` Web site is assigned to the instance of `w3wp.exe` running on PID 3420 and the `www.hawkmoon.org` worker process is PID 2264. It might not sound very exciting at first, but consider this: if a worker process starts eating up all your CPU or memory resources and you configure Task Manager to display a PID column in the Process tab (doesn't every Admin do this?), you can find out what site is having a problem or bogging down the system just by opening the Task Manager and running this single command. It would be even easier if you assigned recognizable application pool ID descriptions—you wouldn't even have to remember which site is running in AppPool #1 and which in AppPool #2.

## Setting Up an FTP Site and Configuring FTP Services

Although many file transfers on the Internet today take place via HTTP, FTP is still an important protocol to support if you will be running a public Web site, simply due to its broad range of client support. FTP client software has been developed for almost every computing platform imaginable—including mainframe and midrange systems. Clients who might not be able to retrieve files from your system via HTTP will most likely be able to do so via FTP.

Again, FTP is not installed with IIS 6 by default. You must specifically add it using the Windows Components Wizard. Refer to the earlier section on installing IIS for more information. The FTP service bundled with IIS 6 now includes one big new feature: *user isolation mode* limits user access to designated home directories. This was designed for use by Internet Service Providers to allow clients to upload files and Web content. However, it might also be useful to permit, for instance, a Macintosh or Unix client user to access their home directory on the file server via FTP. In the following examples, first we'll set up an FTP site without user isolation mode, and then we'll set one up with user isolation mode. As we'll discuss in a moment, FTP supports virtual directories, but not host header names, so multiple FTP sites on the same server can only be configured using different IP addresses or other TCP/IP ports.

### Setting the Master Properties for FTP Sites

Like the Web (HTTP) service, IIS provides a set of master properties pages to allow administrators to specify default settings for all FTP sites. To set master properties for all FTP sites, right-click the FTP Sites folder in the scope pane of `iis.msc`. With one exception (the Service tab, which is not

available at the FTP site level), the master properties pages are identical to the property pages for individual sites. Information that applies only in the context of individual sites (such as site identification and home directory settings) is grayed out and unavailable in the master properties pages. Settings defined in the master FTP properties will be inherited by all new sites and by existing sites if the properties have not already been defined with a different value. For example, if you deny anonymous access at the FTP Sites level, any new sites you create will not permit anonymous access by default. However, if you explicitly permit anonymous access for your public FTP site, that value will override the setting at the higher level. Later, if you decide to reset the master properties to permit anonymous access by default, IIS will ask you if you wish to reset the Allow Anonymous property on any of the individual sites that do not currently permit anonymous access.

There is one master properties page that is unavailable for individual sites. The Service tab, shown in Figure 17.39, permits you to enable bandwidth throttling for all FTP sites. It is not possible to set specific throttling parameters on individual FTP sites as you can for individual Web sites. For more information on bandwidth throttling, review the earlier section “Master Properties for Web Sites.”

**FIGURE 17.39**

The Service tab of the FTP Sites properties pages

## Creating a New FTP Site

To set up FTP services on Internet Information Services, have the following information ready in advance:

- ◆ Which IP address you want this FTP server to listen on (or if it should respond on all available IP addresses).
- ◆ Which TCP/IP port number this FTP server should listen to on the previously specified IP address(es). Typically, this is port 21.

- ◆ Whether to allow read access, write access, or both to your FTP site.
- ◆ Which directory on your system will house your FTP files.

The creation of a new FTP site begins with a wizard—in this case, the FTP Site Creation Wizard. To start the wizard, select the **FTP Sites** folder for your IIS server in the scope pane of the Internet Information Services tool. Select the **New/FTP Site** command from the Action pull-down menu, and the wizard will walk you through the necessary configuration process.

The first step in the wizard, shown in Figure 17.40, will prompt you for a friendly name to use when referencing your FTP site.

**FIGURE 17.40**

Entering an FTP site description in the FTP Site Creation Wizard

Choose a meaningful name for your site, and click **Next** to proceed to the next step of the wizard, shown in Figure 17.41.

**FIGURE 17.41**

Assigning IP addresses and ports in the FTP Site Creation Wizard

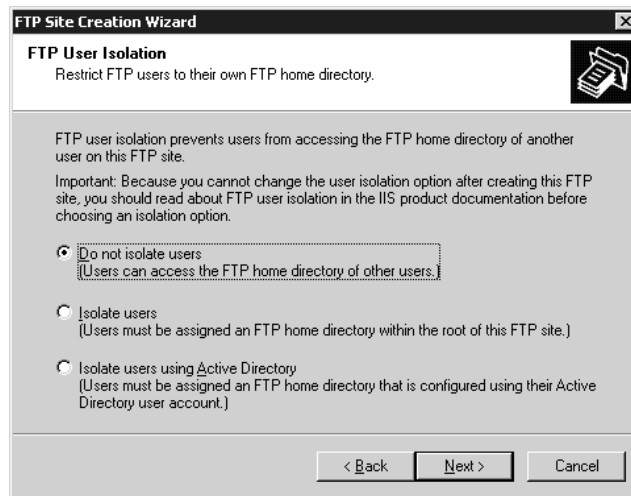

For users to be able to reach your FTP server, you need to assign an IP address and TCP port number for the service to listen to for incoming connections. Host header names are not supported for FTP. By default, the wizard will want to assign your FTP server to listen to TCP port 21 on all available IP addresses on the system. If you have multiple IP addresses assigned to your server (for example, for an internal interface and an external interface), you might want to select the specific address for your system in the IP Address pull-down box. Or if you will be making your FTP site available to the Internet but don't want to have it readily accessible on the default port of 21, you can assign it to any other port number from 1 to 65535.

**TIP** Changing the port number for your FTP site is often a good idea if you will only be using it to publish or receive files for a few selected clients, suppliers, etc. One of my own clients recently had their FTP server discovered (presumably by scanning for devices responding to TCP port 21) and used by hackers as a repository for pirated software.

If the defaults are acceptable, click Next to move on to the next step of the FTP Site Creation Wizard, shown in Figure 17.42.

**FIGURE 17.42**

Setting user isolation options for a new FTP site

This version of FTP is capable of directing users to a specific home directory and limiting access to that directory. In this first example, choose not to isolate users (which is the default selection). I'll discuss the features of user isolation mode and how to configure it later in this section. Click Next to proceed to the next step, shown in Figure 17.43.

When FTP clients initially connect to your server, they will be placed in the home directory of your system and won't be able to proceed any higher on your system than the home directory. For them, the home directory that you specify will be their "root" directory. Their root directory can be either a directory on your IIS server or a share on another system on the same network. From the root directory, you can create subdirectories below your home directory in order to organize the files available for download or the files you expect to be receiving. Enter the appropriate directory name or UNC path here and click Next to proceed. If you enter a UNC path for your root directory, the next step of the wizard will prompt you for a username and password for IIS to use when accessing that share. Otherwise, if you enter a local path, the next step is the final step of the wizard, shown in Figure 17.44.

**FIGURE 17.43**

Setting the FTP site home directory in the FTP Site Creation Wizard

**FIGURE 17.44**

Setting access permissions in the FTP Site Creation Wizard

Once you have defined how your site is reachable and what directory on your system should service the site, the last thing IIS needs to know is whether or not to allow read access, write access, or both read and write access to your site. The choices here are rather self-explanatory: if you're using your FTP server simply to provide downloadable files for users or clients, then read access only would be your best choice; if you want to receive files, then select write access; if necessary, you can also select both. Click Next to finish your site, and the FTP Site Creation Wizard will build your site and start it up for you immediately. If the wizard reports a problem, you've most likely created a site using the same IP address or port number assignments as another pre-existing site. The site will still be created but will not start up until you correct the problem and manually start the site using the Action menu or the context menu for that site.

Once your site is created, all you need to do is place the content in the home directory that you would like visitors to be able to access. This might be anywhere from a few files to a few thousand

files. If you have more than a handful of files, you will probably want to organize them into some logical directory structure to make things easy to find. Whatever the case may be, make the files on your system easy to find and your users will be appreciative.

Also, it is common for FTP sites with more than just a handful of files to put `index.txt` and/or `readme.txt` files in directories throughout the site to help users understand what type of content is available in each directory. After all, nobody likes trying to guess what directory names or 8.3 filenames actually mean.

**TIP** You can create a new FTP site from a command prompt using the `iisftp.vbs` script. For example, to create a new FTP site called *Pizza Recipes* with a home directory at `f:\pizzarecipes` listening only on IP address `204.177.51.199`, use the following syntax (all on one line): `iisftp /create f:\pizzarecipes "Pizza Recipes" /i 204.177.51.199`. You can specify a port other than port 21 with the `/b` port number switch and add `/dontstart` to keep the site from starting upon creation. The switches `/isolation Local` or `/isolation AD` tell FTP to create the site in one of the isolation modes.

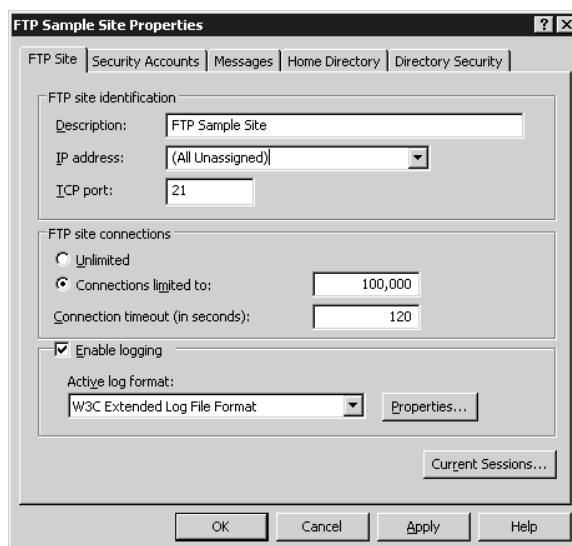

## Modifying FTP Site Properties

Although the FTP Site Creation Wizard does an excellent job of configuring a functional FTP site for you, there are some additional parameters that you might want to adjust for your system. For example, you might want to have a logon message displayed to users connecting to your system, or you may want to limit the number of simultaneous users on your system. In any case, to adjust the parameters for this FTP site after the wizard has created it, you will use the FTP site properties pages. Remember, if you want to set these values for all FTP sites, use the FTP Sites master properties pages.

### FTP SITE PROPERTIES

To open the properties pages for your new FTP site, highlight the icon for your new site in the scope pane of `iis.msc` and then select Properties from the Action menu. This should bring you to a dialog box similar to the one shown in Figure 17.45.

**FIGURE 17.45**  
Editing FTP site  
properties

From this page of FTP site properties, you can change parameters about your site, defined as follows:

**Identification** This group of controls allows you to change the “friendly name” for your site, the IP address your site listens to, and the TCP port number that it listens to. By default, the IP address for your site to listen to (unless you chose something else in the wizard) will be set to All Unassigned, causing your new site to listen for FTP users on any IP address that isn’t already in use by another site on your system. To host multiple FTP sites on your system, assign each site a separate address in this field or adjust the port number.

You can change this port number as a means of securing your site (people won’t know to look for an FTP server on port 28,324, for example) or so that you can host multiple FTP sites on the same IP address. You can enter a value from 1 to 65535 in the TCP Port field. However, once you change the port number, users will need to know which port number to use, since FTP client software uses port 21 by default.

**Connections** Depending on the capacity and bandwidth available for your system, you may want to limit the number of simultaneous connections to your server to maintain adequate performance. If you are planning on running a large site and handling lots of traffic, the Unlimited option might be the best choice. If you choose to limit the connections, users who attempt to log in after the connection limit has been reached will receive a message (which you may define in the Message Properties page, described later in this section).

A “connection”—as far as IIS is concerned—is not necessarily defined as all activity from a single user. For example, a user connecting to your FTP site through a browser could launch multiple simultaneous downloads from your site. Each download session in that case would be considered a connection. Therefore, limiting your server to five connections doesn’t necessarily guarantee that five users will be able to access your site at any time; one user could take up all five connection spots.

**TIP** *If you plan on allowing write access to your FTP site, and you know that you’ll never have more than a few users connected to your FTP server at a time, you might consider limiting your system to one or two connections. If someone on the Internet were to find your server and start using it as a repository for pirated files or pornography, they’ll probably start advertising its accessibility. Limiting connections is a way to at least minimize potential abuse of your system.*

To make sure that users don’t stay connected to your server indefinitely, enter a time-out value in seconds in the Connection Timeout field. The default timeout value is 900 seconds, or 15 minutes. If for some reason an FTP session fails to close its connection appropriately, this will ensure that phantom open connections won’t eventually fill up your server.

**Enable Logging** One of the best ways to keep track of what’s happening on your system is to log the activity. Checking the Enable Logging option (enabled by default) will allow you to log activity on your site in three formats: Microsoft IIS Log Format, W3C Extended Log File Format, or ODBC Logging. Depending on which logging option you choose, clicking the Properties button will yield a specific set of parameters you can adjust for each type of log.

**Current Sessions** Although this technically isn’t a parameter to be adjusted, at times you may need to monitor who is connected to your FTP server and disconnect some or all of the users connected to your site. Clicking the Current Sessions button will take you to the FTP User Sessions dialog box shown in Figure 17.46.

**FIGURE 17.46**

Monitoring current  
FTP user sessions

All users connected to your FTP server will be listed in this dialog box, along with their associated IP address and the amount of time they've been connected. Users who are connected to your system anonymously—logging in via the username “anonymous” (more on this subject in the next section)—will have a question mark located in the user icon and will be listed by the e-mail address they supplied to the password prompt from the FTP server. If the visitor used Internet Explorer to log on anonymously, the e-mail address may be shown as IEUser@ or IE40user@, depending on the version of Explorer being used. The icon will have a small question mark over a face. Users who have logged in with an actual Windows Server 2003 user account will have a normal user icon next to their username. To disconnect any users from your system, highlight their record and click the Disconnect button. To disconnect all users from your system (for example, if you're preparing to shut the system down for maintenance), click the Disconnect All button.

### SECURITY ACCOUNT PROPERTIES

On an FTP server, there are generally two types of connection that users typically make: anonymous logins or user logins. Anonymous logins are overwhelmingly common on the Internet, and this is how most publicly accessible FTP servers run.

In an anonymous login, users connect to an FTP server with the username “anonymous” and an e-mail address for a password. No checking is done on this password; it is simply recorded for informational purposes. By configuring a server in this manner, any user can gain access and get files as necessary. If you plan on running a publicly accessible FTP site, it is customary to allow anonymous logins.

The opposite of an anonymous login is a user login, which requires a valid username and password combination before logging in. User logins allow you to control user access to a greater level—you can assign security to directories on an FTP server and restrict access to certain directories based on username.

**NOTE** FTP passwords are transmitted over the Internet in cleartext. If you have users who will be logging into your FTP server with their Active Directory user accounts, their passwords will be in plain view of anyone who might intercept their traffic.

Once you have decided which type of logins you want to allow, you can enforce these settings via the Security Accounts properties page, shown in Figure 17.47.

**FIGURE 17.47**

Editing security  
accounts properties

This properties page controls what type of logins to allow on your server. If you don't want to allow any anonymous connections at all, uncheck the Allow Anonymous Connections box; this will disable the remaining options on the top half of the properties page. Otherwise, when anonymous users connect to your system, they will end up inheriting the security rights of the account defined in the Username field.

**NOTE** Disabling anonymous logins will force everyone to connect to your FTP server via a username and a password. Since FTP sessions are transmitted over the Internet in cleartext, this could potentially expose user passwords defined on your system to anyone who might be looking for them.

Checking the Allow Only Anonymous Connections check box will effectively restrict any users from accessing your FTP server via a normal user login. This is particularly useful in case any user or administrative passwords within your organization are discovered—FTP cannot be used as a means to gain access through those accounts if this option is checked.

**TIP** By default, most Web browsers will attempt to do an anonymous login when connecting to an FTP site. If the anonymous login fails, the user will be prompted for a valid username and password. To override this behavior, you can place the username and password the browser should use in the URL string. The correct URL format for a user login via a browser is `ftp://username:password@sitename.com`.

### MESSAGE PROPERTIES

Although the FTP client interface is often cold and impersonal, you can add your own messages to your FTP server. Whether you need to inform users about new files that were recently added, tell them what site they are connected to, display a legal warning message, or just send a friendly message, you can do this through the Messages page, shown in Figure 17.48.

**FIGURE 17.48**

Editing message properties

The messages properties are rather self-explanatory. The Banner message is displayed when a user first connects to the FTP site, before logging on. The Welcome message is displayed to users after they log in. If your server has reached the maximum number of allowable connections (set in the FTP site properties discussed earlier in this section), then the Maximum Connections message will be sent to the user and their session will immediately be disconnected.

Speaking of disconnection, if a user (using something other than a browser for FTP access) disconnects properly from your FTP server, they will see the message you have defined in the Exit field. Browsers don't typically display exit messages, so if you have something important to pass along to users, it's better to put it in the welcome message than in the exit message.

### HOME DIRECTORY PROPERTIES

If you read through the previous section on setting up Web sites, the properties page for Home Directory (shown in Figure 17.49) should look somewhat familiar to you. Although some of the settings and options are different for FTP sites, the general concept is the same.

This group of settings lets you control where IIS will look for FTP files and what security permissions to use for this location:

**Content location** By selecting the appropriate radio button on the top of this properties page, you can control whether the content for this site will be stored on the local system, or on a different server's shared folder. Based on the selection you make, the path information box below the radio button options will change. If you select the option for a directory located on this computer, you will need to enter the local path in the lower portion of the properties page.

If you select the option for a share located on another computer, the Local Path field will change to a Network Share field, where you will need to enter the correct \\servername\sharename

UNC path. When you choose to use a share located on another computer for your files, you might need to enter login credentials for the IIS service to use when it is accessing the other system. The IIS service will actually log in to the other system, retrieve the files, and present them to the user just as if the files were local. This allows you to build a distributed FTP site throughout your organization, even though all the files are presented to the user just as if they were all on one machine.

**FIGURE 17.49**

Editing home directory properties

**Security settings** Regardless of the location you choose for your content, you can control whether users are allowed read and/or write access to your files as needed. The FTP service will apply these settings for how it handles the directory overall, and these settings can be complemented by additional security permissions applied to files and directories on files stored on an NTFS partition.

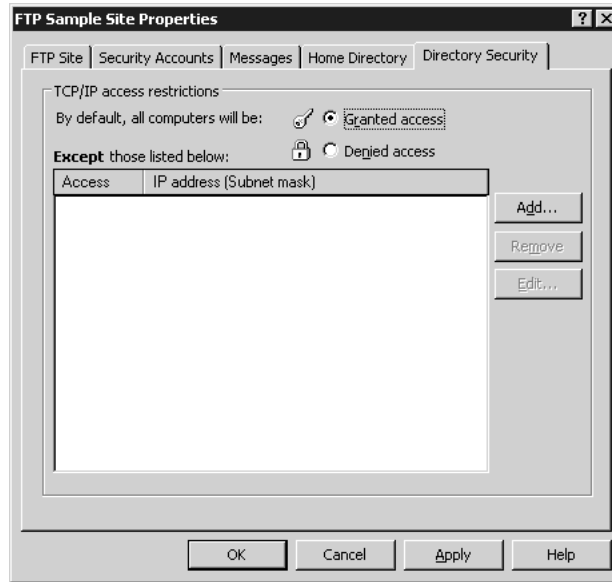

**Log Visits** Depending on whether or not you want logging information stored about visitors to your site, check or uncheck this box. Logs will be stored in the format defined in the FTP site properties dialog box, covered earlier in this section.

**Directory Listing Style** This setting will control how IIS will return directory-listing information to users in response to the `dir` command from an FTP client—in either an MS-DOS-style listing or a Unix-style listing. This setting has no bearing on how IIS will return information in response to the `ls` command from an FTP client.

#### DIRECTORY SECURITY PROPERTIES

The last section of the FTP site properties pages, Directory Security (Figure 17.50), allows you to control who accesses your Web site based on client IP addresses.

**FIGURE 17.50**  
Editing directory  
security properties

Through this page, you can secure your FTP site somewhat by restricting who can access the site based on an IP address or a range of IP addresses. This requires knowing in advance who should be connecting to your site and from where, but it is particularly useful when setting up FTP sites designed to interface with business partners. Select the appropriate radio button to allow access from all IP addresses by default (Granted Access) or to restrict access from all IP addresses by default (Denied Access). Create exceptions to this rule by clicking the Add button and adding an IP address or a range of IP addresses (by using a network mask). IIS will enforce these restrictions with all visitors to your site.

As with IP address restrictions for Web sites, you can set up some highly secure FTP sites by restricting access based on IP address, and then requiring authentication (i.e., denying anonymous connections) to access your site.

## Virtual FTP Directories

If your FTP site begins to grow over time, you might find that you will need to add additional resources to your system as subdirectories off of the main root of the site. Just as with a hard drive on a computer, in time there are often too many files to manage in one directory, so subdirectories become necessary. There are two main ways to do this for an FTP site. The first is to actually create a subdirectory in the site's content directory and place content into that directory. For example, let's say you have a site that is stored in `C:\Inetpub\ftproot` and is accessed on an FTP server at `ftp.companyname.com`. If you decide you want to move all of your executable files to a separate subdirectory, you could create a subdirectory called `C:\Inetpub\FTProot\bin` and then move all of your executable content into that directory. To access files in that directory, FTP clients would access the `ftp.companyname.com/bin` directory.

However, what if you want to have content available as a subdirectory in your site, but you can't move the content to a normal subdirectory within your site's structure? Virtual directories are a means of defining a subdirectory off of the root of your site (or even a lower level of your site) and then creating an alias or a pointer to a directory somewhere else on your system or on another computer on your network. By using virtual directories, you are not forced to move all of your FTP content to one system and then place it in an orderly structure for visiting users. Instead, you can have content stored anywhere on your machine or on any system within your network, and users can access it through a simple directory structure.

Virtual directories can also be used to grant different security permissions to the same set of files, based on which directory the user is in. For example, you might have an alias called `source`, which points to a directory called `C:\source` on your local system. The alias is defined only with read access. You could add a second alias to your system, called `source-RW` for example, which could point to the exact same directory on your system but allow full read/write access.

### DEFINING A VIRTUAL DIRECTORY

To launch the Virtual Directory Creation Wizard, return to the Internet Information Services tool and highlight the FTP site you want to work with in the scope pane of the window. Select **New/Virtual Directory** from the Action menu and the wizard will start walking you through the configuration process. The first step of the wizard is shown in Figure 17.51.

**FIGURE 17.51**

Defining an alias for a virtual directory

The first thing you will need to specify for your virtual directory is the alias that refers to it. The alias is the directory name that FTP clients will use to access the directory. For example, if you want to have a directory called `sourcefiles` available off the root of your site when users first connect, then `sourcefiles` would need to be the alias. The alias does not need to match the name of the directory from where the files are actually coming, so you can use whatever name works best in this field. Click **Next** to proceed to the next step of the wizard, shown in Figure 17.52.

**FIGURE 17.52**

Defining a content directory for a virtual directory

**Virtual Directory Creation Wizard**

**FTP Site Content Directory**  
Where is the content you want to publish on the FTP site?

Enter the path to the directory containing the content for this FTP site.

Path:

If you want to define a virtual directory that points to another directory on the same computer, enter the path name here (such as `D:\sourcefiles`). IIS will define the virtual directory as pointing to another directory on the same server. However, if you want this virtual directory to point to data located on a share on another server, enter the UNC path to that system here. When you click Next, the Virtual Directory Creation Wizard will take you to another dialog box for entering user credentials, shown in Figure 17.53. Otherwise, you will skip ahead to the dialog box shown in Figure 17.54.

**FIGURE 17.53**

Entering a username and password to access shared content via a virtual directory

**Virtual Directory Creation Wizard**

**Security Credentials**  
Specify a user name and password to prevent unauthorized access to the network resource.

Enter the user name and password that should be used to gain access to the network directory (UNC path).

User name:

Password:

☐ Always use the authenticated user's credentials when validating access to the network directory.

When IIS needs to contact another server for FTP files, it will have to do so with a specific username and password combination. Enter an appropriate set of credentials here, one that would have appropriate access rights to the content you are trying to reach. Notice in Figure 17.53 that

instead of entering a user account and password to be used for all connections to the virtual directory, you may alternately use the authenticated user's credentials for access. Click Next to move to the last step of the wizard—defining access permissions—shown in Figure 17.54.

**FIGURE 17.54**

Defining access permissions for a virtual directory

This step in the wizard is identical to the one in the FTP Site Creation Wizard mentioned earlier and shown in Figure 17.44. Decide whether you want to allow read or write access to your system, or both, and check the appropriate boxes.

Once you have entered all of the required information, you should have a new virtual directory item listed below your FTP site. You can test this to make sure that the virtual directory responds appropriately by launching an FTP client and then navigating to your virtual directory. If everything has gone according to plan, IIS should return content from the appropriate location.

In case you aren't already familiar with the concept of virtual directories in FTP, here's an interesting note: virtual directories are not included in the listing returned by a `dir` or `ls` command. These commands query the file system, and virtual directories are not part of the file system. A user has to know the name of the virtual directory in order to navigate to it. For instance, to access the virtual directory we just created named `sourcefiles`, you would have to log on to the FTP server and type `cd sourcefiles` before you could see the contents of that directory. The same is true of virtual directories for Web sites; even if browsing is enabled, the virtual directory can only be accessed by typing in the name of the directory as part of the URL or by using a link created on another Web page. So users can't get to virtual directories if they don't know about them, or if they can't guess their names. Of course, it's not a foolproof security measure, but it's something to consider if you want to create a few directories that are hidden from casually nosy users.

You can modify properties for a virtual directory in exactly the same manner that you do for an FTP site—by editing the properties pages for the directory itself. You can edit the following properties pages for a virtual directory: Virtual Directory and Directory Security. These pages are functionally identical to the pages, defined earlier in this section, for modifying the properties for an entire FTP site.

**TIP** You can use the command-line script `iisftppdr.vbs` to create FTP virtual directories. To add a virtual directory called `VeggieRecipes` to the *Pizza Recipes* FTP site at `f:\vegarchive`, type the following command (all on one line): `iisftppdr /create "PizzaRecipes" VeggieRecipes f:\vegarchive`. One limitation of using the VBScript to create FTP virtual directories is that UNC paths are not supported.

## Using FTP User Isolation

Before the release of IIS 6, there was no clean way to restrict users to particular directories on a given FTP site. You could use NTFS permissions (and still can) to prevent users from making changes or viewing the contents of subdirectories, but they would still see the entire list of directories at the root when they logged in. You could use virtual directories (and still can) to create hidden directories and use NTFS permissions to control access. But this solution is too much work, and it's too complex to deploy for a site that needs to support dozens or hundreds of users. An Internet Service Provider that hosts Web sites for a fee will often provide an FTP account to a site's Webmaster for uploading content. This FTP home directory is often mapped directly to the home directory for the Web site, although in some cases it is only replicated to the actual Web site directory. The Web site creator connects to the designated FTP site and uploads his pages to update the Web site being hosted with the ISP. So it's really important to make this process as easy and as simple as possible for the ISP's clients, while at the same time providing a measure of security. For obvious reasons, they don't want their users to be able to view or modify content from other clients' directories.

User isolation is a new feature of the FTP service bundled with IIS 6. Sites that are configured with user isolation will log users on and shoot them directly into a home directory that appears to be the root directory of the FTP server. Users cannot view or modify files or directories outside of their assigned directory structure. Here's how to set this up:

1. Before you run the FTP Site Creation Wizard, decide where the root of the user isolation site will be. The home directory may be on your local system running IIS or on another server's shared folder on the network. For instance, you may decide to create the site with a home directory located at `d:\ftp-upload`. If you wish to use a shared folder on the network, share the folder on the remote server and set share-level permissions that grant access to your FTP users.
2. Create a subdirectory called `LocalUser` in `d:\ftp-upload`. Yes, it must be named `LocalUser` because this tells FTP where to look for the home directories.
3. Within `d:\ftp-upload\LocalUser`, create subdirectories for each user who will log on to the site. The directory name and the username for the client must be identical and must also correspond to valid user accounts on the local FTP server or the domain. Remember to set appropriate NTFS permissions on these subdirectories so that your users will have the access they need. Now you are ready to run the FTP Site Creation Wizard.
4. When you get to the User Isolation options step, choose the radio button for *Isolate Users* (we'll get to the *Active Directory* option in a moment).
5. In the next step of the wizard, specify the path to the home directory (`d:\ftp-upload` in this case). If you do specify a UNC path for the home directory, you may notice that the wizard does not prompt you for Connect As information. This is because FTP will automatically use the authenticated user's credentials to access the share. So make sure that your users will have permission to access the shared directory on the network server.

6. In the last step of the wizard you may still choose whether to grant read-only permission, write-only permission, or both read and write for the FTP site. In this case, since the user will only be able to access their assigned directory, granting read and write permission to the site does not grant the user permission to read or write to any of the other users' directories.
7. You're done! Use an FTP client to test your configuration by logging on as one of the FTP users.

If you want to make use of the user isolation feature but still want to support anonymous logins, create a subdirectory under the `LocalUser` directory called `Public`. If a `Public` directory exists, and anonymous access is granted to the site, anonymous users will start out in the `Public` directory and will not be able to navigate above that level. If you've enabled read and write permissions for the entire FTP site, you can still use NTFS permissions on the `Public` directory to restrict access. Anonymous connections use the `IUSR_computername` account; simply add an entry to the access list explicitly denying write permission to that account. Now you have a single site that permits read-only access to a `Public` directory structure for anonymous users and directs authenticated users to their own home directories with read and write access.

## Using FTP User Isolation with Active Directory

In the previous example, you set up user isolation for FTP users by creating a root directory and then creating a subdirectory for every permitted user. A disadvantage of this method is that all of the home directories must be physically located in the root directory of the site, under the `LocalUser` subdirectory. There's no way to distribute home directories across disks or servers.

Another option for FTP user isolation uses account properties set in the Active Directory to determine the location of a user's FTP home directory. This simplifies administration of the FTP site and permits home directories to exist in multiple locations. In fact, if you wish to grant a set of users FTP-based access to their regular file server-based home directories, this is a much better option than the standard form of FTP user isolation.

Although a user's FTP directory may point to the same location as the home directory set with group policies or DSA.MSC, these are separate attributes in the Active Directory. When a user logs on to a site configured to use AD for user isolation, IIS asks the Active Directory for the values of two new properties, `FTPRoot` and `FTPDDir`. As far as I know, the only easy way to set these properties is by using a VB script, `iisftp.vbs`.

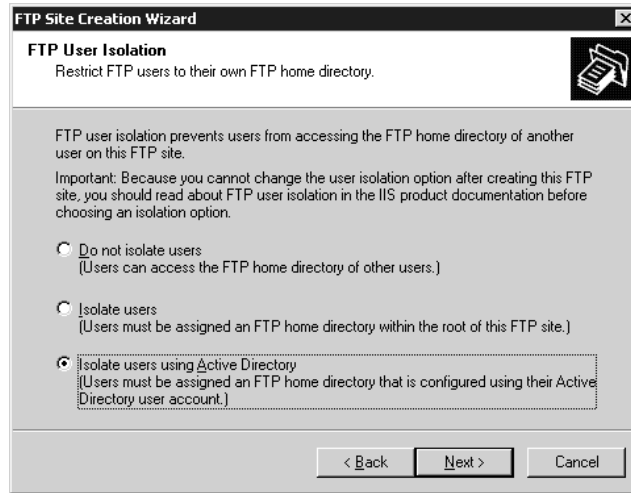

To use this feature, the IIS 6 server must be a member of a Windows Server 2003 Active Directory domain. Only Windows Server 2003 AD supports the `FTPRoot` and `FTPDDir` attributes.

The steps to set up an AD-based user isolation site are simple:

1. If you have not already done so, set up home directories for your users. As always, NTFS and (if applicable) share-level permissions should be set appropriately. Because these directories may be spread across multiple servers and disks on your network, keep track of their locations. You'll need this information later when you set the `FTPRoot` and `FTPDDir` attributes for the accounts.
2. Start the FTP Site Creation Wizard, specify the unique IP address and/or port settings, and choose the *Isolate Users Using Active Directory* option (shown in Figure 17.55).

**FIGURE 17.55**

Isolating FTP clients using the Active Directory

3. Click Next and supply a username and password to be used to gain access to the AD domain, as shown in Figure 17.56. The account you specify in this step does not have to be an administrator account, but it must be a valid user account in the Active Directory domain. If anonymous access is permitted to the site, these credentials will be used to access the AD. Enter the name of the default AD domain (REDHILLTOWN.COM, in the example) to be used when logging on. This default domain name will be assigned to any users who do not specify a domain name at login. For example, if Dave Evans logs in as devans, the FTP service will assume that he's REDHILLTOWN\devans. If you don't set a default value in the wizard, users must specify a domain name at login or access will be denied. Click Next, and the wizard will ask you to retype the user password for confirmation.

**FIGURE 17.56**

Specifying an AD account for FTP user isolation

4. In the final step of the wizard, specify whether users will have read, write, or read and write access to the site. Finish the wizard and IIS creates the site and starts it up for you.
5. Use the VB script `C:\windows\system32\iisftp.vbs` to set FTP home directory information. It doesn't matter whether you perform this step before or after you create the FTP site. In fact, you may set the account attributes as needed to permit new users to access their FTP home directory.

Like other FTP sites, you may specify the home directory path as a local path on the IIS server or as a UNC path. The `FTPRoot` value sets the root directory; this is either a UNC name (such as `\\zooropa\users`) or it may be a local path on the IIS Server (such as `f:\webdirectories\ftpusers`). The `FTPDDir` value is either the name of the user's directory or a relative path to the directory.

The syntax for this operation is

```
iisftp /SetADProp username FTPRoot path
iisftp /SetADProp username FTPDir path
```

For example, if you wanted to use a local path on the IIS server for user Paul, and the path is `F:\ftpusers\paul`, you'd type in the following two commands (for some reason you can't set both properties at the same time):

```
iisftp /SetADProp paul FTPRoot F:\ftpusers
iisftp /SetADProp paul FTPDir paul
```

If you wanted the FTP root directory to be the shared `Users` folder on the server `ZOOROPA`, you'd set the `FTPRoot` and `FTPDDir` attributes like this:

```
iisftp /SetADProp paul FTPRoot \\zooropa\users iisftp /SetADProp paul FTPDir paul
```

In the first case, when Paul logs on to the FTP site, his root directory will correspond to `F:\ftpusers\paul` on the IIS server. In the second scenario, his root directory is `\\zooropa\users\paul`. Like the first method of user isolation, Paul cannot see or navigate to any directories above his starting directory. His ability to read and make changes is determined by the read/write settings on the FTP site, permissions on the shared folder (if applicable), and NTFS ACL entries.

These options for user isolation are pretty neat, but there are a couple of gotchas. My primary complaint is that setting the FTP directory attributes in AD could be a little easier. The `/SetADProp` switch in the `iisftp.vbs` script is not well documented, and you may have to fiddle around with using it until you get the hang of it. Furthermore, IIS doesn't always know right away when the AD attributes for an account have been changed. This is probably due to a replication delay; restarting the site solves the problem. Also, once you create a site with user isolation, you cannot modify that particular attribute. You can't change a regular user isolation site to an AD isolation site, for example.

Finally, although a non-AD user isolation site can be modified and configured in the same way and with the same options as a standard FTP site, the Security Accounts and Home Directory property pages are unavailable for AD isolation sites. After you run the wizard to create the site, you cannot modify read or write permissions on the site, change the directory listing style, or change your mind about anonymous access. In fact, the wizard never asks you whether you want to permit anonymous access on the AD site. In this case, the new site just inherits the global setting for all FTP sites.

This brings us to an interesting question: what if anonymous access is enabled on a user isolation site that uses AD? Well, if no FTP home directory attribute is defined for anonymous users in the Active Directory, then anonymous users cannot log on. But if you do wish to direct anonymous users to a particular directory, define the `FTPRoot` and `FTPDir` attributes for the user account that runs the IIS server (`IUSR_computername`).

Why would you want to enable anonymous access for a site that authenticates users with the Active Directory and then points them to a private home directory? All FTP client software uses port 21 by default and host header names are not supported. You can't tell the FTP server, "By the way, I think I'm connecting to `bigserver.redhilltown.com`." If you want to host a public site and a separate users-only site on the same box, you either have to configure the server with multiple IP addresses corresponding to different user-friendly names (`bigserver.redhilltown.com` and `intranet.redhilltown.com` and `archives.redhilltown.com`, for example), or have clients connect to the server on nonstandard ports. It's definitely a plus to be able to set up one FTP site that can serve both anonymous and authenticated users.

## Using FTP for File Transfer

That's FTP from the server perspective, but what about connecting to an FTP server?

If you have a PC or Macintosh on your desk, think for a moment about how you use that computer in a network situation. You may have a computer elsewhere in your building that acts as a file server, a computer that holds the files shared in your facility or your department. How do you ask that server to transfer a file from itself to your computer? You may say, "I don't do that"—but you do. Whenever you attach to a shared network resource, you are asking that system to provide your computer with shared files. Now, how you actually ask for them is very simple: You just connect to a server, which looks like an extra folder on your desktop if you're a Mac user or an extra drive letter, like X: or E:, if you are a PC user. The intranet world has a facility like that, a facility that lets you attach distant computers to your computer as if that distant computer were a local drive: It is called NFS, the Network File System. But NFS is relatively recent in the TCP/IP world. It's much more common to attach to a host, browse the files that it contains, and selectively transfer them to your local host. You guessed it: the means to do that is FTP.

There are three essentials of using an FTP client: how to start it up, how to navigate around the directories of the FTP server, and how to actually get a file from an FTP server. I'll explain these and, after that, I'll look at a special kind of FTP called anonymous FTP. So let's get started by looking at how the files on an FTP server are organized.

### FTP ORGANIZATION

The first time that you get on an FTP server, you'll probably want to get right off. FTP, like much of the TCP/IP world, was built from the perspective that software must be functional and not necessarily user-friendly. If you're a PC user, the Unix file structure will be somewhat familiar, as the DOS file structure was stolen—uh, I mean, borrowed—from Unix. Mac users will need to find an FTP client, of which there are many.

Now, I just referred to the Unix file structure. That's because FTP servers usually use Unix. But some don't (after all, I just spent several pages talking about how to set up FTP sites on a Windows Server 2003), so you may come across FTP servers that don't seem to make any sense. For the purposes of this discussion, I'll assume that the FTP servers here are Unix, but again, be aware that

you may run into non-Unix FTP servers. FTP uses a tree-structured directory represented in the Unix fashion. Figure 17.57 shows a sample layout for an FTP site. The top of the directory is called `ourfiles`, and it has two directories below it—subdirectories—called `ourfiles/bin` and `ourfiles/text`. In the Unix world, `.bin` refers to executable files, files we might call program files in other operating systems, or more specifically, EXE or COM files in the PC world. The `text` directory contains two directories below it; one's called `contracts` and one's called `announcements`.

**FIGURE 17.57**

An example of how files on an FTP server are organized

A couple of notes here. PC users may think that things look a bit familiar, but there are some differences. First, notice the subdirectory named `announcements`. That name is more than eight characters long—that's quite acceptable, even though it isn't acceptable in the PC world. Unix accepts filenames of hundreds of characters. Second, notice that there are not backslashes between the different levels, but instead forward slashes; that's also a Unix feature. Now, what complicates matters for users of non-Unix systems is that FTP pretty much assumes that your system uses the Unix file system as well. That means that you have to be comfortable with traversing two directory structures—the one on the remote FTP server and the one on your local hard disk.

### FTP CLIENT TYPES

How FTP looks to you from this point depends on what kind of client software you use to access an FTP server. With today's Windows clients (Windows 2000 and XP or Windows 9x), you have three choices: a standard command-line interface, Internet Explorer, or My Network Places. First, let's look at the command-line interface.

### FILE NAVIGATION WITH COMMAND-LINE FTP CLIENTS

You get an FTP command line—I'll demonstrate it in a minute—that expects you to tell it where to get files from, and where to send files to, using these two commands:

- ◆ remote: `cd`
- ◆ local: `lcd`

That's because there's a tree structure on both the remote system—the one that you're getting the files from—and the local system. Let's look at a few examples to nail down exactly how all this `cd`-ing works.

### Moving Around in FTP

When I enter an FTP site, I start out at the top of the directory structure. This top is called the root of the directory. In my example, the root is called `ourfiles`. To move down one level, to `ourfiles/text`,

I could type **cd text**. That says to FTP, “Move down one level relative to the current location.” Alternatively, you could skip the relative reference and say absolutely, “Go to **ourfiles/text**”—the way you do that is by typing **cd /ourfiles/text**. The fact that the entry starts with a slash tells **cd** that your command is not a relative one, but an absolute one.

Now let’s try moving back up a level. At any point, you can back up one level either by typing the command **cdup** or by typing **cd ..**. The two periods (..) mean “one level upward” to both DOS and Unix. Or you can do an absolute reference, as in **cd /ourfiles**.

Now suppose I’m all the way at the bottom of this structure. It’s a simple three-level directory, and you often see directory structures that are a good bit more complex than this one. To move back up from **ourfiles/text/announcements** to **ourfiles/text**, you can do as before and either type **cdup** or **cd ..**. Or you could do an absolute reference, as in **cd /ourfiles/text**. To go back two levels, you can either issue two separate **cdup** or **cd ..** commands or use an absolute reference, as in **cd /ourfiles**. To type two **cdup** or **cd ..** commands, you type the command, then press Enter, then type the second command. Do not try to issue two commands on the same line.

#### AN FTP EXAMPLE OF NAVIGATION: GET A SCANDAL

There’s a really neat project run by a group of volunteers called The Gutenberg Project. They take text whose copyright has expired and type it into text files. They then put these text files on both FTP and Web sites for anyone to download and read.

For example, one of my favorites of Arthur Conan Doyle’s Sherlock Holmes stories is “A Scandal in Bohemia,” which Gutenberg has at <ftp://sailor.gutenberg.org/pub/gutenberg/etext99/advsh10.txt>. (Their general Web home page is at <http://promo.net/pg/>.) Let’s go fetch the scandal.

First, I’ll FTP to **ftp.gutenberg.org**. From a command prompt, I type **ftp ftp.gutenberg.org**, and then I get a **User:** prompt. This site doesn’t know me, so I can’t log in with a local name and password. That’s where the idea of anonymous FTP becomes useful. You can often log in to an FTP site and download data that’s been put there specifically for public use. Anonymous FTP is just the same as regular FTP except that you log in with the name “anonymous.” It responds that a guest login is okay but wants my e-mail address for a password. I put in my e-mail address, and I’m in. Now, it might be that there are places on this server that I cannot get to because I signed on as anonymous, but that doesn’t matter—Sherlock is in the public area. Next, I can do a **dir** command and see what’s on this directory:

```
ftp>dir
200 PORT command successful.
150 Opening ASCII mode data connection for /bin/ls.
total 20
d--x--x--x  2 0      0      4096 Jul 6 2001 bin
d--x--x--x  2 0      0      4096 Jun 28 2001 etc
d--x--x--x  20 0     0      4096 Jun 28 2001 lib
dr-xr-xr-x  20 0     0      4096 Jun 26 2002 pub
226 Transfer complete.
ftp> 321 bytes received in 0.11Seconds 2.94Kbytes/sec.
ftp>
```

It’s not a very pretty sight, but let’s see what we can see. Notice the letters **r**, **x**, and **d** to the left of each entry? They represent the privilege levels of access to this file. One of the important things

is whether or not the leftmost letter is `d`—if it is, then that’s not a file, it’s a directory. Notice the `pub` entry; that’s commonly where generally available files are stored—`pub` is short for public.

Typing `cd pub` takes me a level down. Another `dir` shows a directory named `gutenberg`—a likely candidate—and I could keep searching around, but I know from Gutenberg’s Web site that the file I’m looking for is at `ftp://sailor.gutenberg.org/pub/gutenberg/etext99/advsh10.txt`. I can navigate there by typing `cd gutenberg/etext99`.

Notice that there are no spaces except between the `cd` and the directory name, and notice also that, in general, you must be careful about capitalization—if the directory’s name is `Literature` with a capital `L`, then trying to change to a directory whose name is `literature` with a lowercase `l` will probably fail. Why “probably”? It’s another Unix thing; the Unix file system is case sensitive. In contrast, if you found yourself talking to an NT-based TCP/IP host, then case would be irrelevant. How do you know what your host runs? Well, it is sometimes announced in the sign-on message, but not always. The best bet is to always assume that case is important.

Anyway, once I get to the directory, I can do a `dir` command to see if `advsh10.txt` is there. `dir advsh10.txt` confirms that the file is there.

Before I get the file, there’s one more thing that I should point out. Years ago, most files that were transferred were simple plain-text ASCII files. Nowadays, many files are not ASCII—even data files created by spreadsheets and word processors contain data other than simple text. Such files are, as you probably know, called binary files. FTP must be alerted that it will transfer binary files. You do that by typing `binary` at the `ftp>` prompt. FTP responds by saying, “Type set to I.” That is FTP’s inimitable way of saying that it’s now ready to do a binary file transfer or, as FTP calls it, an image file transfer.

### TRANSFERRING A FILE

Now I’ll get the file. Because it’s a text file, I just type `get advsh10.txt`, press Enter, and wait. Once the transfer’s done, I get some throughput statistics.

Now, when I get the file, it’ll take some time to transfer. There’s no nice bar graphic or anything like that to say how far the transfer has proceeded. There is a command, however, that will give me some idea about how the transfer is progressing—`hash`. I type `hash`, and from that point on, the system prints an octothorp (`#`) for each 2K of file transferred. For example, say I’m on a Gutenberg system and I want to download the Bible, `bible10.zip`. (Is it sacrilegious to compress the Bible? Interesting theological question.) The file is about 1600K in size, so I’ll see 800 octothorps.

Each line shows me 80 characters, so each line of `#` characters means 160K of file were transferred. It’ll take 10 lines of `#` characters (10 lines!) before the file is completely transferred.

Remember that Gutenberg location. If you’re ever stuck for something to read, they’ve got hundreds of books online. Even better, as they are just simple ASCII, there are programs that will transfer the files to a small computer such as a Palm handheld or a Windows CE palmtop—the easily portable, electronic book is almost here!

### Downloading to the Screen

Before leaving the command-line FTP client, there’s one more tip that I’d like to share with you: how to download directly to your computer screen.

Sometimes you’ll come across a short file, like the READMEs that are so common around the computer world. Such a file may describe what’s in an FTP directory. You’d like to examine it but

the whole idea of first downloading it and then bringing up the file in Notepad seems a lot of work. In that case, download it instead to the screen.

You do that by typing **get filename -**.

Of course, this depends on the system that you're working with, but it may only be possible to do this "get" if your FTP session is set for ASCII transfers rather than binary transfers. You can change that by just typing **ascii** at the command line. You'll see the response "Type set to A."

### GRAPHICAL FTP CLIENTS

In one example of how the world keeps getting better, you can often avoid command-line FTP. In many cases, all you need do is to point your browser to an FTP site by typing **ftp://address**, like **ftp://ftp.3com.com**, in the Address field.

***TIP** You need the ftp:// prefix on the address on some browsers because when you just type in an address, like ignatz.mouse.com, then the browser assumes that you want it to connect to a Web server rather than an FTP, telnet, or other server, and so it interprets the address as http://ignatz.mouse.com. What's the difference between ftp://ignatz.mouse.com and http://ignatz.mouse.com? It's a matter of addresses. It's possible to have many kinds of servers running on the same system. They're distinguished by their port numbers. Just as your dentist's office might be at 210 Main Street and your dermatologist's office might also be at 210 Main Street, they probably don't share an office. The dentist's full address isn't 210 Main Street; it's more like Suite 118, 210 Main Street, and perhaps the dermatologist is at Suite 305, 210 Main Street. Different ports on a server are like different rooms in a building. Web servers are by default at port 80—but http:// is easier to remember than "connect me to port 80." FTP works on another port, actually two ports—20 and 21; telnet uses 23; and so on.*

In any case, most Web browsers can double as a graphical FTP client. You can navigate a directory structure by just clicking a directory to enter it or pressing the Backspace key to back up a level. The trouble with most Web browsers as FTP clients, however, is that they only work when you're logging in to the FTP site as anonymous; they don't give you a chance to specify a user ID and password. Thus, if the site requires an account to access it, your browser is just booted off the site.

A feature available on Windows 2000 and later clients, called FTP folders, solves that problem. Just open My Network Places and double-click Add Network Place. You'll be prompted to type either a UNC, like **\\someserver\somevolume**, or a URL, like **http://www.someplace.com** or **ftp://ftp.someplace.com**. What's particularly nice about this is that the wizard creating the new Network Place entry asks you if you need to specify a user ID and password to access the new Network Place. The FTP site then shows up in My Network Places as if it were a local set of folders, combining the simplicity of a GUI front end for FTP with the flexibility of being able to control how you log on.

That's about all that I'll say here about FTP. There is lots more that FTP can do, but I've given you the basics that you can use to get started and get some work done in the TCP/IP world. If this all looks ugly, user-unfriendly, and hard to remember, then, well, it is—at least to someone used to a Macintosh or Windows. If you're not comfortable working from the command line, you may be better off with one of the graphical FTP programs available, which can make uploading and downloading files a drag-and-drop procedure more like using Windows Explorer than like using the command prompt. FTP is two things—the FTP protocol, which is the set of rules that the computers on an intranet use to communicate, and the program called FTP that you start up in order to do file transfers. The FTP protocol doesn't change and probably won't change. But the FTP program, which is usually known as the FTP client, can be as easy to use as its designer can make it. So go on out, learn to spell anonymous, and have some fun on those FTP sites!

## Setting Up an NNTP News Server and Configuring NNTP Services

Newsgroups are one of the Internet's older technologies, but they're not as well known as some of the Internet's more visible counterparts—namely Web browsing and e-mail. Newsgroups are a way of collecting and threading messages posted by users together to form a sort of “conversation” database between the participants of a newsgroup.

These conversation databases can be used to discuss almost anything you can think of—questions about company benefits, organizational news releases, politics, society, technology, etc. This concept was once referred to as collaboration or groupware, in which companies within an organization could collaborate and share ideas electronically on a set of “bulletin boards” focusing on a specific topic. While some organizations have been able to implement this and make their organizations more productive, this capability still hasn't caught on as much as it should have.

The Internet is filled with literally tens of thousands of these groups, covering every imaginable topic under the sun. You name it, and there has probably been a newsgroup defined somewhere to discuss it. Thanks to IIS 6, you can easily set up and administer your own NNTP server for internal users to read, post, and reply to messages related to topics important for your organization.

When you install NNTP, a default virtual server is created. By default, newsgroup messages are stored in `c:\inetpub\nttpfile`.

### Creating a New NNTP Server

Even though IIS installs and configures a default newsgroup server when you set it up, you might need to have another server on your system. For example, you might need to have a public newsgroup server available to anyone on the Internet, and then a private newsgroup server available to internal staff.

To get started with setting up a newsgroup server, you'll need to know the following:

- ◆ Which IP address you want this NNTP server to listen on (or if it should respond on all available IP addresses).
- ◆ Which TCP/IP port number this NNTP server should listen to on the previously specified IP address(es). Typically, this is port 119.
- ◆ Whether to allow anonymous access to your site or to require user authentication.
- ◆ Which directories your system will use to store and manage your NNTP database files.

To start installing your server, begin by making sure that you have all of the bullet items listed above ready, and then select your IIS server in the Internet Information Services Management tool. Selecting the New/NNTP Virtual Server option from the Action pull-down menu will launch the New NNTP Virtual Server Wizard. In the first step of the New NNTP Virtual Server Wizard, specify a friendly name to use when referencing your new NNTP virtual server. This name is simply for administration purposes; your users won't see it, so choose a name that's appropriate, and then click Next to proceed to the next step of the wizard, shown in Figure 17.58.

In order to access your NNTP server, users will need to establish a TCP/IP connection to your server on a specific IP address and TCP port number. By default, NNTP servers typically communicate on port number 119. Unless you have special circumstances, you will probably want to use this as the default port number for your system.

**FIGURE 17.58**

Defining IP addresses and TCP ports for an NNTP virtual server

If you are going to be running only one newsgroup server on your system, these settings might be just fine, depending on the content on your newsgroups and the configuration of your system. For example, if you were going to run an internal confidential database for the discussion of sales and marketing strategies, you probably wouldn't want to make that database available on a publicly accessible IP address. Users from the outside world could potentially connect to your system and read all of your confidential information stored in the newsgroup, so make sure you correctly determine which IP address(es) to use for your site.

Newsgroup readers—by default—will look on port 119 for a newsgroup server, so enter 119 here in the port field. If you would prefer to change the TCP port that your server responds on (necessary if you only have one IP address and you want to run multiple newsgroup servers), you can do so here. Keep in mind that all the clients connecting to this system will probably have to manually change their configurations accordingly.

Click Next when you've completed the IP configuration, and you'll move to the next step of the wizard, shown in Figure 17.59.

**FIGURE 17.59**

Defining directories for an NNTP virtual server

IIS requires two separate directories on your system to maintain an NNTP virtual server: one in which to store internal files for its own processing, and one to store the actual newsgroup content. In this first screen, you need to supply the directory that IIS should use for its own internal files. When you've entered this, click Next to continue to the next step, shown in Figure 17.60.

**FIGURE 17.60**

Defining a storage area for NNTP content files

In this step of the wizard, you will be defining a “storage medium” for IIS to use when storing news content. This storage medium can be either on the IIS server itself or on another server. If you will be storing the news content directly on your IIS server, select the radio button for File System and then click Next to proceed to the next step of the New NNTP Virtual Server Wizard, shown in Figure 17.61.

**FIGURE 17.61**

Defining a path to store newsgroup messages

If you decide to store news content on another system, select the radio button for Remote Share. Doing so will change the next step of the wizard to prompt you for a share name and username/password combination to use to access the news content stored on another system. For the sake of brevity, I'll assume you chose the File System option and proceed directly to the next step of the wizard.

**NOTE** IIS will require approximately 548 bytes of storage in its internal working directory for each newsgroup message that will be stored on your system, in addition to the space required for the articles themselves.

Click Finish after this step, and you will have a functional NNTP virtual server running on your IIS server.

## Modifying NNTP Virtual Server Properties

Since the New NNTP Virtual Server Wizard only has a few steps to it, there are settings and parameters that you will probably need to set for your site. For example, you might want to define newsgroup names, control security, limit the size of postings, etc. To adjust the parameters for your NNTP site after the wizard has created it, you will use the NNTP virtual server properties pages.

### GENERAL PROPERTIES

To reach the NNTP virtual server properties pages, highlight your new NNTP virtual server in the scope pane of the Internet Information Services tool and then select Properties from the Action pull-down menu. This should bring you to a dialog box similar to the one shown in Figure 17.62.

**FIGURE 17.62**

Configuring general settings for an NNTP virtual server

Through this page, you can change the following items to fit your needs:

**IP Address** Select the IP address for your site to use here. If you intend to have multiple IP addresses servicing the same site or you want to change the ports this site uses, click the Advanced button.

**Advanced TCP Port and SSL Port** By default, NNTP sites typically use TCP port number 119 for standard connections and port 563 for secure connections. Changing these values will usually require changing the configuration of newsreader software on client computers as well.

**Connection Time-out** Depending on the capacity of your server and the other jobs it's responsible for, you might want to limit the number of connections you allow into your NNTP server. A timeout interval of 10 minutes for idle connections is defined by default.

**Path Header** Path headers refer to a string that is used for the "path" line in each newsgroup posting. Path lines are used to determine how a newsgroup posting will reach its destination. For more information on path lines and having newsgroup servers pass messages to each other, see RFC 1036.

**Enable Logging** If you are running an anonymous NNTP server, you might want to enable logging for your system in case you ever need to trace where a specific posting came from.

### NNTP SETTINGS

For settings specific to newsgroups and postings themselves, go to the Settings properties page, shown in Figure 17.63.

**FIGURE 17.63**

Configuring settings for an NNTP virtual server

From this page, you can edit the following options:

**Allow Client Posting** To disallow client posting on this system, uncheck this box. Obviously, on most systems, you will want to leave this checked.

**Limit Post Size** For publicly accessible NNTP servers, you might find a need to limit the size of any one message that can be sent to your system. Otherwise, individuals might overload the server by loading huge binary files to the system, quickly filling up all the available disk space. Enter a reasonable limit here, or accept the default values of 1 megabyte (1000 kilobytes) for clients or 1.5 megabytes (1500 kilobytes) for newsfeed posts.

**Limit Connection Size** Much like the Limit Post Size setting, another way that individuals could potentially overload your system is by flooding it with numerous smaller messages that fit within the Limit Post Size restriction. In order to compensate for this, you can set a maximum limit, in megabytes, that an NNTP user can post during a single session to your server.

**Allow Feed Posting** When an NNTP server is configured to receive newsgroup data from another server instead of from individual users, or when an NNTP server replicates its own newsgroup data to another server, that flow of information is called a newsfeed. Unfortunately, IIS 6 (like IIS 5) doesn't support newsfeeds at this time. Perhaps this is because Exchange does support newsfeeds? Like the SMTP/POP3 service issue, Microsoft might be reluctant to provide a free service or feature when they have a perfectly good one for sale.

**Allow Servers to Pull News Articles from This Server** This option would theoretically permit the server to participate in a newsfeed configuration. Like the Allow Feed Posting option, it's apparently a placeholder for a future implementation of NNTP. Newsfeeds are not supported in IIS 6.

**Allow Control Messages** Control messages are specially formatted newsgroup messages designed to control the configuration of an NNTP server; for example, to create a new newsgroup across a collection of NNTP servers, a control message can be sent out instructing all servers to create the new group. Or a control message might instruct all other participating news servers to cancel (delete) a specific message from all systems.

**SMTP Server for Moderated Groups** Moderated groups (discussed a bit later in this section) are newsgroups that have their postings approved by a moderator before they are publicly posted. This is done via e-mail, so the NNTP process needs to have an accessible SMTP server to use for sending messages. If you will be configuring the SMTP service on your IIS server (discussed later in this chapter), you can use your own system as the SMTP server.

**Default Moderator Domain** When moderated e-mail messages are sent from your IIS system, they will be sent with a To: address of `newsgroup_name@default_moderator_domain` unless a specific moderator is specified for a group. Enter the domain portion of the address to use in this field.

## SECURITY ACCOUNT PROPERTIES

In order to define operator permissions for specific user accounts on your NNTP server, click the Security tab to get to the Security properties page (shown in Figure 17.64). Here, you can define operators capable of accessing and making configuration changes to a virtual NNTP server.

Add the Windows user accounts that should have operator privileges to this window by clicking the Add button and selecting the appropriate accounts.

## ACCESS PROPERTIES

Through the Access properties page, you can make changes to how your NNTP server is to be accessed. For example, you can allow for anonymous access (this is typically enabled by default), which means that any user who can successfully connect to the IP address of your NT server can access the newsgroups contained on it. Or you can require authenticated access. You can also define SSL encryption certificates (discussed later in this chapter) to use when communicating with your server, and grant or deny connections based on IP addresses. The Access properties page is shown in Figure 17.65.

**FIGURE 17.64**

Editing security properties

**FIGURE 17.65**

Editing access properties

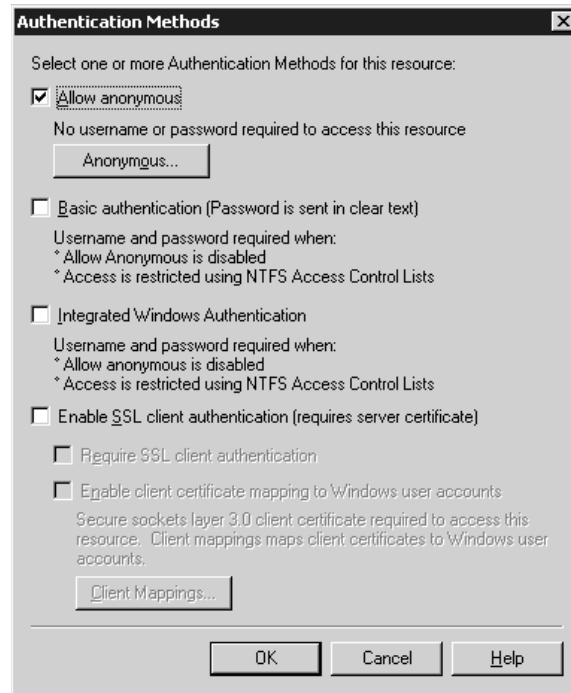

**Access Control**

Clicking the Authentication button in the Access Control area will take you to another dialog box, shown in Figure 17.66, for editing what type of authentication users should use when connecting to your system.

**FIGURE 17.66**

Editing authentication methods

As you can see in Figure 17.66, anonymous access is permitted by default. Anonymous access is rather straightforward; no username or password is required to connect, and all requests for content will be directed through the anonymous account defined on the Security Accounts properties page.

Basic authentication utilizes an authentication protocol built into NNTP called AUTHINFO. This protocol negotiates a username and password authentication over the Internet in cleartext. This authentication method will have the widest means of support but at the risk of transmitting passwords from your system in plain view of anyone who might be looking for them.

Integrated Windows authentication is another way of saying Windows challenge/response authentication. This typically limits client support to Windows platforms only, but it provides a secure means of authenticating users without passing cleartext passwords over the Internet.

If you would prefer to encrypt the authentication process between the client and your NNTP server, you can select the Enable SSL Client Authentication check box. This will allow your server to authenticate the client connecting to it in order to set up a secure, encrypted SSL tunnel. However, the client connecting to your server must have an SSL certificate installed for this to work. If you've enabled SSL client authentication, you can require this type of authentication for all users by checking the Require SSL Client Authentication check box. Based on the certificates that your users have installed, you can have those certificates map directly to a Windows user account by checking the Enable Client Certificate Mapping to Windows User Accounts box and then entering appropriate mappings by clicking the Client Mappings button. Doing this will basically tell IIS, "If someone hands you this certificate, assume that it is Windows user XYZ." The user does not need to actually provide a username and password; simply having the certificate is enough identification.

### Secure Communication

If you would like to protect your NNTP data as it travels from your server to the client (and vice versa), you can set up SSL communications properties through the Secure Communication area. This requires having an SSL certificate installed on your system and is discussed in greater detail in the “Communicating Securely with SSL” section later in this chapter.

### Connection Control

Another means of securing your NNTP server is to restrict who can access the site based on IP address, a range of IP addresses, or a domain name. This requires knowing in advance who should be connecting to your site and from where. By clicking the Connection button in the Connection Control section of the Access properties page (shown in Figure 17.65), you will see a screen similar to the one back in Figure 17.22, in which you can enter any restrictions you’d like.

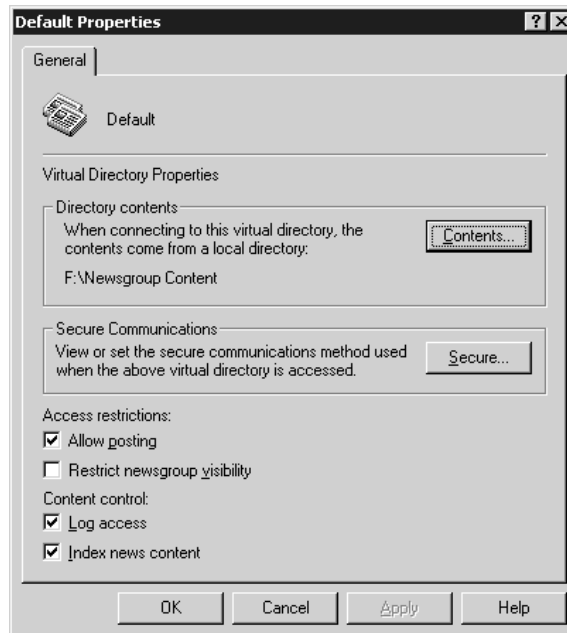

### DIRECTORY PROPERTIES

Since all newsgroup content must be stored in files, you will need to define where those files are to be stored. Initially, you did that in the wizard when you provided the system with directories to use for the NNTP content. However, since the wizard assumes several defaults for you, you might want to edit the directory properties yourself.

To edit the directory properties, go back to the Internet Information Services console and expand the NNTP server item that you created. Select the Virtual Directories item in the scope pane, and you should see the directories you originally specified for newsgroup content in the results pane. Highlight the appropriate directory to modify, and then either select Action/Properties from the pull-down menu or right-click the directory and select Properties. You should see a properties page similar to the one shown in Figure 17.67.

**FIGURE 17.67**

Directory properties page

You can store content in a directory on the IIS server itself or on a share on another server by clicking the Contents button in the Directory Contents portion of this properties page. If you decide to use a network share for storing your content, you will need to define an account that IIS uses to connect to the share.

Based on the newsgroups stored in this directory, you can control some specific parameters:

**Allow Posting** To disallow posting to newsgroups—that is, to the newsgroups stored in this directory—uncheck this box.

**Restrict Newsgroup Visibility** If you will be using access controls on your system to define who can access which newsgroups, you can control what newsgroups those users will even see by selecting this option. Choosing this option can add a significant amount of processing overhead to your system if you have a large number of groups, so you might want to leave this option disabled.

**Log Access** This setting works in conjunction with the Enable Logging check box on the General properties page for the NNTP site. If you want to log access to your system, you must have both check boxes checked. This allows you to log access to some directories as needed, without necessarily logging all access to all directories.

**Index News Content** Checking this box will instruct the Microsoft Indexing Service to index the content of this site, allowing users to search for text in postings.

The Secure Communications section of this properties page is used to require SSL communication sessions for newsgroups stored in this directory. SSL is discussed in greater detail later in this chapter in the “Communicating Securely with SSL” section.

## DEFINING GROUPS

Messages on an NNTP server are typically stored in different hierarchical groups based on their content. Levels of hierarchy are delineated by a dot between each word. For example, on the Internet, common newsgroup names such as `rec.pets.dogs` (for dog lovers) are part of the overall recreation hierarchy (`rec`), then the `pets` subhierarchy. This type of organization gives users an easy way to find the information they are looking for. Additional groups could include `rec.pets.cats` and `rec.pets.ferrets`, thus keeping the messages for each topic isolated from other messages.

Within your organization, you can also use a similar structure for newsgroups. For example, you might choose to define groups along divisional, departmental, and then topical lines. For example, a group called `accounting.payroll.withholding` could be used to handle discussion messages and questions from employees regarding their withholding from their paychecks, whereas `sales.advertising.radio` could be used to discuss the effectiveness of radio advertisements and to brainstorm for new topics.

For each level of hierarchy in the name of the newsgroup, IIS will create a separate directory in the content directory defined for your site (discussed earlier in this chapter). For example, if you create a group called `accounting.payroll.withholding`, IIS will create three subdirectories in your content directory. The first subdirectory will be called `accounting`. Within the `accounting` subdirectory, there will be another subdirectory called `payroll`, and within the `payroll` subdirectory, there will be another subdirectory called `withholding`. If these directories are created on an NTFS volume, you can control which users can access which groups (assuming you’ve required authenticated access) by

applying appropriate permissions to each directory. Therefore, you can restrict confidential information to only the individuals who should receive it and leave everything else open to the public.

As you can see, there are many possible uses for newsgroups. Since the default configuration of a newsgroup server doesn't typically include any groups (other than control groups, if needed), you will most likely want to add some groups to your system.

Define newsgroups from the main Internet Information Services screen by expanding your NNTP server item in the scope pane, and then highlighting the Newsgroups option below it. Once you have the Newsgroups item highlighted, you can select the New/Newsgroup option either from the Action pull-down menu or by right-clicking the Newsgroups option. Selecting New/Newsgroup launches the New Newsgroup Wizard, which will walk you through the process to define a new newsgroup. The first step of the wizard, shown in Figure 17.68, will prompt you for an appropriate name for your newsgroup. As previously discussed, enter the name for your desired newsgroup here and then click Next to proceed to the next step of the wizard, shown in Figure 17.69.

**FIGURE 17.68**  
Defining a new  
newsgroup name

**FIGURE 17.69**  
Defining a news-  
group description  
and pretty name

To enter descriptive information about this group above and beyond the information that the name of the group gives, use the Description field. You can also enter a “pretty name” for this newsgroup that will be returned to NNTP clients that issue a LIST PRETTYNAMES command.

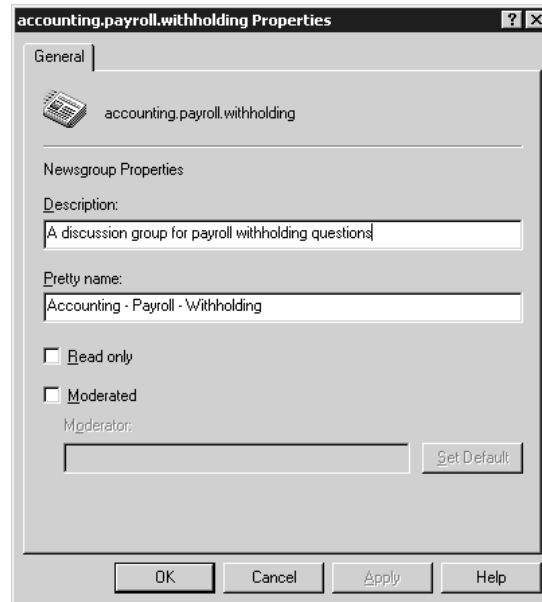

Once you have entered this information, click the Finish button and your new newsgroup will be created. However, as is true with most of these wizards, a few assumptions are made for this group and automatically saved as defaults. If you would like to change the properties of the group you’ve just created, highlight it in the results pane of the MMC and then select the Properties option either from the Action pull-down menu or by right-clicking the group. That should bring you to a group properties page similar to the one shown in Figure 17.70. In this screen, you can edit the properties you just defined for this group, plus enable some additional options, as defined next:

**Read Only** If only the moderator should be allowed to post to this group, check this box. No other users will be allowed to make postings to this group.

**Moderated** The default setting for new newsgroups is to leave them unmoderated—meaning that all postings are publicly available immediately; there is no “checking” process that occurs. If you prefer to have a moderator manage the messages on your system, click the Moderated option. Enter an appropriate e-mail address for the moderator in the Moderator field, or click the Set Default button if you prefer to use the moderator defined in the NNTP settings (discussed earlier in this section). Newsgroup messages will be e-mailed to the Moderator for approval before being published.

**FIGURE 17.70**

Editing newsgroup properties

## Defining NNTP Server Expiration Policies

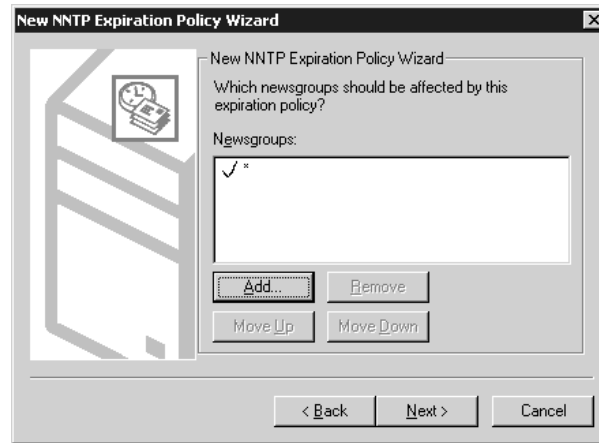

In a perfect world, disk space would be amazingly dirt cheap, and installing terabytes worth of storage would simply be a Plug-and-Play operation. This would allow you to keep all news articles posted on your server forever and ever (amen).

Welcome to reality. If you're running an NNTP server that will be handling a fair amount of traffic, it will eventually consume all available disk space on your system, unless you expire old articles. To add an expiration policy to your system, select your NNTP server in the scope pane of the Internet Information Services tool and expand it. Select Expiration Policies, then select New/Expiration Policy from the Action pull-down menu.

This will start you through a wizard in which you define which newsgroups to expire and when. The first step of the wizard will prompt you for a friendly name for your expiration policy. Enter whatever you feel is appropriate in this box and then click Next to move on to the next step of the wizard, shown in Figure 17.71.

**FIGURE 17.71**

Choosing all groups or selected groups

The asterisk and check mark shown in the Newsgroups list box in Figure 17.71 indicate that all groups are included in this policy. If you want to have IIS simply expire all newsgroup articles on your system after a set number of hours or days, accept the default setting and click Next. Otherwise, if you want to have custom expiration policies for certain groups (for example, you might want some groups to never expire), select the Add button. You will be taken to an Add Newsgroup dialog box where you will enter a group name to include or exclude from this policy. Excluded groups appear in a list of newsgroups with an X instead of a check mark. Use the Move Up and Move Down buttons to set the order for application of the policy. For instance, to have the policy apply to all groups on the server except for alt.payroll.accounting, put the wildcard include entry first on the list and the exclude entry for alt.payroll.accounting last. Once you've configured the list of newsgroups and included or excluded them from the policy in the desired order, click Next to move on to the next step of the wizard (shown in Figure 17.72). Now you will enter the number of hours that IIS should wait before purging a newsgroup article. The default value is 168 hours, or 7 days. If you have a low-traffic site and want to keep articles around longer, then increase this value accordingly.

Click Finish when you are done, and you should see your new expiration policy appear in the details pane of the console. To go back and make changes to the policy, simply edit the properties for the policy item.

**FIGURE 17.72**

Setting an expiration interval, in hours

## Virtual NNTP Server Directories

Virtual NNTP server directories have a bit of a different function than virtual directories defined for Web and FTP sites. On Web and FTP sites, users can navigate through different directories on your system, but on a newsgroup server the only thing users can navigate to are newsgroups. So what's an NNTP virtual directory designed to do?

NNTP virtual directories are designed primarily as a means to spread newsgroup content out across systems. Content is spread across systems based on hierarchy names. For example, you might have the content for the entire `accounting.*` hierarchy stored on one server and have the content for the `sales.*` hierarchy stored on another server.

The primary benefits of doing this are increased speed and performance (you don't have one server doing all the work), and if you suddenly run out of disk space on one system, you can start spreading the content around. To create an NNTP virtual directory, begin by selecting your NNTP virtual server in the scope pane of the Internet Information Services console and highlighting the Virtual Directories option below it. Select the New/Virtual Directory option from the Action pull-down menu to launch the New Virtual Directory Wizard, shown in Figure 17.73.

**FIGURE 17.73**

Defining a subtree for an NNTP server virtual directory

To carve off an entire section of your hierarchy structure and store it in a virtual directory, enter the left-most portion of the group name you want to store. For example, if you entered `rec.pets` in this field, you would end up storing the groups `rec.pets.dogs`, `rec.pets.cats`, and `rec.pets.ferrets` in this virtual directory, but `rec.games.chess` would still be stored in the primary directory defined for this NNTP server. Enter the appropriate hierarchy name and then click Next to proceed to the next step of the wizard.

The next step of the wizard will ask you for a “storage medium” for this content—this is exactly the same as what you saw back in Figure 17.60. The wizard will also prompt you for either a directory or a remote share and username/password combination based on your answer. The location you provide the wizard with is where all of the content for the hierarchy you specified will be stored. By clicking Finish, you will have created a virtual directory on your server for your NNTP content. Once created, you can modify the properties of a virtual directory by right-clicking the item and choosing Properties from the context menu. Refer back to the section “Directory Properties” for more details.

## Setting Up an SMTP Server and Configuring SMTP Services

As you’ve seen throughout this chapter so far, there will probably come a time when your IIS server will need to send e-mail to someone. Whether it is for support of FrontPage extensions or to forward a newsgroup posting to a moderator for approval, your server will need to communicate with another host for the transfer of e-mail. The protocol you’ll use to perform this communication is called the Simple Mail Transfer Protocol—SMTP for short.

Microsoft has included a basic SMTP server with IIS 6 for exactly this reason—so that services on your server can send e-mail out to other hosts as needed. Without the optional POP3 component, however, it is *not* a complete mail server, as you’ll see, but it can be useful for other things.

### Internet E-Mail Protocols

There are two main Internet e-mail protocols that most of us care about: The Simple Mail Transfer Protocol (SMTP) and the Post Office Protocol (POP3).

SMTP is the “mail” Internet e-mail protocol. SMTP grew up at a time when most users on the Internet were running Unix machines, each with its own IP address. Each Unix machine ran two mail programs. The first was a program that could package up a mail message and send it to its destination; the most common one was one named Sendmail. The second program was a so-called daemon, a program that always runs in the background, kind of like a DOS Terminate and Stay Resident (TSR) program. The daemon would constantly listen for incoming mail in the form of TCP/IP packets sent from another system running Sendmail.

The SMTP/Sendmail approach worked fine as long as every system on the Internet could run some kind of mail daemon, and so long as every system was up and running 24 hours a day, seven days a week. But primitive PC operating systems don’t handle daemons well, and most people don’t leave their workstations up and running all of the time, even if they are running an operating system that handles daemons well. Additionally, while many systems may run all of the time and while they may have an operating system that likes daemons just fine, they aren’t connected to the Internet all of the time.

In any case, it’d be nice to enhance SMTP with some kind of mail storage system, allowing one computer to act as a kind of “post office.” Suppose you have 500 people on your network with varying operating systems and uptimes. So you set up one computer that is up 24 hours a day, 7 days

a week. This computer runs the mail daemon, the program that listens. You tell that computer, “Accept mail for everyone in the company, and hold onto it.” That’s the computer I’ll call a post office. Then, when a user wants her mail, she just connects to that post office and pulls down her mail. In the Internet world, we let a client computer like the one on her desktop communicate with a post office computer with a protocol called POP3, the Post Office Protocol. Such a program is a small application referred to as a POP3 client. Actually, every POP3 client that I know of might be better referred to as a POP3 Message Receiver/SMTP Message Sender. The program only uses POP3 to get your mail; when you create a new message, it just sends it to a computer running the SMTP receiver service (the daemon), which then hands it to the SMTP delivery service (Sendmail or one of Sendmail’s cousins).

In order for your office to send and receive Internet mail, you’ll need a computer to act as a post office. The computer uses SMTP to talk to other post offices, and those post offices may choose to communicate with you at any hour of the day, so the computer must be attached to the Internet 24 hours a day, 7 days a week. So that your users can retrieve their mail, they’ll need programs that act as POP3 clients. Finally, that post office computer will need to run a POP3 server so that it can respond to mail requests.

In the past, if you wanted a POP3 Server for Windows NT or 2000, you had to buy Exchange, some other commercial mail software package, or use the free EMWACS Internet Mail Service software. Now Windows Server 2003 includes a very simple POP3 Server component that you can install from the Control Panel. This is a great option for organizations that don’t want all the bells and whistles of Exchange or some other big software package but still need an Internet e-mail solution. We’ll talk about the POP3 Server component a bit later.

Where can you find a POP3 client? Right in Windows—the program attached to the Inbox tool (on 95) or Outlook Express (on 98, Me, 2000, XP, or NT 4 with IE 4) can act as a POP3 client. Or, if you find the Microsoft tool not to your liking, surf on over to [www.eudora.com](http://www.eudora.com), where you’ll find Eudora Light, an excellent mail client written by the Qualcomm people. They write terrific software, and even better, they have a 32-bit version of their Eudora mail client that they give away absolutely free. You can even get the full version of the software for free if you’re willing to put up the displayed ads. I’ll talk about how to configure these clients a little later.

## Creating a New SMTP Server

As I stated in the earlier section, a default virtual SMTP server is created during the IIS 6 installation. The SMTP server is configured to listen on TCP/IP port 25 for all configured IP addresses. The mail directory for the default virtual server is `\inetpub\mailroot`. Since the virtual server can accept and deliver mail for multiple domain names, it may never be necessary to create another SMTP virtual server on the same system. However, if you find you do need to set up a new SMTP server on IIS, you will need to know the following information in advance:

- ◆ Which IP address you want this SMTP server to listen to for inbound connections (or if it should respond on all available IP addresses).
- ◆ Which TCP/IP port number this SMTP server should listen to on the previously specified IP address(es). Typically, this is port 25.
- ◆ A “default domain” name to use for the sending of messages.
- ◆ Which directory on your system to use for incoming and outgoing e-mail files.

Once again, Microsoft has included a wizard to make the creation of a new SMTP server relatively straightforward.

To begin the creation of a new SMTP server, start by selecting your IIS server in the scope pane of the Internet Information Services tool, then select the New/SMTP Virtual Server option from the Action pull-down menu. This should bring you to the first step of the New SMTP Virtual Server Wizard, shown in Figure 17.74.

**FIGURE 17.74**

Defining a friendly name for an SMTP virtual server

This step of the wizard wants you to specify a friendly name to use when referencing your new SMTP virtual server. This name is simply for administration purposes; your users won't see it, so choose a name that's appropriate and then click Next to proceed to the next step of the wizard, shown in Figure 17.75.

**FIGURE 17.75**

Defining IP addresses for an SMTP virtual server

In order to access your SMTP server, other SMTP servers will need to establish a TCP/IP connection to your system on a specific IP address and TCP port number. By default, the New

SMTP Virtual Server Wizard will want to have your site listen on all available IP addresses for incoming connections. If you are going to be running only one SMTP server on your system, these settings should be fine. However, if you intend to run multiple SMTP servers on your system (for example, if you plan on hosting several virtual domains on your IIS server), you might want to specify a specific IP address for this server to use.

Click Next when you've completed the IP configuration, and you'll move to the next step of the wizard, shown in Figure 17.76.

**FIGURE 17.76**

Defining a directory for an SMTP virtual server

Since IIS will need a location to store incoming and outgoing e-mail messages, you must create a directory on your server to store this information. Unlike other services within IIS, in this service, you cannot define a share on another computer as the target location for your files. Instead, you must define a local path to be used for storing your SMTP content. Enter the appropriate directory to use, and then click Next to proceed to the final step of the wizard, shown in Figure 17.77.

**FIGURE 17.77**

Defining a default domain

The last step of the wizard will ask you to enter the default domain that this virtual server should serve, such as `redhilltown.com` (you don't need to use the `@` sign). Enter the appropriate domain to use, click the Finish button, and your new SMTP virtual server should be created. If you receive an error message at this point, check back in the Internet Information Services tool to see if the default SMTP server installed with IIS is running on the same IP address and TCP port of the system you've just defined. If it is, stop that virtual server and then start your new server again.

## Modifying SMTP Virtual Server Properties

Because the New SMTP Virtual Server Wizard only asks you for a few configuration items, there are settings that you will probably want to adjust for your system. To adjust the parameters for your SMTP virtual server after the wizard has created it, you will use the SMTP virtual server properties pages.

### GENERAL PROPERTIES

To reach the SMTP virtual server properties pages, highlight your new SMTP virtual server in the scope pane of the Internet Information Services tool and then select Properties from the Action pull-down menu. This will bring you to a dialog box similar to the one shown in Figure 17.78.

**FIGURE 17.78**

Configuring general settings for an SMTP virtual server

From this page, you can edit options for your server, including the following:

**IP Address** Enter the IP address for your SMTP server to use here. You can assign your server to a specific IP address or have it respond on any free IP addresses on the system by selecting

the All Unassigned option. To edit the TCP port number for this SMTP server, click the Advanced button.

**Concurrent connections and idle timeout** Enable the Limit Number of Connections To option and supply a value in the corresponding field to control the number of concurrent connections. Idle connections will timeout after 10 minutes by default unless you modify this value.

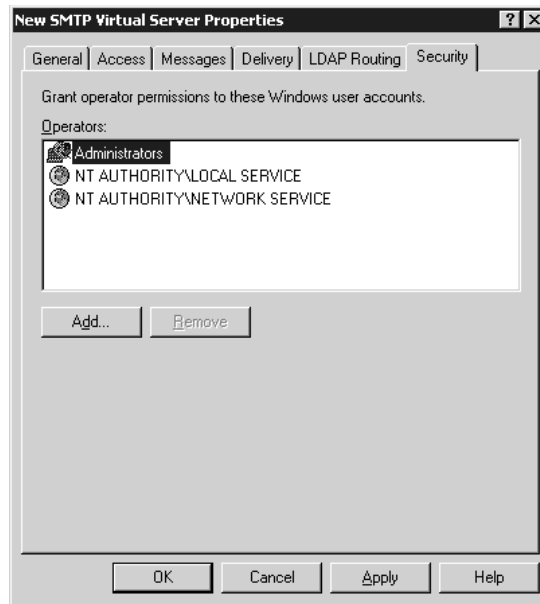

**Enable Logging** To keep track of what e-mails your server has sent and received, turn on logging by checking the Enable Logging box. Logging choices include W3C Extended Log Format, IIS Log File Format, NCSA Common Log File Format, and ODBC Logging.

### SECURITY PROPERTIES

To delegate administrative controls for this server to specific users, click the Security tab to get to the Operators properties page, shown in Figure 17.79.

**FIGURE 17.79**

Configuring operators for an SMTP virtual server

This dialog box is really quite self-explanatory. Simply click Add to add Windows server accounts or groups to the list of administrators for this SMTP server. Users listed here will be able to change parameters for this specific SMTP server via the Internet Information Services tool.

### MESSAGES PROPERTIES

Abuse via SMTP—such as someone e-mailing you a 1GB file and consuming too much disk space, or the unauthorized relaying of messages—is not uncommon. To protect your system, you can set parameters regarding the delivery of messages on your system. To fine-tune the default message properties, select the Messages tab, shown in Figure 17.80.

**FIGURE 17.80**

Configuring message properties for an SMTP virtual server

You can change a few properties here that handle how both inbound and outbound messages are controlled. They are as follows:

**Limit Message Size To (Kilobytes)** To limit how large a message a mail client can send to your server, enter an appropriate value in this field. This limit will be applied after a message has been received in its entirety. The minimum for this value is 1KB.

**Limit Session Size To (Kilobytes)** Instead of waiting around to receive the end of a message that has already exceeded the maximum message size, you can enter a value in this field; when a session reaches this point, IIS will close off the connection. The minimum value for this field must be equal to or greater than the previously defined maximum message size value.

**Limit Number of Outbound Messages per Connection To** During a connection to an SMTP server, a client may send several messages to the system for delivery. Unfortunately, some SMTP servers are unknowingly used for the unauthorized relay of junk e-mail (often referred to as spamming), delivering hundreds of thousands of messages. By forcing a client to establish a new connection every x number of messages, an SMTP server becomes less desirable to a spammer for use as a relay point. I would recommend leaving the default value in this field.

**Limit Number of Recipients per Message To** Although this setting would seem to limit the number of people you can send a single message to, it is really included for compliance with RFC 821, which defines SMTP. RFC 821 states that the maximum number of recipients per e-mail message is 100. But what if you have a message destined for 150 recipients? The message will be sent in one session to the first 100 recipients, and then a second session will be opened for the remaining 50 recipients.

**Send Copy of Nondelivery Report To** Nondelivery of a message, for whatever reason (invalid e-mail address, etc.), will typically cause the SMTP server to generate a nondelivery report (NDR) e-mail message for the sender. If you would like to have a copy of the NDRs also e-mailed to a specific mailbox, enter the appropriate e-mail address here.

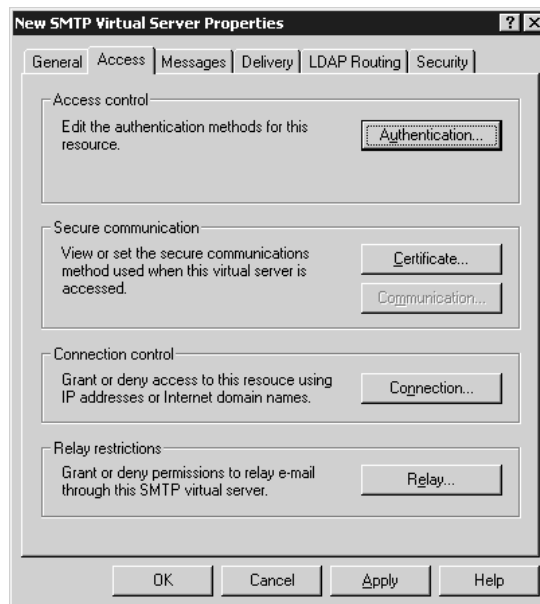

**Badmail Directory** When the SMTP service sends a nondelivery report (as mentioned above), it will go through the typical delivery routine for an e-mail message. However, under certain circumstances, the nondelivery report might be undeliverable. In such cases, the SMTP service will automatically place the message in this directory and consider the message permanently undeliverable. It's a good idea to check this directory every now and then to see if anything is piling up in there.

### ACCESS PROPERTIES

Although most SMTP communications across the Internet occur anonymously, you can require authenticated access to your system if you desire. If you choose to require authenticated access to your SMTP server, the Access properties page is where you will make these changes. You can also control what IP addresses and domain names can attach to your system, define secure communications, and set relay restrictions here. The Access properties page is shown in Figure 17.81.

**FIGURE 17.81**

Configuring access properties for an SMTP server

From this dialog box, you can control authentication, secure communications, address restrictions, and relay restrictions on your SMTP server by clicking the appropriate button.

### Access Control

By default, SMTP connections are anonymous in nature: no authentication is required from a client accessing your SMTP server in order to send messages through it. If you want to change this

behavior, click the Authentication button in this box to go to the Authentication dialog box, shown in Figure 17.82.

**FIGURE 17.82**

Configuring authentication properties for an SMTP server

**Anonymous Access** By default, all three authentication options are initially selected. If you don't want clients to be able to send messages anonymously through your SMTP server, uncheck this first option.

**Basic Authentication** If you choose to disable anonymous access, this is the first option that you can choose for client authentication. Basic authentication works via AUTH and USER/PASS commands sent between systems in cleartext. User accounts are verified against the accounts database local to the IIS machine. If a valid account is found, message processing can proceed. Otherwise, the SMTP session is never completed. Although this isn't necessarily a secure means of authentication, it will have a wider base of support than the next authentication option.

**Integrated Windows Authentication** Another name for the Microsoft challenge/response authentication, this option requires that both the SMTP server and SMTP client be running a Windows platform. User accounts are verified against the accounts database local to the IIS machine. If a valid account is found, message processing can proceed. Otherwise, the SMTP session is never completed.

### Connection Control

If you prefer to control who accesses your SMTP server via IP addresses or domain names instead of authentications, click the Connection button in this area to edit the connection properties, shown in Figure 17.83.

Select the radio button option to either allow only the addresses and domain names you specify or allow everyone except the addresses and domains you specify. Enter the exception list by clicking Add. From the dialog box that follows, you can either grant or deny access to a single computer

(via an IP address), a group of computers (via an IP address and a subnet mask), or an entire domain (via a domain name). IP addresses are usually the best option if you know which addresses to allow or deny. Since IIS only knows who is connected to it by an IP number, the server must do a reverse-DNS lookup if you select the domain name option, which adds quite a bit of processing for the server to do just to determine if it's okay to let the user in. Unless your situation requires using domain names, it's probably worthwhile to find out the exact IP address ranges to allow into your site and configure them accordingly.

**FIGURE 17.83**

Configuring IP address and domain name restrictions for an SMTP server

**NOTE** Many hosts out on the Internet don't actually have reverse-DNS records assigned to them, and some hosts have incorrect reverse-DNS records assigned to them. Therefore, even if you were to put in a restriction based on a host/domain name, it might not work quite as well as you want it to.

### Relay Restrictions: Stopping Spammers

Because an SMTP server will typically deliver any message sent to it, abuse can become a problem if someone decides to park tens of thousands of messages on your system for delivery. Spammers will often find misconfigured third-party SMTP servers to relay their junk mail, park a few thousand messages on the system, and then move on to another server. This behavior is known as relaying a message, and it is an inherent part of the SMTP protocol—a protocol that was designed when the Internet was a more trusting, friendly place.

To defeat this behavior, many SMTP servers (including Microsoft Exchange) now include powerful relay controls that will allow you to determine whether or not the SMTP server should receive any messages for domains other than the ones that it hosts. For example, if your system lives in a domain called mycompany.com, then your SMTP server will—by default—only accept incoming messages destined to e-mail addresses ending in @mycompany.com. Any other messages will be denied, unless you specifically allow relaying by clicking the Relay button in the Relay Restrictions area and adjusting the properties page shown in Figure 17.84.

The format of this dialog box is similar to that for allowing and denying IP address restrictions to the SMTP service as a whole. By default, all hosts are denied relay access, unless you enter specific hosts in the list box. You can either grant or deny access to a single computer (via an IP address), a group of computers (via an IP address and a subnet mask), or an entire domain (via a domain name). IP addresses are usually the best option if you know which addresses to allow or deny.

**FIGURE 17.84**  
Configuring relay controls on an SMTP server

If you have enabled authentication options on your system, you can check the Allow All Computers Which Successfully Authenticate to Relay box at the bottom of this dialog box, giving anyone with an appropriate user authentication the rights to relay.

**DELIVERY PROPERTIES**

Click the Delivery tab (Figure 17.85) to define parameters about how messages are delivered into and out of your SMTP server.

**FIGURE 17.85**  
Configuring delivery properties on an SMTP server

This page is divided up into multiple options, both inbound and outbound, for controlling the delivery of messages.

### **Outbound**

When an SMTP server receives a message, it will attempt to deliver it almost immediately. For various reasons, it is possible that the SMTP server will fail to deliver the message—the receiving host might be too busy, the receiving host might be down, or Internet connectivity might not be available. For whatever reason, the SMTP service will continue to try to deliver the message for the intervals specified in this section.

If the SMTP server fails at delivering the message after the first attempt, it will try again three times at the minute values specified in the First Retry Interval, Second Retry Interval, and Third Retry Interval fields. After the third retry value, if the message still hasn't been delivered, the SMTP service will attempt to deliver the message at the interval defined in the Subsequent Retry Interval field.

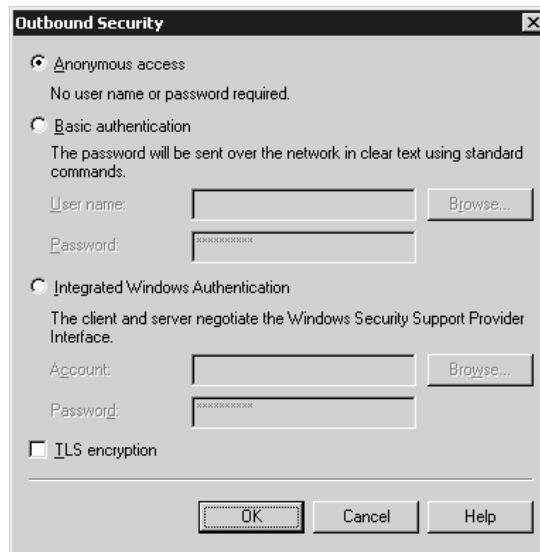

Eventually, if the message has failed enough times, the SMTP service will send a notification e-mail message to the user listed in the From: field of the e-mail message, letting him or her know that the message is still “in the queue” but hasn't been delivered to its destination yet. This interval is defined in the Delay Notification field. If the message eventually hits the value defined in the Expiration Timeout field, the message will be aborted and sent back to the user who sent it, along with a notification of the failure. These same values can be set for local delivery as well at the bottom of this screen.

### **Outbound Security**

Inbound authentication controls can be set for the IIS SMTP service using the Access Properties page discussed earlier in this section. However, SMTP servers must connect to other SMTP servers to deliver messages. If the SMTP server that your system will be communicating with requires a similar means of authorization, you will need to define these options in the Outbound Security settings area. Click the Outbound Security button to edit the Outbound Security properties page, shown in Figure 17.86.

**FIGURE 17.86**

Configuring  
outbound  
authentication  
for an SMTP  
server

For more detailed information on the types of outbound authentication available, the “Access Control” discussion earlier in this section contains working definitions of anonymous access, basic authentication, and integrated Windows authentication. Whatever authentication your receiving systems will require, select a radio button to enable that type of security and supply the appropriate account information. For basic authentication or integrated Windows authentication, you can click the Browse button to select a username and password to use.

### **Outbound Connections**

To modify the default settings that control outbound connections, click the Outbound Connections button to open the Outbound Connections properties page (shown in Figure 17.87). From here, you can specify a limit for concurrent outbound connections and a timeout value in case a connection becomes idle after communication is established with another SMTP (for example, the remote server might stop responding for some reason). You may also specify a limit for the number of simultaneous connections to a given domain or modify the default connection port. TCP/IP port 25 is the standard port used for SMTP communications between servers; if you change the port setting for outbound connections, any remote servers must also be configured to accept incoming SMTP connections on the same nonstandard port.

**FIGURE 17.87**

Configuring outbound connection parameters

### **Advanced Delivery Options**

The following options are advanced parameters for controlling the outbound delivery of messages. Clicking the Advanced button on the Delivery page will take you to a screen similar to the one in Figure 17.88.

**Maximum Hop Count** When an SMTP server receives a message, it may be sent through other servers before reaching its final destination (a mailbox). However, a pair of misconfigured SMTP servers might bounce a message back and forth between themselves indefinitely (known as ping-ponging), with the message getting larger at each step of the way and never reaching its destination. To prevent this, the SMTP service can perform a “hop count” on a message—basically, counting the number of Received headers present in a message—and reject the message if there are too many hops in the message path. By default, this is set to 15, which should be acceptable for most circumstances. If a message exceeds its maximum hop count, then the message fails and the sender gets an error message telling them that the message couldn’t be delivered.

**FIGURE 17.88**

Configuring  
Advanced Delivery  
properties

**Masquerade Domain** To override the domain name in an outgoing message with a specific domain name, enter the domain name here. The domain name entered in this field—if any—will replace the existing domain name listing in the From: field of the outgoing message.

**Fully Qualified Domain Name** Enter the fully qualified domain name (FQDN) of your SMTP server in this field. An FQDN typically has at least three segments to it: host.domain.tld (tld is for top-level domain). When the SMTP service is installed and the default SMTP virtual server is created, IIS automatically takes the fully qualified domain name from the full computer name specified in the System properties. So, for example, my SMTP server name is `zooropa.redhilltown.com`. This is the format for the name that normally appears in the FQDN field for the default SMTP virtual server. Usually, though, people send mail to addresses that read like `username@domainname.tld` instead of addresses like `username@SMTPservername.domainname.tld`. So you can specify your fully qualified domain name in this field as `redhilltown.com` (for example) instead of `zooropa.redhilltown.com`, as long as you create the appropriate DNS mail exchange (MX) records that point to the SMTP server. Use the Check DNS button to query DNS for an MX record using the FQDN you typed in to verify that a valid record exists and that users can send mail to the server using this name.

**Smart Host** One common mail server configuration involves having one SMTP server running on an Internet-accessible network segment, and another running behind a firewall or other gateway device on an internal, protected network. In this case, the external SMTP server handles all of the incoming and outgoing Internet mail while the internal server hosts user mailboxes. Incoming mail is relayed through the external server (called a relay server or a smart host) to the internal mail server, and outgoing mail is relayed from the protected server to the smart host for delivery on the Internet. This configuration protects the internal mail server from direct attack and eases the burden of servicing POP3 clients and delivering messages to other SMTP servers simultaneously.

If you would prefer to have another SMTP server handle all of the outgoing messages, enter a domain name or host address of the smart host here. If you enter an IP address, Microsoft suggests

entering it in brackets [ ] so that the SMTP service will immediately know that it should try to connect to the smart host via IP address and skip name resolution.

**Attempt Direct Delivery Before Sending to Smart Host** If you have defined a smart host in the previous field, you can tell SMTP that it should try to deliver messages on its own first. If it cannot deliver the messages on its own, it will immediately send them on to the smart host for delivery.

**Perform Reverse DNS Lookup on Incoming Messages** When incoming messages are received by SMTP, IIS can perform a reverse-DNS lookup on the IP address noted in the header of the message and insert the fully qualified domain name of the IP address into the Received header. If the reverse-DNS lookup fails, no FQDN is put into the Received header. Reverse-DNS lookups can slow message processing, so depending on the volume of messages that you're receiving, you might want to leave this option unchecked unless necessary.

### ADDING ADDITIONAL DOMAINS

By default, your SMTP server will only process messages destined for the domain you specified during the New SMTP Virtual Server Wizard. All other domain names will be considered by IIS to be “nonlocal” and therefore need to be relayed.

However, if you want to host multiple domain names on your system for e-mail or allow relaying for specific domains, you can do so by adding additional domain names through the Internet Information Services tool. Select your SMTP virtual server from the scope pane of the console and expand it. Below the SMTP server, you should see an item for Domains. Select that item, and you will see your currently defined domain in the results pane on the right side of the console. With the Domains option highlighted, select New/Domain from the Action pull-down menu, or simply right-click Domains and choose New/Domain.

Selecting the New/Domain option brings you to a two-step wizard, the first step of which is shown in Figure 17.89.

**FIGURE 17.89**

Adding a domain to an SMTP server

The first step of the wizard wants to know whether to add a local (alias) or remote domain. This will define whether the SMTP service should immediately store the message in the Drop directory

once it receives it (local/alias), or if it should try to pass it on to another mail system (remote). Make the appropriate selection and then click Next to proceed to the last step of the wizard, entering the actual domain name. Once you enter a new domain for your system, the SMTP server will begin receiving/accepting traffic for e-mail addresses within that domain.

Local, or Alias, domains are pretty easy to understand. It's not uncommon for a company to have several different domain names and corresponding Web sites. If a company undergoes a name change, or if it operates with several identities, alias domain listings simply tell the SMTP server that mail destined for a user in the alias domain (ljustice@hawkmoon.org, for example) is to be handled as if it were addressed to a user on the default domain (ljustice@redhilltown.com). Since the alias domain is identical to the default domain, there are no separate properties pages for alias domains.

Remote domains are a little different. These may be other domains that you specifically want to relay mail for (recall that relaying mail to other domains is not allowed by default), or you may need a subset of your incoming mail to be relayed to or retrieved by another SMTP server. Accordingly, you may need to set a couple of configuration options in the properties pages for remote domains. Right-click the remote domain name in the Details pane of the console, and choose Properties from the context menu (or choose Properties from the Action pull-down menu) to access the General properties page (shown in Figure 17.90).

**FIGURE 17.90**

Configuring mail relay for remote domains

If you want mail for this domain to be relayed to another SMTP server, check the box labeled Allow Incoming Mail to Be Relayed to This Domain. It's worth noting that this option is not checked by default. So if you create a remote domain and don't enable some sort of relay, incoming mail for that remote domain will just sit on the server. Use the checkbox labeled Send HELO instead of EHLO to prevent error messages if you know that the remote server doesn't support ESMTP. The

Outbound Security button allows you to set authentication options and is identical to the settings shown back in Figure 17.86.

Use the radio buttons to choose whether to locate a mail server for the domain using DNS, or to simply forward all mail destined for the remote domain to a smart host. If you want to use a smart host, type in the name of the host in the space provided.

The Advanced properties page shown in Figure 17.91 permits you to configure the remote domain for ATRN. ATRN is an acronym for TURN with Authentication. TURN (also known as Mail Turn; TURN is not an acronym) is a protocol that permits one SMTP server to connect to another one and, instead of delivering mail, become a client and retrieve or “dequeue” mail destined for its own domain. ATRN is simply an implementation of TURN that requires the SMTP server to authenticate before retrieving mail. As far as I know, IIS 6 mail servers can’t do this, but if you have servers that are capable of retrieving mail in this way, you may choose to enable queued messages and specify the accounts that are authorized to retrieve messages in this manner.

**FIGURE 17.91**

Configuring the server for ATRN retrieval

## Maintaining Your SMTP Server

After you’ve gone through all of these configuration items, you should have a fully functional SMTP server on your system servicing the domain you defined in the New SMTP Virtual Server Wizard. As with any process on your system, it will require a bit of maintaining and fine-tuning from time to time.

### SMTP DIRECTORIES

If you look at the directory you defined during the setup of your site, you should see four subdirectories, titled Badmail, Drop, Pickup, and Queue.

These are the directories that the SMTP service will use when processing incoming or outgoing messages. Incoming messages for your default domain or any alias domain will end up in the **Drop** directory, so it is worth looking in there every once in a while to see if mail has been sent to your system.

**TIP** You can specify another location for the default drop directory as long as it is a local directory and it's not the designated pickup directory. Right-click the default domain name in the Details pane of the IIS management tool (*iis.msc*) to access the General properties page for the domain. Type a local path in the Drop Directory dialog box or use the Browse button to locate the target directory.

Incoming e-mail messages will be stored in .eml files and will look somewhat like this:

```
Received: from october.redhilltown.com ([192.168.1.3]) by
zooropa.redhilltown.com with Microsoft SMTPSVC(6.0.3663.0);
Sat, 11 Jan 2003 13:32:09 -0500
From: lnjustice@adelphia.net
Bcc:
Return-Path: lnjustice@adelphia.net
Message-ID: <Z0OR0PAUimGFX8nwn4000000002@redhilltown.com>
X-OriginalArrivalTime: 11 Jan 2003 18:32:17.0011 (UTC)
FILETIME=[C4A87C30:01C2B99F]
Date: 11 Jan 2003 13:32:17 -0500
Hello. This is a test message.
```

Outgoing messages from your system will be placed in the **Pickup** directory, either by the FrontPage extensions or the NNTP service as needed. However, you can also use the **Pickup** directory for your own administrative uses by placing properly formatted messages in there for delivery. For example, if you have a service process that generates a status report every night (perhaps a backup log) and want to have it automatically e-mailed, you can simply have a process create a properly formatted text file and place it in the **Pickup** directory. The SMTP service will see the file there and attempt to deliver it. A properly formatted outgoing SMTP message would look similar to the following:

```
x-sender: lnjustice@redhilltown.com
x-receiver: lnjustice@adelphia.net
From: lnjustice@redhilltown.com
To: lnjustice@adelphia.net
Subject: Hello from REDHILLTOWN
```

Hello Lisa. Hope that everything is going well with you.

If you intend to use the **Pickup** directory for your own messages, I'd recommend that you compose your text file in another directory first before placing it in the **Pickup** directory. If you begin to compose a message directly in the **Pickup** directory, the SMTP service will attempt to pick it up while you are working on it.

If the SMTP service runs into a message that it can't deliver to its intended recipient, and for which a nondelivery notification can't be returned to the sender, it will drop the message in the **Badmail** directory and leave it there. Every now and then it is probably worthwhile to check the **Badmail** directory and see if any messages have piled up.

Lastly, the `Queue` directory is where the SMTP service holds messages that it has pulled out of the `Pickup` or `Drop` directory. It will try sending a message immediately upon taking the message out of the `Pickup` or `Drop` directory, but if for some reason it can't deliver the message, it will hold it in the `Queue` directory until such time that it can be successfully delivered. If you want to make sure that incoming and outgoing messages aren't backing up on the server, a quick and dirty script to check the queue directory would be a very useful thing to run at regular intervals.

### SENDING E-MAIL FROM ACTIVE SERVER PAGES

If you're building a Web site that uses IIS's built-in SMTP server and want to mail more sophisticated things—even HTML pages—then you can do that with some built-in capabilities of IIS's Active Server pages. While this isn't a book on Web site construction, I've found this useful.

The key is an object called CDONTS, the Collaboration Data Objects for NT tool. I don't propose to explain it in detail, but I've cooked up a simple example. It sends two pieces of mail: first, a simple one-liner, and second, an HTML file.

To see this work, create the following file (see Listing 17.1). Call it `mailex.asp` and store it in your `wwwroot` directory:

#### LISTING 17.1: THE MAILEX.ASP FILE

```
<html>
<head>
<title>Mail Example</title>
</head>
<body>
<%
dim fso
htmlfile = ENTER THE NAME OF YOUR HTML FILE IN QUOTES
fromaddr = ENTER A "FROM" ADDRESS IN QUOTES
toaddr = ENTER A "TO" ADDRESS IN QUOTES
'Copy HTML file to a string variable
set fso=createobject("Scripting.FileSystemObject")
Set MyFile = fso.OpenTextFile(htmlfile,1) '1=read
HTML=""
while not myfile.atendofstream
    HTML=HTML+myfile.readline
wend
myfile.close
set fso=nothing
set myfile=nothing
'
' First mail:  create and send a simple message
'
'Create mail object
Set objNewMail = Server.CreateObject("CDONTS.NewMail")
objNewMail.From = fromaddr
objNewMail.To = toaddr
objNewMail.Subject = "Simple mail test"
```

```

objNewMail.Body = "Hi there; this is a test from the Web server."
objNewMail.BodyFormat = 1 '1=text, 0=HTML
objNewMail.MailFormat = 0
objNewMail.Importance = 1
objNewMail.Send
    if Err <> 0 Then Response.write "<p>CDONTS reported
    an error:" & Err.Description & "</p>"

'
' Second mail: A piece of HTML mail
'

Set objNewMail = Server.CreateObject("CDONTS.NewMail")
objNewMail.From = fromaddr
objNewMail.To = toaddr
objNewMail.Subject = "Simple HTML mail test"
objNewMail.Body = HTML
objNewMail.BodyFormat = 0 '1=text, 0=HTML
objNewMail.MailFormat = 0
objNewMail.Importance = 1
objNewMail.Send
    if Err <> 0 Then Response.write "<p>CDONTS reported
    an error:" & Err.Description & "</p>"
    set objNewMail=nothing
%>
</body>
</html>

```

Create a simple HTML file and put it somewhere on your Web server that the IUSR user account has read access to. For example, you might call the file `test.html` and put it in `C:\JUNK`. Then fill in values for the *htmlfile*, *toaddr*, and *fromaddr* variables. For example, if your e-mail is `wally@acme.com`, you might send this mail to yourself with these three lines:

```

htmlfile="c:\junk\test.html"
toaddr="wally@acme.com"
fromaddr="wally@acme.com"

```

Then run the page by opening your Web browser and calling the `mailex.asp` file. For example, if your Web server is on `192.168.0.2`, then you could type into the address bar `http://192.168.0.2/mailex.asp`. Unless you haven't permitted Active Server Pages, or you have mistyped the text or IUSR is denied permission to `test.html`, you won't see anything in your browser. But open up your mail client and you should have two pieces of mail.

## A POP3 Server for Windows 2003

Computers all by themselves are of little value for anything more than acting as a glorified calculator or typewriter. Hooking up computers via networks has been what has really made computers useful, and of course networks are a big part of communications. But networks are of no value unless people use them—and people won't use them without a reason. This brings me to electronic mail. E-mail

is often the “gateway” application for people, the application that is the first network application that they’ll use; for some people, it’s the only application that they’ll ever use. And e-mail is probably the most important thing running on the Internet.

I just talked about setting up SMTP on your IIS server so that it could send e-mail to other hosts. However, although SMTP is the protocol used to send e-mail, setting up SMTP support does not make your IIS server an e-mail server. You see, SMTP doesn’t sort the mail into individual user mailboxes, and there’s no method for individual users to retrieve mail. For that, you need the POP3 protocol. Windows 2000 didn’t include a POP3 server; if you wanted your Windows 2000 system to be an e-mail server you had to rely on a separate product. These ranged from huge packages like Microsoft Exchange to bare-bones free software like the Internet Mail Service (IMS), which was developed by the European Microsoft Windows Academic Centre (EMWACS). At long last, Windows Server 2003 comes with an optional POP3 service. Although it’s not a component of IIS, it can work with the IIS SMTP service and Active Directory to provide full-fledged e-mail services at no additional cost.

## Setting Up the POP3 Server

Use Add/Remove Programs in the Control Panel to install the POP3 service, which you’ll find listed as E-Mail Services in the Windows Components Wizard. Once you’ve completed the installation, which is similar to every procedure to install optional Windows components, a new tool called POP3 Service (p3server.msc) is available in the Administrative Tools group. Open p3server.msc (shown in Figure 17.92) to begin configuring your POP3 server.

**FIGURE 17.92**

The POP3 Service MMC

As you can see in Figure 17.92, the POP3 Service console uses extended views and MMC taskpads to help you accomplish your tasks. Before adding a mail domain, you need to configure the POP3 server properties and, in particular, select an authentication method. This authentication method is not configurable on a per-domain basis. If you want to change the authentication method later, you’ll need to delete all of the existing e-mail domains first. Changing the authentication method, or any of the other server properties (like the TCP/IP port or the root mail directory location), also requires you to restart the POP3 service. You can stop, start, pause, or restart the POP3 service from the POP3 Service MMC or from the Services tool.

To configure POP3 Server properties, highlight the POP3 server name in the console, right-click, and choose Properties from the context menu. The server properties page is shown in Figure 17.93. The Windows POP3 server supports three different authentication options: Active Directory Integrated, Local Windows Accounts, or Encrypted Password File.

**FIGURE 17.93**

Configuring server properties for the POP3 Server

**Active Directory Integrated authentication** The Active Directory Integrated option tells POP3 to authenticate users using an AD domain controller. Use this option if the mail server is a member of an Active Directory domain, or if it is an AD domain controller. Mailboxes must correspond to an existing account in the AD, or you can create a new account at the same time as you create the mailbox. The AD integration option supports multiple domains, and users can access mailboxes in separate mail domains with the same username and password (1njustice@redhilltown.com and 1njustice@hawkmoon.org, for example).

**Local Windows Accounts authentication** Use Local Windows Accounts authentication if the server is not a member of an AD domain, or if you just prefer to use local accounts instead of AD accounts. Mailboxes must correspond to accounts on the local system and be authenticated against the server's security accounts database (SAM). This option supports multiple e-mail domains, but mailboxes must correspond to local user accounts and local usernames must be unique. Therefore, this option does not support using the same username across multiple domains.

**Encrypted Password File authentication** If you don't want to create and maintain user accounts on the POP3 Server at all, choose this authentication type. Hey, if you are going to be hosting thousands of mailboxes, and especially if those mailbox users are not actually users on your corporate radar, there is no way you want to manage all of those local or AD accounts. Usernames must be unique to the e-mail domain, but identical usernames can exist across domains. For example, you can have mailboxes for 1njustice@myisp.net and 1njustice@bignetwork.com, but you cannot have two mailboxes for 1njustice@myisp.net. When a mailbox is created, the administrator also supplies a password for the user. This password is encrypted and stored in a file in the user's mailbox directory.

**POP3 Server Port** To modify the TCP/IP Port that POP3 uses, type in a port number in the Server Port field. Port 110 is the standard port for POP3. If the server is modified to listen and respond on a nonstandard port, the POP3 client software must also be modified to use the same port number.

**Logging Level** The POP3 server sends logging information to the Event log service. Events are written to the Application log and viewable from Event Viewer. To configure the level of event logging for the POP3 server, choose an option from the Logging Level pull-down box.

**Root Mail Directory** The default root mail directory, or mail store directory, is `c:\Inetpub\mailroot\Mailbox`. For each domain created on the mail server, a subdirectory with the same name will be created in the Mailbox directory. Within the domain subdirectory, mailbox users will have their own directories. For example, I have a user named paulhewson in the redhilltown.com mail domain. If I keep the default mail store location, the path to Paul's mailbox will be `c:\Inetpub\mailroot\Mailbox\redhilltown.com\P3_paulhewson.mbx`. Individual message files in the .mbx directory will carry the .eml extension. These files are viewable with a text editor like Notepad, but Windows recognizes them as Internet E-mail messages and opens them in an e-mail message window. When you configure the mail directory, NTFS file and directory permissions are set to permit access only to administrators, the System account, and the Network Service account, which runs the Microsoft POP3 service.

**Other Server Options** The last two options shown in Figure 17.93 are to require Secure Password Authentication and to automatically create user accounts for new mailboxes. If Active Directory integration or local Windows account authentication is selected, the SPA option requires clients to use SPA-encrypted passwords instead of cleartext. For encrypted password file authentication, POP3 supports the APOP protocol. Both SPA and APOP encrypt the username and password.

Only the Local Windows Account and AD integrated authentication methods use real user accounts, so the option to automatically create user accounts is not available when encrypted password file authentication is chosen. User accounts will be automatically created on the local system or on the AD directory, depending on the logon method in use. Since you will probably create some mailboxes for pre-existing accounts, you can always deselect this option when you are actually creating the mailbox.

### CREATE AN E-MAIL DOMAIN AND MAILBOXES

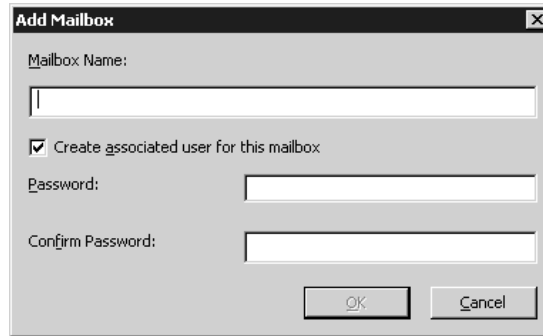

Now that you've configured the server properties for your POP3 Server, it's time to create one or more e-mail domains. You should note that, in this context, the e-mail domain is not the same entity as the AD domain. Sure, you may have an AD domain named, for instance, redhilltown.com, and you may want to configure your server to handle mail addressed to *someuser@redhilltown.com*, but the POP3 and SMTP servers don't care whether there is a corresponding AD domain. The SMTP server component must be configured to accept mail for a given domain name, and the POP3 server must have a corresponding directory for that domain as well, but the only other limitation is name resolution. If you want the same server (zooropa.redhilltown.com, for instance) to accept mail for redhilltown.com, hawkmoon.org, and reallybigISP.net, then you also need mail exchange (MX) records in DNS to point to that server.

To create an e-mail domain on the POP3 server, select the server in the Scope pane of the console and click on the New Domain link, or right-click and choose New/Domain from the context menu. A simple dialog box appears prompting you for a domain name; type in the name of the domain and click OK. A subdirectory in the mail store will be created for that domain. There are no options to configure on a

per-domain basis; the POP3 server handles e-mail for all domains equally. Now it's time to add a few mailboxes. Highlight the domain name in the scope pane of the console, right-click, and choose New/Mailbox from the context menu (or use the Add Mailbox link in the details pane, or choose New/Mailbox from the Action pull-down menu.) You should see a dialog box like the one shown in Figure 17.94.

**FIGURE 17.94**

Adding a mailbox to the POP3 server

The 'Add Mailbox' dialog box contains the following fields and controls:

- Mailbox Name:** A text input field.
- ☒ **Create associated user for this mailbox**
- Password:** A password input field.
- Confirm Password:** A password input field.
- OK** and **Cancel** buttons at the bottom right.

Type in the name of the mailbox. If you want the mailbox to belong to a pre-existing user account on the local system or in the AD, type in the exact name of the user account and deselect the option to create an associated user account. To create a new user account on the server or AD, supply the account name and an initial password. If you are using encrypted password file authentication, the dialog box is identical except that the option to create a new user account is not available. Repeat this procedure as necessary to create additional mailboxes, or use the nifty little command-line tool, `winpop.exe`, located in the `\Windows\system32\pop3server` directory:

```
winpop add phewson@redhilltown.com
```

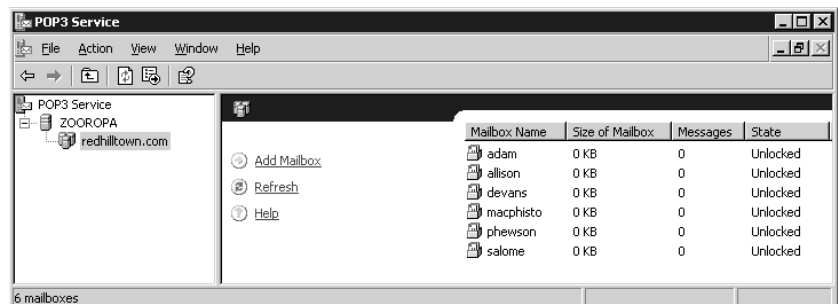

Or, to create a new user account at the same time:

```
winpop add devans@redhilltown.com /createuser password
```

Figure 17.95 shows six newly created mailboxes in the redhilltown.com domain. Again, the POP3 server treats all mailboxes equally, so there are no configuration options to set. As you can see from Figure 17.96, the only options available for existing mailboxes are to delete the mailbox or to lock the mailbox. When a mailbox is locked, incoming mail for the user is still accepted, but the user cannot connect to the server and retrieve mail. You may also lock or unlock an entire domain, which prevents any users on the domain from retrieving mail.

**FIGURE 17.95**

A list of mailboxes in the POP3 mail domain

**FIGURE 17.96**

Mailbox options  
in the POP3  
Service MMC

**A FEW CLOSING THOUGHTS ON POP3 SERVER**

As you can see, administration of the Microsoft POP3 Server is not complicated. However, you should do some planning to ensure that you allocate sufficient disk space for the mail store, based on the numbers of domains and mailboxes you will be hosting and the volume of e-mail that users will receive. It's not a bad idea to enable disk quotas on the partition where the mail store is located. Quotas can be used to set a per-mailbox limit or a domain-wide limit on the disk space used by the mail store. And it goes without saying that your mail store should be located on an NTFS partition both for security purposes and because quotas are only supported on NTFS.

**Setting Up Your E-mail Client**

A server's no good without clients. In the case of a mail server, the accompanying clients are of course called e-mail clients.

To connect to your mail server, you'll need an Internet mail client of some kind. Examples include Outlook (which can act as an Exchange client, an Internet mail client, or both), Outlook Express, Eudora (the free version or the professional version; it's a great program, and you can find it at [www.eudora.com](http://www.eudora.com)), Pegasus (free, [www.pmail.com](http://www.pmail.com)), or the mail client built into Netscape Navigator. Technically, they are all POP3/SMTP clients. Some support a third protocol, IMAP4, but that doesn't matter to us, as our POP3 and SMTP components don't support IMAP4.

To tell your e-mail client to look to your POP3 server for mail, you've got to configure it to look for your mail account. Exactly how you do that varies from client to client software, but in every case the e-mail software will probably need to know a few things:

**Do you use POP3 or IMAP4?** POP3; again, IIS and the POP3 server don't support IMAP4.

**The name of your SMTP server** Fill in the name of the server running the SMTP service.

**The name of your POP3 server** Usually your SMTP server is also your POP3 Server.

**Your e-mail address** Your e-mail address is *name@servername*, where *name* is your Windows user account name. For example, if your mail server is on the domain FLOWERS.COM and you log in to the FLOWERS.COM domain as JaneD, then your username and the name portion of your address is janed. The *servername* will either be the fully qualified domain name of the machine running SMTP/POP3, such as violets.flowers.com, or just the name of the domain, if you've directed people to the server with an MX record. If an MX record for FLOWERS.COM in

DNS says that mail for FLOWERS.COM should go to `violets.flowers.com`, then your e-mail address is `janed@flowers.com`. Without an MX record, e-mail addresses must specify the particular server, so in that case the address would be `janed@violets.flowers.com`.

**Your account name and password** Fill in the username and password. Although not all types of mail servers require it, you should include the domain prefix if you are connecting to a Windows Server 2003 SMTP/POP3 Server. Enter a username like `mark@redhilltown.com` rather than just `mark`.

From there, any other configuration options will be matters of taste—how often to check for mail and the like. Once your client's set up, send yourself a piece of mail and your mail server will be officially operational!

## E-mail Security Concerns

As the Internet grows, more and more gateways will be built to other e-mail systems. You can't get everywhere, but in time, you'll be able to reach anyone from the Internet. Now, that's a good thing, but as e-mail becomes more important, it's also essential to keep your mind on the fact that e-mail is not secure. Your mail packets get bounced all around the Internet, as you know—but think about what that means. Suppose you send a message to someone on the Internet, and my computer is part of the Internet—a piece, as it happens, that sits between you and the person to whom you're sending mail. Mail can sit in intermediate computers like mine, on the hard disk, for seconds, minutes, or hours at a time. It's a simple matter to use any number of utility programs to peek into the mail queue on the mail that's "just passing through." Never say anything on mail that you wouldn't want as public knowledge. Even if someone doesn't peek at your mail, that someone probably backs up his or her disk regularly, meaning that the message may sit on magnetic media for years in some archive. I sometimes imagine that in the middle of the twenty-first century, we'll see "the unpublished letters of Douglas Adams"—e-mail notes that someone stumbled across while picking through some 70-year-old backups; you know, it'll be the latter-day equivalent of going through some dead celebrity's trash. Anyway, the bottom line is this: Don't write anything that you wouldn't want your boss, your spouse, your parents, or your kids to read.

## Using Telnet for Remote Login

Back in the mid-Triassic period of computing, around 1973, you wouldn't sit at a computer; you'd sit at a terminal that was connected in some way to a computer. If a computer at the National Institutes of Health contained some database that I wanted to do analysis on, I'd put a modem on my terminal, get an account at NIH, find out the phone numbers of their dial-in modems, and then I'd dial one of those numbers. Once the modem was done squawking and I was connected at the princely speed of 300bps, I'd interact with NIH. But I'd interact solely with characters—25 lines of 80 columns of characters.

From the '60s on, the government has maintained a lot of mainframes with some very useful data on them. Before the growth of the Internet, anyone doing research could get an account and dial in to those mainframes to use the government's data—but the long-distance bills could bankrupt you.

## Early Telnet Uses

But then the Internet appeared.

For the early Internet—ARPAnet, actually—programmers built a set of programs, a server program and a terminal program, that would let a mainframe accept incoming connections over the Internet,

much like modem dial-ins, and let someone sitting at a Unix terminal somewhere attach to that mainframe as if dialing in. The early (mid-Cretaceous, actually) programmers called the pair of programs *telnet*.

For years, telnet was a great way for groups to offer information over the Internet. Some people adapted programs used to host dial-in PC-based bulletin board systems to telnet. Others put data of general interest on telnet—for example, the University of Michigan once had census data available over telnet, and a travel agency let you book tickets on telnet. Network Solutions, the people who run DNS, had a search engine built into telnet that would let you look up a domain name to see if it was taken. Most of those are gone now, replaced with Web sites.

## Modern Uses for Telnet

But telnet's still quite useful for network administrators, so it's great that Windows Server 2003 includes a telnet server. Think of telnet on Windows 2003 as being sort of a low-bandwidth form of Windows Terminal Server. You can't run any graphical applications over it; you just get a C:\> style command line, but you can get an awful lot done with just that.

Before you can telnet into your machine, though, you must start up the server part of telnet. That part's easy, but you have to then configure it to accept regular telnet connections.

## Setting Up the Telnet Server

Telnet is built as a service under Windows Server 2003. You can start it by just opening up a command line, typing **net start tlntsvr**, and pressing Enter. Alternatively, you can tell your system to always have the telnet server available by setting up the telnet service to start automatically.

Here's what you need to do to set up the telnet service to start automatically:

1. Right-click the My Computer icon, and select Manage.
2. Under Computer Management, you'll see **Services and Applications**; open it by clicking the plus sign next to it.
3. Inside **Services and Applications**, you'll see **Services**; click that and the list of services in the system will appear in the right pane of the window.
4. The service you're looking for is named just telnet; right-click it and choose Properties.
5. You'll see a single-selection drop-down list box labeled Startup; choose Automatic, then click OK to close the window. Close the Computer Management window.

The telnet server supports two simultaneous connections by default, although you can use the command line administration tool **tlntadm** to modify this parameter. Because of potential security issues (telnet is a powerful tool), users must also be members of the Administrators group to log in. To grant additional uses permission to telnet to the server, create a local users group called Telnet-Clients and grant membership only to the users who need telnet access. Presumably, any users added to this special group will inherit the right to log on locally, which is also required for telnet access to the server.

While telnet is often a potential security risk because it passes passwords in cleartext over the network, Microsoft has reduced that risk by modifying the way that the telnet server behaves. The Windows Server 2003 telnet server does accept cleartext password authentication by default, but

it also uses an NT-style authentication approach called NTLM. The telnet server negotiates the authentication method with connecting clients, and NTLM is the preferred method. It requires not only a modified telnet server but a modified telnet client as well—but Windows 2000 and XP come with a client like that. If the client supports NTLM authentication, not only are passwords encrypted, but the client automatically handles the authentication using the existing security context. With NTLM authentication, users will not be prompted for a username and password. By default, if the client does not support NTLM authentication, cleartext password authentication is used. For maximum security, you can disable cleartext authentication and only permit connections from clients that are capable of NTLM authentication. I'll explain how to do that in a moment.

The command-line tool that you use to configure the telnet server is `t1ntadmn.exe`. Among other things, you can use `t1ntadmn.exe` to start and stop the server, configure authentication settings, and increase the number of simultaneous connections that are permitted. To see the current settings for the telnet server, type `t1ntadmn config` at a command prompt to view a list of settings similar to this:

```
C:\> t1ntadmn config
The following are the settings on localhost

Alt Key Mapped to 'CTRL+A' : YES
Idle session timeout       : 1 hours
Max connections            : 2
Telnet port                 : 23
Max failed login attempts  : 3
End tasks on disconnect    : YES
Mode of Operation          : Console
Authentication Mechanism   : NTLM, Password
Default Domain             : REDHILLTOWN
State                      : Running
```

To tell a server's telnet server software not to accept cleartext logins, type the following command:

```
t1ntadmn config sec -passwd.
```

If you want to disable NTLM authentication and permit only cleartext authentication, use the `config sec` option like this:

```
t1ntadmn config sec -NTLM +passwd.
```

To increase the maximum number of concurrent connections to, say 10 connections, type the following:

```
t1ntadmn config maxconn = 10
```

To see the full syntax and options for the `t1ntadmn` command, type

```
t1ntadmn /?
```

Now that you've configured the telnet server to start up and set other options using the `t1ntadmn` tool, let's connect to the server using a telnet client. Assuming that you're already logged onto the domain, you can just start a session from a command line by typing `telnet servername`, where

*servername* is the name of the server that you want to establish the telnet session on. From there, you can do anything that you can do from the command line: run batch files, run scripts, or use command-line versions of utilities.

There are a couple of limitations when using the Windows Server 2003 telnet server. First, and this is nothing new to telnet, applications that use a graphical interface are not available. You must use command-line tools or scripts that run from a command line. Second, and this is not so obvious, you cannot use any existing drive mappings or other connections to network resources. Because those connections were established using a different security context, they are not available to telnet clients. You can, however, create new connections. For example, when I telnet to my server Zooropa and run the **net use** command, I can see that there are already two drives mapped to folders on another server. However, these are listed as unavailable. I have to type **net use \* \\servername\sharename** to create a new drive mapping. Because of a limitation of the NTLM authentication method, I also have to enter my username and password again to map the drive to make this new network connection available for my use over the telnet connection.

A final word on using telnet: even when NTLM authentication is used to encrypt the sign-in process, the actual data that passes between the client and the server is not encrypted and is visible to anyone who might be capturing packets on the network. Therefore, administrators should not use telnet to perform functions that expose sensitive information to eavesdroppers. This is not specific to Microsoft's implementation of telnet; rather, it's a limitation of telnet in general. In the Unix world, many administrators are disabling telnet access to systems in favor of an encrypted remote shell program called **ssh** (short for secure shell). Maybe Microsoft will include an **ssh** program with a future version of Windows Server.

## Communicating Securely with SSL

We all know that the Web is a great place to find information, but I have a feeling that we've only seen the tip of the iceberg as far as the Internet is concerned. The force that is truly driving the Internet into the future is commerce. The Internet lends itself to transactional chores very well, just due to its nature and makeup. However, most commercial transactions contain some form of proprietary or confidential data, whether it's bank account numbers or corporate plans for a new product launch. All sorts of information that is confidential in nature is being transmitted across the Internet, and that trend will continue in the future.

To meet the challenge of securing confidential data, Netscape developed a protocol called Secure Sockets Layer (SSL) to be used in conjunction with HTTP as a means of providing secure communication channels between clients and servers. Through the use of certificates—encryption keys handed out by a trusted third-party organization—Web servers and Web browsers will negotiate an encrypted connection between themselves, preventing any data from being intercepted during transmission.

Some reasons to implement SSL are obvious—for example, if you intend to accept credit card numbers on your Web site from clients who are ordering products. Obviously, your clients might be concerned about their confidential information (their credit card number) crossing the Internet in the clear, so you can encrypt the ordering process to ensure that even if someone does intercept the transmission, it will be in a useless form. However, some reasons for implementing SSL are less obvious but equally as important—for example, confidential information such as brokerage statements, corporate financial statements, tax returns, medical records, etc. All are equally private as far as most

individuals are concerned, and will be transmitted over the Internet more and more frequently as time goes on.

Fortunately, Microsoft has made the process of obtaining a security certificate easy in IIS 6 through the inclusion of the IIS Certificate Wizard, an administrative wizard that will create a certificate request for your system. You will, in turn, submit that request to a certificate authority—commonly referred to as a CA—which is the trusted third party. The CA will then send you a certificate that the wizard will help you install on your server. Before getting this process started, you will need to have the following ready:

**A functional IIS server** Although this seems obvious, there's more to it than simply having an IIS server that runs. Since certificates are highly specialized encryption keys—they even have the name of your server embedded in them—it's best to have your site working exactly how you want it first, and then add the security certificate and turn on encryption as one of the last items to do.

**Organizational details** Details that a CA will require from your organization include name, organizational unit, country, state, locality, and a name, e-mail address, and phone number for the contact individual requesting the certificate.

**Server details** Certificates are based on the server that they were requested for and will have that server name (either an internal NetBIOS-style name or an FQDN) embedded within the key. Therefore, once you enable encryption, it's important that you don't change the name of your server—otherwise you will need to request a new certificate.

## Requesting a Certificate

To begin the process of requesting a certificate, start the Internet Information Services MMC and select your Web site in the scope pane. Then, select the Properties option from the Action pull-down menu. This will get you into the properties pages for this Web site, as discussed earlier in this chapter. Click the Directory Security tab to get to the security properties pages, shown earlier in Figure 17.20. Click the Server Certificate button to launch the Web Server Certificate Wizard. The first screen of the wizard (after the welcome screen) is shown in Figure 17.97.

**FIGURE 17.97**  
Starting the IIS  
Certificate Wizard

Assuming that you are requesting a new certificate for your site, select the Create a New Certificate option. Clicking Next will take you through roughly six steps required to collect the necessary information about your organization: organization name, organizational unit, server name, contact information, etc. Enter the information requested at each step and click Next to move through the wizard. One of the final steps of the wizard will ask you where you want to store your request (assuming you selected the Prepare the Request Now, but Send It Later option in the second step of the wizard); the default is C:\certreq.txt. If this name is acceptable, click Next to proceed to the final step of the wizard.

After you have entered all of the necessary organizational and server information for your certificate request, the wizard should show you the information it has collected in a step similar to the one shown in Figure 17.98.

**FIGURE 17.98**

Certificate request confirmation step

Assuming your information is correct, click Next, and the wizard will create the appropriate certificate request and place it in the file you specified. This file is simply a text file containing all of the information you entered through the wizard, encoded in a certificate request. A sample certificate request is shown here:

```

nezonQ==
-----END NEW CERTIFICATE REQUEST-----
```

Once you have your request file, you need to submit that file to a CA so that they can issue a certificate to you. For my testing purposes, I chose to use VeriSign over at [www.verisign.com](http://www.verisign.com). In any case, choose a CA that you would like to use and then submit your request file through whatever mechanism they provide.

Depending on the CA you are working with and the level of trust you want for your certificate, your request might take anywhere from a few minutes to a few days or weeks to process. Once your request has been approved, you will receive a certificate for installation on your server (a sample certificate basically looks exactly like the encryption key in the certificate request). To install the certificate, return to the Directory Security tab in the properties of your Web site (you need to install your certificate to the same site you requested it from) and click the Server Certificate button again.

This time when you launch the IIS Certificate Wizard, it will realize that you have previously requested a certificate for this Web server and it will ask you if you would like to import that certificate now (see Figure 17.99).

**FIGURE 17.99**

Importing a certificate with the IIS Certificate Wizard

Import the certificate by entering the path to the certificate in the next step of the wizard. If everything goes as it should, you should see a summary of your certificate, similar to the one shown in Figure 17.100.

If this certificate is acceptable, click Next, and the certificate will be installed into your Web server.

**FIGURE 17.100**

Summary of an imported certificate

## Securing a Site or Directory

Once your certificate is installed, the Edit button should light up in the Directory Security properties page for your Web site. You can require SSL security for your entire site or in directories (real or virtual) within your site. In either case, the settings are mostly the same.

To enable encryption on a specific directory or site, go to the Directory Security properties page for that directory or site. Click the Edit button to enable security, and you will go to a Secure Communications properties page similar to the one shown in Figure 17.101.

**FIGURE 17.101**

Implementing secure communications

In this page, the most important setting to enable is Require Secure Channel (SSL). This will enforce secure communications for anyone trying to reach this resource (directory or site). Anyone attempting to access this resource over a standard HTTP connection will be instructed that they cannot reach the content unsecured and that they must use HTTPS to access the desired content. If you have a domestic-only build of Windows Server 2003, you will also have the option to enable strong (128-bit) encryption, instead of relying on standard 40-bit encryption (sometimes referred to as weak encryption).

As clients access your system, you can also accept or require client certificates as a means of authenticating who can access your system. If you want to require that only users with certificates access your system, select the Require Client Certificates radio button, and any users who do not have a client certificate installed in their system will not be able to access the secure content of your site.

Since it is possible for clients to provide certificates to your server (in addition to your server presenting a certificate to your clients), you can use this as a means of authenticating users and knowing exactly who is accessing your Web site. By checking the Enable Client Certificate Mapping check box, and then clicking the Edit button, you can “map” specific certificates to specific Windows user accounts. In effect, you are telling your IIS server, “If you receive this particular certificate, then assume that this is user John Doe accessing the Web server.” If IIS knows who the exact user is, it can take advantage of permissions placed on files and directories for controlling who can access what content.

Finally, you can also create and enable a Certificate Trust List (CTL). This is a signed list of root certificates issued by various certificate authorities. A CTL allows administrators to specify which certificate authorities will be trusted by this Web site.

Once you’ve installed the certificate and enabled SSL for the Web site, use a browser to test for secure access to the Web site. Unless you’ve specified a nonstandard port for SSL to use, simply access the site using `https://` and the URL instead of `http://` and the URL. For instance, `http://www.redhilltown.com` will now be accessible at `https://www.redhilltown.com`.

## Configuring and Troubleshooting Indexing Service and Building Web-Based Query Pages

Next, let’s take up an IIS-related topic: Indexing Service. Index Server has surely gotten a fair amount of press attention because it contained the security hole that the Code Red weasels used to attack Web servers around the world. But it’s harder to find useful information on making Indexing Service *work*, and that’s a shame, as it can be a useful tool. This section describes how it works and offers some very simple Web pages that will let you exploit the service’s power.

### What Indexing Service Does

First of all, note that its name is Indexing *Service* rather than Index Server, as 2000 and later OSes include it “in the box.” Many people (myself included) tend to erroneously call it Index Server because it was originally a separate add-on program that shipped for NT 4 called Index Server. Windows 2000 Server and Windows Server 2003 include it as a basic system service named Indexing Service. What it *does* is make searching today’s huge hard disks a tractable affair.

Working in the background, Indexing Service examines and analyzes the files on your system, building and maintaining an index of the words that it finds there. At first blush, that’d make Indexing Service sound like something that just keeps track of every word, where “word” is just defined as a

bunch of letters surrounded by spaces or punctuation. But think a bit more about it, and you'll see that Indexing Service has a harder job than that. Extracting words is simple if your document is plain ASCII text. But if it's an HTML file, how would Indexing Service know whether "<br>," the HTML command for "break the line here," is or isn't a word? How would it understand words in a Microsoft Word document? The answer is that Indexing Service includes a bunch of *filters*, programs that understand particular file formats. Indexing Service comes with filters that let it understand ASCII files, HTML files, Microsoft Office files, and what Help calls "Internet mail and news documents." There's no PDF filter included; you can download it, I'm told, from Adobe's Web site at [www.adobe.com/support/downloads/](http://www.adobe.com/support/downloads/). Do a search for the product name, PDF filter.

### The Annoying Thing about Indexing Service: Little Documentation

The fact that Microsoft first documented it when it was Index Server means that, unfortunately, most of the Index-related documentation that you'll find on Microsoft's Web site and in books refers to the Index Server, which sort of works like Indexing Service, but not quite. To make things worse, the old Index Server documentation explained how to build HTML pages to query a cataloged directory, and for some reason Microsoft chose not to do that in the Indexing Service documentation. You're just supposed to know that things "kind of" work the same with Indexing Service as they did with Index Server, so I guess you're supposed to try the old code and hope it works. It does, sometimes; but I'll give you some basic HTML pages that you can use to create a Web page that will let you search any catalog from a Web browser. As always, once you know the magic words, then you can extract the information that you need from Microsoft's Web site.

What documentation there *is* about Indexing Service is in the Windows Server 2003 Server Help and Support Center files and in old-fashioned Windows Help files. Open the Help and Support Center from the Start menu and search for Indexing Service. One of the sublinks that you'll see is called Indexing Service. Or check out the Windows Help file found at `\Windows\help\is.chm`.

### How You'll Use It (Why You Care)

I've found Indexing Service a great tool for building a fast, flexible Web-based search engine. But you can also use it within your network or just on your computer without any Web interface at all. For example, if you had a huge directory of ASCII, Office, and HTML documents, then you could catalog that and search for particular files extremely quickly.

#### HOW IT WORKS

You tell Indexing Service that you want to create a catalog of a particular directory by telling Indexing Service two things: what directory you want to index (catalog) and where to put that catalog—after all, the catalog files must reside somewhere. Indexing Service creates a folder named `catalog.wci` in the directory that you've told it to store the catalog in. That leads to the following *very* important performance concerns—ones that I learned the hard way.

- ◆ Do *not* put the catalog in the directory that you're cataloging. If you want to catalog `C:\MYSTUFF`, then nothing at all will stop you from *storing* its catalog in that same directory. But it's a bad idea, and here's why. Let's say that you put a new file into `C:\MYSTUFF`, and so Indexing Service notices the new file and indexes it. That indexed information goes into the `CATALOG.WCI`

directory, which is *inside* C:\MYSTUFF. This causes Indexing Service to notice that—aha!—there is some new data in C:\MYSTUFF and... oh, no, that's just the catalog, I'll ignore it. I know this sounds insignificant, but it isn't; I created a small directory with just a couple dozen files and put the index inside the directory; Indexing Service took about 10 minutes to index it. When I put those files into a different directory and cataloged that new directory—but put the catalog in still another directory—then Indexing Service cataloged the new directory almost instantaneously.

- ◆ IIS *really* doesn't like catalogs anywhere in the `wwwroot` directory or in the directories under it. It seems to slow down both IIS *and* Indexing Service.

## MANAGING IT

Indexing Service is a service that you handle much like other services—you can start it, stop it, or restart it. A standard Windows Server 2003 install sets it up as an automatic service that runs as the local System account. You can start or stop the service using the Services applet, from the Indexing Services node in Computer Management, or with the stand-alone Indexing Service tool (`ciadv.msc`), which is also available as an MMC snap-in. The Indexing Service console looks like Figure 17.102.

**FIGURE 17.102**

Initial Indexing Service, showing System and Web catalogs

Like DNS and IIS, the Indexing Service's snap-in is incorporated in Computer Management under Services and Applications. Open it and you'll see one or more icons that look sort of like a stack of pages with a wrench paperweight on top—those are the catalogs, and we'll get to them in a minute. First, though, right-click the Indexing Service icon and choose Properties. As you see in Figure 17.103, you'll see two tabs on the page—Generation and Tracking.

Generation controls how Indexing Service creates indexes. One check box says Index Files with Unknown Extensions; it's not checked here, but if you check it, then Indexing Service just says, "Damn the torpedoes," and indexes *everything*, even if it doesn't have a filter for it. I don't use it, but I'm sure that *someone* thought it was a good idea. The other check box, Generate Abstracts, is also unchecked by default, but might be worth checking. When checked, Indexing Service tries to create an abstract of each file that it indexes. It's a nice feature but isn't always that smart; for example, it seems to create abstracts of HTML files by displaying the `<h1>` and `<h2>` elements of the document, which may not correctly characterize that document. Click the other tab, Tracking, and you'll see a page like the one in Figure 17.104.

**FIGURE 17.103**

Indexing Service properties

**FIGURE 17.104**

Tracking tab in Indexing Service properties

The Tracking tab just includes one check box, Add Network Share Alias Automatically, and it's checked by default. This ensures that if Indexing Service indexes a drive that it sees as a mapped drive letter, it remembers not only the drive letter, but the entire UNC. For example, if you've mapped \\server01\data to X: and indexed X:, then Indexing Service would remember that those files are

available at `\\server01\data` even if you don't have that UNC mapped back to X: when you try to retrieve the indexed documents.

### STANDARD CATALOGS

Even if you've never used Indexing Service before, you're likely to already see two catalogs: one called System and, if you're running a Web server on the computer, another catalog called Web. As their names suggest, they index system information and whatever content there is on your Web server.

Personally, the first thing I do is to delete both of them. Having my entire Web site as well as every hard disk on my server indexed gives me the heebie-jeebies. I mean, why *not* just make it easy for crackers to spy on my system once they've cracked Indexing Service? My feeling is that *I'll* decide what gets indexed on my system, thanks very much.

To delete a catalog, you must stop the Indexing Service. Then just left-click the catalog and press the Delete key, or right-click the catalog and choose the Delete option from the context menu.

### CREATING A CATALOG

You create a catalog in Indexing Service by right-clicking the Indexing Service icon and choosing New and then Catalog to raise a dialog like the one in Figure 17.105.

**FIGURE 17.105**

Creating a new catalog

This dialog box, labeled Add Catalog, contains just two text fields: Name and Location. In Name, just fill in the descriptive name of your catalog—no spaces allowed! This name doesn't have to relate in any way to the name of the directory that you're going to index. For example, I named the catalog for my online newsletters "Newsletters" even though they don't reside in a directory named `Newsletters`. Location is the location of the *catalog files*, not the files to be cataloged. This was what I was talking about a while back: specify a location for your catalog that is different from the location *to be* cataloged. For example, if I were indexing newsletters in a directory named `C:\Newsletters`, I might put the catalog's location in, say, `C:\NewsLetter Index`. But no matter where you put the catalog, remember not to put it in `wwwroot` or anywhere under that directory.

If Indexing Service is off when you create the catalog, you'll get a dialog to that effect: "Catalog will remain offline until Indexing Service is restarted." No surprise there.

### TELL IT WHAT TO CATALOG, AND WHAT NOT TO

Now Indexing Service knows that you want to catalog *something*, but it doesn't know what. So add one or more directories to its list of things to index. Right-click the catalog's icon and choose New/Directory and you'll see a dialog box like the one in Figure 17.106.

**FIGURE 17.106**

Adding a directory to the catalog

That dialog asks you to fill in the path and, if relevant, the UNC of the directory to catalog. If the directory points to a network resource, type in a username and password to be used to access the directory. Next to that is an odd-looking set of radio buttons asking, “Include in Index?”

Is this about the dumbest question you can imagine, or what? Here you are, adding a directory to a catalog—whose sole function in life is to *index* data, and this dialog asks if you want to index the data. What were they thinking? Well, Indexing Service not only indexes the top level of the directory that you specify, but any *subdirectories* as well. So suppose I’ve decided to index C:\Newsletters, as it contains my old newsletters. But suppose that *inside* the C:\Newsletters directory is a C:\Newsletters\In-Progress directory, where I keep my newsletters that I’m still working on. Well, by default, Indexing Service would catalog *that* directory as well—so a well-placed query would let you see my newsletters before I’m even finished writing them! That’s not what I want, so I might add C:\Newsletters, as I’ve described, and then add C:\Newsletters\In-Progress—and then tell Indexing Service *not* to include C:\Newsletters\In-Progress in the catalog. The net effect would be to defeat Indexing Service’s natural inclination to index everything in C:\Newsletters, even my work-in-progress directory.

You can also block Indexing Service from cataloging a file or directory by using that file or directory’s advanced attributes. Locate the file or directory in Windows Explorer or My Computer, right-click the file or directory, choose Properties, and then click the Advanced button in the General tab to open the Advanced Attributes dialog box (shown in Figure 17.107).

**FIGURE 17.107**

A folder’s advanced attributes

Uncheck the option labeled For Fast Searching, and the folder will be essentially invisible to Indexing Service.

### **CONSIDER FILE PERMISSIONS, OR YOUR CATALOG WON'T WORK**

Sometimes security gets in the way of Indexing Service. So take a minute and consider the file and directory permissions on the things that you want to index.

When I first used Indexing Service, it drove me absolutely crazy. It could index many files, but not the ones that I wanted—not the ones on my Web server. I set up a pristine new computer, built a catalog on it with copies of the exact same data files that I wanted to index, and it worked...but not on my Web server. Then it dawned on me: I'd monkeyed with the directory permissions on my server.

My original plan had been to adjust the permissions so that the IUSR account didn't have access to parts of the disk that it had no need to have. But in the process of disconnecting some directory permissions from inheriting permissions from their parent directory, I cleared all previous permissions. Including the System account.

But, as you've already learned, the Indexing Service runs *under* the System account. And therein lay the problem. I'd set up the catalog right; I'd just denied Indexing Service the ability to actually read the files that I wanted it to index. Now, in my defense, let me just squawk a bit that it'd have been nice if Microsoft offered a verbose logging feature of Indexing Service, where I'd have gotten a clue a bit earlier...but it was still dumb on my part. So let's stop for a minute and consider permissions.

- ◆ Indexing Service needs to be able to read whatever you want cataloged, so make sure that System can read whatever you're cataloging.
- ◆ Indexing Service needs to be able to write and modify its catalog, so be sure that System can write, read, and modify whatever directory you've put the catalog in.

But we're not done yet. Eventually you will want to query that catalog, using either the query tool built into the snap-in, which I'll show you in a minute, or perhaps through a Web interface. Before releasing the answers to a query, Indexing Service checks that the asker has the permissions to see the answer. So let's see what that means for my example of a Web-based search engine for my online newsletters.

Suppose the newsletter directory gave System Full Control permissions, but denied the IUSR account all access. What would happen? Well, Indexing Service would build the catalog for the newsletter directory just fine. And if I logged onto the server as an administrator and queried that catalog with some command-line tool or the built-in one that I'll show you in a minute, then perhaps the query would work fine. But from the Web-based interface, the query failed—why? Indexing Service sees that the IUSR account isn't allowed to see that data.

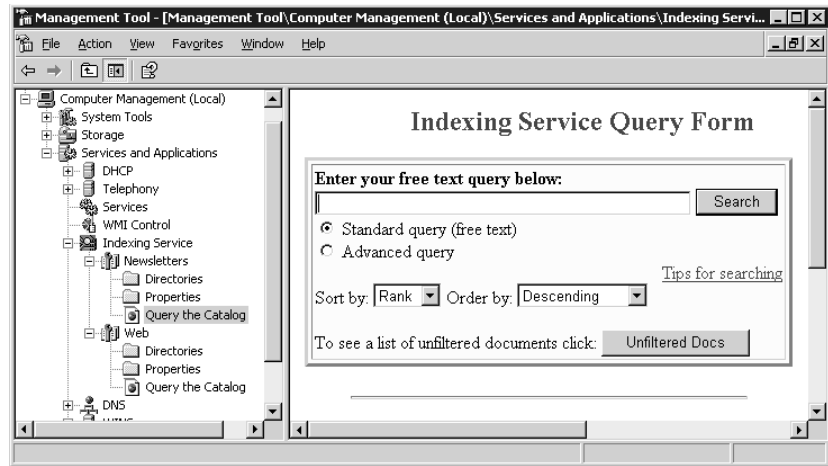

In my experience, security is a major cause of failed queries, so keep it in mind when using Indexing Service-based tools.

### **Using the Catalog: Querying Indexing Service from Computer Management**

Once you've created that catalog, how do you try it out? You use a tool built into the Computer Management tool, under the Indexing Service icon, called Query the Catalog, as you see in Figure 17.108.

**FIGURE 17.108**

Sample Indexing Service query

As you see in that figure, you'll see a field where you can type in your query words next to a button labeled Search. The query tool will show you all of your hits and provide hyperlinks that you can click to view the files that matched your query.

This isn't really an all-purpose tool, as it's cumbersome to search a catalog unless you're physically seated at the server whose Indexing Service hosts that catalog. But it's a great debugging tool because it's a quick-and-dirty way to find out if your catalog is working. And because you're usually running it while logged in as an administrator, you typically do that test query with maximum permissions. *Then*, if you try the same query from a Web page and it fails while the Query the Catalog tool succeeds, you can be pretty sure that the problem lies with permissions rather than with something else.

### USING THE CATALOG: THE QUERY LANGUAGE

But how do you address queries? Indexing Service has its own built-in query language that's pretty extensive but also pretty ugly. You can get the whole scoop in the Indexing Service help file, `\Windows\help\is.chm`. Open the top-level booklet icon, Indexing Service, and inside that you'll see another booklet, Concepts. Inside there you'll find another booklet entitled Using Indexing Service, and finally, below that, is a topic called Making Queries. In this section, I'll just offer a short summary of the Indexing Service's query language and provide a few examples.

#### Simple Words

Of course, you can type just one word and Indexing Service will look for that. Searching for "Kerberos" will turn up any document with the word "Kerberos" in it. Indexing Service seems not to care about case—"kerberos" would turn up the same hits as "Kerberos."

#### Word Variations Work, Too

Indexing Service understands variations on words. For example, if you search for "patches," then you'll not only get hits that match "patches," you'll also get hits that match simply "patch" or "patching."

To do an exact search, surround the search with double quotes. Thus, if you type **patches**, you'll get patch, patches, patching, and the like, but typing **patches** will match only that exact phrase.

### Wildcards Are Harder

But recall that Indexing Service tries to understand text not merely as a sequence of characters, but instead as a series of *words*, so searching for “Kerb” would not yield any hits that matched “Kerberos.” How, then, to do wildcards? By giving Indexing Service what Microsoft calls a phrase, wherein you surround your query with {phrase} and {/phrase}; it’s sort of HTML-ish. The asterisk is the generic wildcard, as always, so to search for any line that contains “Kerb,” type

```
{phrase}Kerb*/{phrase}
```

In theory, you can make Unix-style regular expressions work by surrounding them with {regex} and {/regex}, but I’ve not been successful making them work.

### Logical Operators

Indexing Service also understands AND, OR, NOT, and parentheses. You could search for:

```
"domain controller" and (kerberos or "LAN Manager")
```

It also understands NEAR, but only in a very lame way—NEAR is defined as “within 50 words” and, no matter what the docs say, it’s not possible to redefine. So this works:

```
"domain controller" near Kerberos
```

It’s a pretty powerful language—it’s just a little cryptic.

### Filtering “Noise” Words Via noise.enu—And, Or, Numerals, Etc.

A large number of the words in English text are simple words that you probably would never search on: and, or, also, have, could, and the like. You don’t want your catalog to track every single use of *those* words. So Indexing Service includes a file called `noise.enu` in `\winnt\system32`. It’s a simple ASCII file listing “noise” words—words not to index. You can change it to include (or exclude) any word, as you like. It’s called `noise.enu` because it lists the *English* noise words. Look in `\winnt\system32` and you’ll also see `noise.esn` (Spanish), `noise.deu` (German), and `noise.ita` (Italian), among others.

## Using the Catalog: Querying Indexing Service from the Web

Now that you have a working catalog and can query it from the Query the Catalog option in the Indexing Service node of Computer Management, how do you let the rest of the world (or maybe just the rest of your intranet) query the catalog? With a Web-based query client. While this isn’t a programming text—nor am I an expert programmer—here’s a very bare-bones, stripped-down set of Web pages that you can modify and put up to let people query some catalog.

### GETTING READY

For this example, let me assume that you’re going to index files in a directory called `Newsletters`, which sits in your `wwwroot` directory. (Yes, you can do this for files that *aren’t* in `wwwroot`, but this is simplest.) You have already:

- ◆ Set up IIS on a computer (with all the current security patches, please!)
- ◆ Created a directory named `Newsletters` inside `\Inetpub\wwwroot`
- ◆ Placed a few text, HTML, or Office documents in `\Inetpub\wwwroot\Newsletters`

- ◆ Started Indexing Service on that computer
- ◆ Created a catalog called Newsletters, which indexes the Newsletters directory inside wwwroot
- ◆ Tested that queries to it work with Query the Catalog

### CREATING THE HTML

You'll need two files: `ask.htm`, which contains a form that lets people type in their queries, and `find.asp`, which takes the information collected in `ask.htm`, executes the query, and returns the answers. `Ask.htm` is pretty short, as you can see in Listing 17.2.

#### LISTING 17.2: THE *ASK.HTM* FILE

```
<HTML>
<HEAD>
<TITLE>Search Newsletter Archive</TITLE>
</HEAD>
<BODY>
<Form ACTION="find.asp" METHOD=POST>
Type in your query<br>
<INPUT TYPE=TEXT NAME="SearchString" SIZE="94" MAXLENGTH="100" VALUE=""><br>
<BUTTON TYPE=SUBMIT>Submit</BUTTON>
<BUTTON TYPE=RESET>Clear Form</BUTTON>
</FORM>
</BODY>
</HTML>
```

This just prompts you to “Type in your query,” then packages your query in a variable called `SearchString`, and then calls another HTML page called `find.asp`. (Both `ask.htm` and `find.asp` should be in your `wwwroot` directory.)

`Find.asp` is a bit more complex (see Listing 17.3), as it must first perform the query and then format it nicely for the user.

#### LISTING 17.3: THE *FIND.ASP* FILE

```
<HTML>
<HEAD>
<TITLE>Search Results</TITLE>
</HEAD>
<BODY>
<%

'Set the search parameters

'The following line is a comment; it shows how you'd restrict the search
'To just a directory "folderinnews" inside Newsletters.
'FormScope = "/folderinnews"
```

'These lines set the search parameters

```
FormScope = "/"
PageSize = 1000
MaxRecords=1000
SearchString = Request.Form("SearchString")
CatalogToSearch = "Newsletters"
SearchRankOrder="rank[d]"
OrigSearch=SearchString
```

'  
' Create query object

```
set Q = Server.CreateObject("ixsso.Query")
set util = Server.CreateObject("ixsso.Util")
Q.Query = SearchString
Q.Catalog = CatalogToSearch
Q.SortBy = SearchRankOrder
Q.Columns = "DocTitle, vpath, filename, size, write,
↳characterization, rank, directory, path"
Q.MaxRecords = MaxRecords
'util.AddScopeToQuery Q, FormScope, "deep"
```

'  
' Do query  
,

```
set RS = Q.CreateRecordSet("nonsequential")
RS.PageSize = PageSize
response.write "<p>Your search for <b>" & OrigSearch & "</b> yielded "
```

```
If RS.RecordCount=0 then response.write "no results."
If RS.RecordCount=1 then response.write "1 result:"
If RS.RecordCount>1 then response.write RS.RecordCount & " results:"
```

```
response.write "<table
↳border=1><tr><td>Doctitle</td><td>Vpath</td><td>Filename</td>"
response.write "<td>Size</td><td>Write</td><td>Characterization</td><td>Rank</td>"
response.write "<td>Directory</td><td>Path</td></tr>"
```

'Display the results

```
Do While Not RS.EOF
' loop through the results.
' Build a hyperlink to the document
hlink = "<a href=" & "/" & RS("filename")
↳& " " & RS("doctitle") & "</a>"
' Display attributesresponse.write "<tr><td>" &
↳hlink & "</td><td>" & RS("Vpath") & "</td><td>"
```

```

response.write RS("filename") & "</td><td>" & RS("size")
&& "</td><td>" & RS("write")
response.write "</td><td>" & RS("characterization") & "</td><td>" & RS("rank")
response.write "</td><td>" & RS("directory") & "</td><td>"
&& RS("path") & "</td><tr>"
'Get the next result
RS.MoveNext
Loop 'end of DO WHILE loop

response.write "</table>"
set rs=nothing
set q=nothing
set util=nothing
%>

</BODY>
</HTML>

```

---

If you just want to try these out, then type the lines into Notepad and copy the files to your `wwwroot` directory. While still sitting at that computer, open up Internet Explorer, type `http://localhost/ask.htm`, press Enter, and you'll see your form come up.

### HOW THE QUERY CODE WORKS

To understand `find.asp`—which, again, is a very stripped-down query page—let's take it in pieces. The first part, through the `<BODY>` command, is just HTML. After that, you see this:

```

<%
' Set the search parameters
' The following line is a comment; it shows how you'd restrict the search to
' just a directory "folderinnews" inside Newsletters.
' FormScope = "/folderinnews"
' These lines set the search parameters
FormScope = "/"
PageSize = 1000
MaxRecords=1000
SearchString = Request.Form("SearchString")
CatalogToSearch = "Newsletters"
SearchRankOrder="rank[d]"
OrigSearch=SearchString

```

That line with just the `<%` tells the IIS server that a program is starting. Lines that begin with a single quote are just ignored by the server; they're comments. The next bunch of lines sets the parameters for the search. `FormScope` lets you tell Indexing Service that you don't want to search an entire directory, just a subdirectory. If, for example, you had a directory called `\inetpub\wwwroot\newsletters\goodstuff` and you wanted the search to *only* look in the `\goodstuff` directory, then you'd change the line to

```
Formscope = "/goodstuff"
```

PageSize and MaxRecords restrict the search, limiting the number of hits that Indexing Service reports. SearchString just retrieves the search text. CatalogToSearch, of course, says to search “Newsletters.” If there were other catalogs on this server, then you’d change this variable to point the search elsewhere. SearchRankOrder just says to report them from the best to the worst match. OrigSearch is just for programming convenience.

The next set of lines forms and executes the query:

```
' Create query object

set Q = Server.CreateObject("ixsso.Query")
set util = Server.CreateObject("ixsso.Util")
Q.Query = SearchString
Q.Catalog = CatalogToSearch
Q.SortBy = SearchRankOrder
Q.Columns = "DocTitle, vpath, filename, size, write,
↳characterization, rank, directory, path"
Q.MaxRecords = MaxRecords
' util.AddScopeToQuery Q, FormScope, "deep"

'
' Do query
'

set RS = Q.CreateRecordSet("nonsequential")
RS.PageSize = PageSize
```

The piece toward the top is just “boilerplate,” the particular magic words that you must say to ask Indexing Service a question. Note, however, types of “objects”—that’s the programmer word for them—in the ServerCreateObject commands. The first in particular, ixssso.Query, is the built-in set of routines that controls queries. To find all of the developer documentation about it, search [msdn.microsoft.com](http://msdn.microsoft.com) for “ixssso.query.”

### CONTROLLING A QUERY: WHAT TO RETRIEVE

If you did that search, you’d see that the “query” method of the “ixssso” object—I’m so glad the developers kept it simple for us—has attributes with names like Query, Catalog, SortBy, and so on. You needn’t look that stuff up unless you want to extend this example; I’ve already done most of the work. But you *do* have to fill those attributes with values, and that’s what the Q.Query=, Q.Catalog=, and nearby lines do—they just transfer the values that we set up top into a place where Indexing Service can find it.

A couple of the lines need a bit more explaining. First, notice the Q.Columns= line; that tells Indexing Service exactly which data to retrieve.

- ◆ DocTitle is the title, if the file has one. HTML files have titles; ASCII files don’t; Office files can have titles.
- ◆ Vpath is the relative path from the top of the catalog. In other words, you’re looking in a directory called `\Inetpub\wwwroot\newsletters` for files, but what if the files are in a directory *inside* that directory? Vpath would show that. If it turns up a file named `\Inetpub\wwwroot\newsletters\goodfiles\hints.txt`, then the Vpath would be `goodfiles`, as it’s the subdirectory inside the catalog.

- ◆ Filename is, logically, the filename—`hints.txt` in the previous example.
- ◆ Size is the size in bytes.
- ◆ Write is the date the file was last written to.
- ◆ Characterization is the “abstract” that Indexing Service can optionally create.
- ◆ Rank is a numeric score that Indexing Service uses to rate how well something matches a query.
- ◆ Directory is the complete directory path of the file `d:\inetpub\wwwroot\Newsletters\goodfiles` in the example.
- ◆ Path is the combination of the filename and the directory; in the example, it’d be `d:\inetpub\wwwroot\Newsletters\goodfiles\hints.txt`.

You can see the entire list of columns in a catalog in the Indexing Service snap-in in Computer Management. Under the icon for the catalog itself there is a folder named **Properties**. Look in there and you’ll see the entire list of a catalog’s properties or, as the query calls it, columns. (Most of them are of no value—the preceding list is about all you’d probably want.)

### CONTROLLING A QUERY: WHERE TO LOOK

Second, note the comment that starts `util.AddScope`. This tells Indexing Service two things about the search: first, which directory in the catalog should it search and, second, should it search at that directory level, or search that directory and the directories *inside* of it? Recall that Indexing Service automatically *catalogs* as far down as the directory structure goes; this command doesn’t affect that. Instead, it reflects the fact that Indexing Service doesn’t automatically show all of its cards when you make a query—it only reveals what the query asks for.

Suppose you’ve got that directory structure that I mentioned before, `\Inetpub\wwwroot\Newsletters\goodfiles\hints.txt`. Suppose also that you chose this time to index the *whole* `wwwroot` directory. What would that mean for the scope of the search? Without an `AddScopeToQuery` command, Indexing Service will only show results that it found in the top-level directory of the catalog, `\Inetpub\wwwroot`. To search the *whole* directory and the directories inside it, including `\Inetpub\wwwroot\Newsletters`, `\Inetpub\wwwroot\Newsletters\goodfiles`, and whatever else is in there, you’d use this command:

```
util.AddScopeToQuery Q, "/", "deep"
```

That says that the query defined by the object `Q` should start at the top—“/”—and should search all directories. The “deep” keyword is the part that says to search the directories inside the directories.

But what if you only wanted to search `\Inetpub\wwwroot\Newsletters`? Then you’d use a scope of `/Newsletters`—note that this uses the forward slash rather than backslash. The command would look like this:

```
util.AddScopeToQuery Q, "/Newsletters", "shallow"
```

Finally, what if you wanted to restrict the search to keep it out of the `\Inetpub\wwwroot` directory and start searching at `\Inetpub\wwwroot\Newsletters`, but also search directories below `Newsletters`? Then you’d do this:

```
util.AddScopeToQuery Q, "/Newsletters", "deep"
```

It's a *really* good idea to restrict your query scopes—you'll be surprised what Indexing Service turns up! For example, if you *did* index your entire Web site, then you'd probably be exposing things like code in progress, old code, or notes to yourself, much of which you might not want publicly visible.

To finish examining `find.asp`, the `set RS=` line tells IIS where to put the output of the query: into an object called a "record set" that I've unimaginatively called "RS." And finally, the rest of the program just loops through the returned values and creates a table that reports what it found. The three commands that say "`set something=nothing`" recover memory on the IIS server.

## Troubleshooting Failed Queries

When you first get started with building your search pages and catalogs, you'll probably turn up a lot of failed queries. They can be frustrating; here's what to check:

**Permissions** SYSTEM must have read access to the data to be cataloged, full control of the directory where the catalog is stored, and, Microsoft adds (although I've not checked it), that SYSTEM must also have full control to the root of the drive where the catalog is stored. But the querying person must also have the permissions to see the documents, or Indexing Service won't even display it. So, for example, if your query fails from your Web browser, try logging onto the server as an administrator and try the query tool in Computer Management. If *that* works and the Web browser doesn't, chances are good that IUSR doesn't have the permissions necessary to see the data. And when you're testing your Web-based app, make sure that you're not logged on as an administrator of the domain. Depending on how you have IIS set up, it may try to get you the catalog info as IUSR and, when that fails, it may automatically try again using your currently logged-on credentials as an administrator, and succeed. But non-admins won't be able to access the data.

**Check the query syntax** It's a bizarre language. Make sure you have a few simple queries whose syntax you *know* works.

**Be patient** Indexing Service is built to run in the background, which means that when you're fussing with it, the indexing part of Indexing Service goes to sleep, waiting for the server to quiet down before it does its work. Get a cup of coffee or check your e-mail, give it a few minutes, and then try again.

**Dump the catalog and start over** Stop the Indexing Service, then right-click the icon for the catalog, and choose All Tasks/Empty Catalog. Then restart the Indexing Service. You start out with a fresh catalog this way, and you know that no old junk's sitting around in it.

**Go to the directories and files that you want to catalog, right-click them and choose Properties, then click the Advanced button** There's a check box on the resulting dialog box labeled For Fast Searching, Allow Indexing Service to Index This Folder. It's checked by default, but if someone's unchecked it, then Indexing Service will skip it altogether.

By now, you should not only have a working catalog, but also a nifty Web-based front end for it. Indexing Service is pretty cool once you get it set up, but, as always with complex tools, it's the initial setup that's the pain.

## Windows Server 2003 Internet Security: Some Thoughts

A security engineer at a major tier-one ISP recently told me his opinion of Windows NT in regard to security. “It’s an exploit in a box,” he told me, very matter of factly, and you know what? Even though he’s a “Unix guy,” he was absolutely right. Windows NT was extremely permissive in its default configurations. However, Windows 2000 Server made a bunch of improvements in the security arena, and Windows Server 2003 is the most secure operating system that they’ve ever published. But does that mean that you should simply accept it with its default configuration? In the pages that follow, I’ll walk through some items that you should be certain to secure on your Windows Server in order to protect it even more.

Although the security suggestions that follow will help secure your system, it is important to realize that there is no quick fix for Internet security. Entire volumes are published on the subject, much more than I could possibly cover in the pages of this book.

There are, however, several types of actions you can take to detect and/or deter an outside attack. In this section, I’ll talk about deterring and detecting attacks and cover security recommendations for three primary areas: accounts, file and print sharing, and network services.

Whether “security” is officially part of your job description or not, the twenty-first century seems to have a few new truths about it. First, we seem to be running a lot more Web servers than before. Even simple network-attached appliances like JetDirect modules or 3Com’s Lanmodem make you control them via a Web interface, which means that—you guessed it—they’ve all got a Web server built into them. But what’s the second truth of the twenty-first century? Virus- and worm-writing jerks the world over have targeted IIS. So anyone running an IIS-based Web server should understand that it is *very* likely that his or her system will be attacked by a worm; such an attack is a near certainty. But there’s a third and final truth here: If you put an insecure Web server on a network, then you aren’t merely a neutral party in the ongoing war between the worm-writing weasels and systems administrators; rather, you are helping the weasels.

To see what I mean by that, let’s look at who would get hurt if I set up a Web server but didn’t protect it from a worm. Worms like Code Red, Code Blue, Nimda, and their successors do several things. First, they usually rewrite and damage Web pages. That means that if I don’t do anything to protect my Web server from infection, then I may be hurt, in that I must restore my Web pages to their predefacement state. But what if I’ve put a system on the Internet that runs a Web server, but only because I installed with the defaults? In that case, I shouldn’t care whether a worm attacks the Web server, should I?

Of course I should, because of the *second* effect of a worm. Once planted in a Web server, worms seek out other Web servers to infect. That means that my unwitting Web server might end up as the vehicle that some weasel uses to infect an important Web server. At minimum, that’s certainly not nice and I would prefer *not* to be a vector of e-infection; at worst, I might even be sued over it.

Even worse, a worm has a third effect: it chomps bandwidth. There have been days when so many copies of a given worm are busy scanning IP addresses trying to find potential victim servers that they have significantly slowed down the Internet.

The bottom line is this: If I’ve put an unsecured computer on the Internet, then I’ve put a loaded weapon into the hands of a network criminal. I’ve aided and abetted one of the bad guys. I worry that as more and more home users get high-speed DSL and cable-modem connections, and as those home users’ operating systems get more and more sophisticated, that it will be possible for one cleverly written worm to simply shut the Internet down. Edmund Burke is credited with saying that all that

is required for evil to triumph is for a “few good men to do nothing.” Let’s update that to say that all that is required for the weasels to destroy or severely damage an important artery of communication—the Internet—is for a few otherwise-good people to get lazy about securing their operating system’s Web servers.

The most important point here, however, is that you can do some very simple, basic things to secure your IIS servers; let’s see how.

## **Disable IIS If You Aren’t Using It**

Probably the most effective and simplest way to secure your server is to disable unnecessary services. You can test if a computer is running a Web server in a few simple ways. First, check its services in Computer Management: right-click My Computer, choose Manage, then locate the object labeled Services and Applications and click the plus sign next to it. That should reveal, among other things, an object named Services; click it and the right panel will show the services that your computer is running. You’ll see that there isn’t a service called IIS or Internet Information Service or anything like that; it’s called World Wide Web Publishing Service. Right-click it, choose Properties, and you’ll get a property page that lets you stop the service. But that only stops the Web server for now—reboot, and it’ll probably start up all by itself. You can change that by clicking a drop-down list box labeled Startup Type, which offers you three choices: Automatic (which starts the service up at boot time), Manual (which does not start the service at boot time but lets you turn it on when you feel like it), or Disabled (which doesn’t start the service and doesn’t give you the option to start it). Just choose Disabled if you don’t want this server to be a Web server, and then click OK.

Windows Server 2003 makes this less of a problem, as it discontinues Microsoft’s practice of automatically installing a Web server on every system. Additionally, IIS 6 first comes up in a very “locked-down” mode, making it harder to attack an IIS 6 server whose administrator has chosen all of the defaults for it.

## **Get and Apply the Latest Service Packs and Hotfixes**

Whenever a new worm appears, people castigate Microsoft for being “unprepared” for this latest attack, and administrators everywhere bemoan Windows’ “terrible security.”

Just about anyone who’s ever been hit by an IIS-based worm could have avoided the infection had he just kept up-to-date with Microsoft’s patches. (Up-to-date Web servers were safe from Code Red, Blue, and Nimda, for example.) The problem is that most of us are a bit sloppy about getting around to downloading and applying the latest patches, and for years that wasn’t really a problem. Unfortunately, our modern-day “world of worms” has made staying on top of patches mandatory.

Windows Server 2003 makes it easier than ever to stay up to date on service packs, patches, and hotfixes. The Autoupdate feature, available in the System applet, lets you configure a server to automatically check for updates and download them when they are released. Or you can use the Windows Update Web site (<http://windowsupdate.microsoft.com>) to scan your system, review and then install updates.

But service packs aren’t the end of your update task. Stay up to date on the latest developments by checking out the security bulletins that you can find at [www.microsoft.com/technet/treeview/default.asp?url=/technet/security/current.asp](http://www.microsoft.com/technet/treeview/default.asp?url=/technet/security/current.asp). This site gets rearranged on a regular basis, so if that doesn’t work, just search for “security bulletin” on the [microsoft.com](http://www.microsoft.com) site. The Security Bulletins site offers a notification service when new bulletins are issued, and access to the Microsoft

Baseline Security Analyzer (MBSA) tool, which scans a system for vulnerabilities and missing hotfixes. The patches released from the bulletin site are EXE files with names like Q329390\_WXP\_SP2\_X86\_ENU.exe. The first part refers to the Knowledge Base article that explains what the patch does, WXP clearly says that it's a Windows XP patch, and SP2 means that it is a *post*-Service Pack 2 fix and that this patch will eventually be part of Service Pack 3.

**NOTE** Microsoft is retiring the “Q” naming scheme for Knowledge Base articles. Articles previously named “QXXXXX” will retain the same number, but without the “Q” prefix.

## Simplifying Hotfix Application

If you've ever downloaded and applied a hotfix, then you're probably shaking your head and thinking, “Has this guy ever actually *done* this?” But, wait, give me a chance.

Hotfixes are a pain for two reasons. First, there are a *lot* of them. It's not unusual to see a couple or three dozen hotfixes that you need to apply *even if you have the most recent service pack*. Second, try applying one and you'll see that most of them force you to reboot after you apply them. So let's see, first I download the 18 relevant hotfixes. Then I apply the first one and wait for my system to reboot, then I do the second, and... wait a minute, you mean that I've got to do that for *all* of my computers? And then how do I check which computers have and don't have a given set of hotfixes?

Thankfully, Microsoft has offered a couple of programs to simplify the process, `qchain.exe` and `hfnetchk.exe`. You can find the link for `qchain.exe` at Knowledge Base article 296861, or if that article's gone by the time that you read this, then search for “`qchain.exe`.” You can find `hfnetchk.exe` at article Q303215, or, again, if that doesn't exist when you look for it, search on the program's name.

`qchain` lets you apply a whole bunch of hotfixes all at once. You invoke the hotfixes—each with the options `-m`, `-z`, `unattended`, and don't force reboot—and then `qchain` rearranges them on disk and in the Registry so that they don't conflict with one another. Then you can reboot. For example, suppose you had some hotfixes with the names `q335825_w2k_sp3.exe`, `qf843615_w2k_sp3.exe`, and `q745622_w2k_sp3.exe` (all imaginary hotfix names, by the way). You could put them on a server named `srv1` on a share called `patches`, and then put the hotfixes, `qchain.exe`, and a batch file to install the patches in that share. The batch file could look something like this:

```
set lc=\\srv1\patches\
%lc%q335825_w2k_sp3.exe -z -m
%lc%qf843615_w2k_sp3.exe -z -m
%lc%q745622_w2k_sp3.exe -z -m
%lc%qchain mylog.txt
```

Create the batch file by opening up Notepad and typing those lines into Notepad, but don't type the names of the imaginary hotfixes; instead, type one line for each of the hotfixes that you've got in that directory, prefixing them with “`%lc%`” and adding “`-z -m`” to the end. Then save them as `applypatches.bat`, again in that share. Now you can, from any machine on the network, just type

```
\\srv1\patches\applypatches.bat
```

and it'll apply all of the patches. You can then reboot the system, and it'll be up-to-date. But how do you check later to see what hotfixes have been applied to a given system and if it's still up-to-date? That's where `hfnetchk.exe` helps out. In its simplest form, you just run `hfnetchk.exe` on a system without any options. It then contacts the Microsoft site, downloads information about the latest

hotfixes, and checks that your system has those hotfixes. It'll then report about hotfixes that Microsoft thinks that you should have but that you don't.

You can run it with the `-v`, verbose, switch to find out why `hfnetchk` thinks that you don't have a given hotfix. There are a few that apparently don't leave enough of a fingerprint behind for `hfnetchk` to be able to verify whether or not you actually have the hotfix installed, like one that appeared in 2001 named MS01-022. Apparently you could apply it all that you wanted, but `hfnetchk` couldn't find it. But running `hfnetchk -v` could allay your fears:

```
WARNING           MS01-022           Q296441
The XML file does not contain any file or registry details
  ↳for this patch.  As a result, this tool is unable to
  ↳confirm that this patch has been applied.  Please
  ↳verify patch installation or refer to Q303215 for
  ↳more information.
```

In other words, `hfnetchk` is saying, “Well, I can't *prove* that this is here, so I won't say that it's there...but I couldn't prove it in either case.”

## Use IIS and NTFS Permissions

When the bad guys get control of your IIS server, the system sees them as one of two user accounts—either the IUSR account or the System account. If they're running a script or a Web page, then they're the IUSR account. Intruders can only act as the System account in those cases where IIS has some pretty egregious bug and the intruder exploits that bug.

Let me underscore that point: visitors to your Web site are actually logged into your Web server's security system, whether it's a local SAM or a domain-based Active Directory. Such so-called “anonymous” Web visitors are logged in as the IUSR account. Armed with that knowledge, you can recruit NTFS to help you secure your system.

Unlike Windows 2000 and earlier systems, which set all of their NTFS permissions to Everyone/Full Control (of course IUSR is a member of Everyone), Windows Server 2003 sets more restrictive permissions on disk resources:

1. The `wwwroot` directory only grants the IUSR account NTFS permissions to read and list folder contents. This will work fine unless there is a script in `wwwroot`, in which case you need to grant execute permissions as well. You'll only need to give IUSR write permissions on any directories that Web-based scripts use to write files to.
2. In the Windows directory, IUSR has the same permissions as Authenticated Users: read, execute, and list folder contents.
3. Throughout the rest of the server's hard disk, IUSR has no access permissions.

**TIP** *Your system might need somewhat different permissions. Microsoft has a pretty nitty-gritty Knowledge Base article about required IIS 5 permissions at 271071. As far as I know, they haven't updated it for IIS 6 yet.*

Now, you might be running some set of programs or scripts that require different permissions than the defaults; work with the content folks to find out what permissions you need for each directory but, again, in my experience IIS works very well with extremely minimal permissions for IUSR.

But IIS itself also has a set of permissions that you can use to secure your Web site. They work in tandem with NTFS permissions in the same way that file-sharing permissions work with NTFS permissions: both apply and the most restrictive ones win. IIS permissions are simpler and less flexible than NTFS permissions, as they apply to everyone accessing a site—there’s no way, for example, to say that the IIS read permission (which is different from the familiar NTFS read permission) should be granted to Administrators and denied to everyone else. Instead, you just check the Read box and every visitor gets it.

Although the default IIS permissions are more restrictive in IIS 6 than they were in IIS 5, you should still check out the Execute Permissions box for every directory in your Web site. My site was once composed of a basic `wwwroot` directory that contained a bunch of directories, most of which contained only static HTML pages and images. I was surprised to find that the IIS permission on all of those directories was scripts and executables!

To view a given directory’s IIS permissions, just open up the site in the IIS administration snap-in, and you’ll see a folder icon for each directory. Right-click the folder and choose Properties, and you’ll see the IIS permissions for that directory in the Directory, Home Directory, or Virtual Directory tab, depending on the context.

## Disable Indexing

The Indexing Service is not installed by default in Windows Server 2003, but if you do install it, delete the two default catalogs named Web and System to prevent automatic indexing of all your hard drives and Web sites. Only create catalogs for folders you explicitly want indexed, and keep in mind that all files and subfolders will be indexed from that point in the directory structure. Be sure to disable indexing for any subfolders with content you don’t want to include in the catalog. Consider taking the extra precaution of explicitly disabling indexing for all other files and directories on your hard disks. I know this seems like overkill, but there are some directories that you don’t ever want to be indexed, even if some bright-eyed administrator later decides that it would be a good idea to index all the hard drives on the server. Mail directories would fall into this category. Imagine doing an innocent search and having the query return a confidential e-mail from the accounting department on salary reviews!

## Disable All Nonessential Ports

In Chapter 6, you learned how to enable TCP/IP filtering to close particular ports on the server. Consider doing this for your Web servers. But remember, if you close all incoming ports except for 80 and 443, then you won’t be able to do remote administration of your computer. You can close ports from the GUI in the Advanced properties of the TCP/IP protocol, or use IPSec, as you saw in Chapter 6.

## Move `wwwroot`

By default, IIS puts its `wwwroot` directory on the same drive as the operating system, in the `\Inetpub` directory. Some particularly badly written worms can’t even *find* your Web site to attack it unless the site is in `Inetpub`. So moving the root of your document directories will provide some small protection.

## Get Rid of the IIS Admin, Documentation, Web-Based Printing, Extra Directories, and Samples

IIS ships with a whole bunch of sample files and extra doodads. Many are useful, but they're also potential security holes.

For example, there is a Web-based administration tool for IIS. If someone cracks that, they *own* your Web site. Don't install it. It's not installed by default with the rest of IIS. If it is installed, get rid of it from the Control Panel in Add/Remove Programs/Windows Components. Highlight the Web Application Server option and click the Details button. From here, choose Internet Information Services (IIS) and then the Details button again. Uncheck Remote Administration (HTML), which you'll find among the list of World Wide Web server components. And while you're at it, if you don't use FrontPage-based Webs, then uncheck the box next to FrontPage Server 2002 Extensions. Personally, I find the FrontPage bots to be fragile, so I avoid them altogether. I would also take this opportunity to remove anything else I don't need. Then click Next, OK, and Finish until you're out of Add/Remove Programs. Back in the IIS snap-in, go ahead and also delete the Microsoft SharePoint Administration site, as well as the Printers folder (in the default Web site) to get rid of Web-based printing. In fact, before I start using a newly built IIS system, I just delete everything in `wwwroot`.

## Disable Unnecessary Services on Your Servers

You can safely shut down unused services on Web servers or, for that matter, shut them down on *any* server—it saves CPU power and RAM, and closes any potential security holes that those services might contain. Here are some other services that you might disable or remove using Add/Remove Programs in the Control Panel:

**Server service** This isn't a generic service required by all server services; instead, it's just the file and print server service. And while it's true that Web servers are a kind of file server, they do *not* necessarily need a working file server service.

**FTP service** If you need this to let Web authors upload content changes, then enable it. But be careful about running anonymous FTP sites; you'd hate to find out that you accidentally let the bad guys store their stuff on your FTP site. Consider using WebDAV instead of FTP for uploading content.

**Simple Mail Transport Protocol** If your Web site doesn't do automated mail-outs, stop this service; SMTP holes have been giving Unix administrators fits for years.

### Routing and Remote Access Service

**WebDAV** A sort of twenty-first-century upgrade to FTP server, it lets you do what basically looks like normal file sharing over HTTP. It's far better than FTP, but you have to wonder if it's secure. If you're not using it, get rid of it. (It's off by default.) One way to make sure that it stays off is to deny the Everyone group access to `winnt\system32\inetssrv\httpext.dll`.

But you know which service I'd *really* like to kill? The GUI. It sucks up all kinds of CPU and RAM, and what do I need it for when my Web server is just sitting in the corner waiting for requests? Maybe in Windows 2015, I guess. Here the Linux guys have the right idea.

## Consider Disabling Microsoft File and Print Sharing

The same file and print sharing protocols that let you build file/print servers in your organization let you share files and printers over the Internet as well. You might want to disable that service—the Server service. Here's why.

First of all, what is it that you want to secure? I'll assume it is your data. Because you don't want an outside intruder to be able to destroy data on your servers or lock you out of your own network, let's consider this question: How could someone get access to your data?

Assume that you weren't even running a Web or FTP server; consider what an attacker could do just to a simple file/print server that's exposed to the Internet. Attacks could come in the following forms:

- ◆ Someone with read access to your files could steal company information.
- ◆ Someone with write access to your files could modify or delete them.
- ◆ Someone with write access could use your file servers to store their own personal data—data they might not want to keep on their own computers, perhaps because the data is unlawful to have, like someone else's credit card numbers.
- ◆ Someone with write access could cripple your servers by filling up their free space with nonsense files, crashing the servers.
- ◆ Presumably someone could crash your mail servers by sending thousands of automatically generated pieces of mail to the servers. Enough mail messages will fill the hard disks of those servers as well.
- ◆ Access to your print servers could, again, let intruders fill up the print servers' hard disks with spooled files, as well as cause your printers to run out of paper.

## Eliminate Nonessential ISAPI

ISAPI filters are an IIS-specific alternative to scripts and CGI programs. They were introduced back in IIS 2 and allow IIS to support some very fast extensions to basic Web functionality, like Active Server Pages.

You can see your site's ISAPI filters from the ISAPI Filters tab of the properties pages. Take a look at the file extensions associated with various ISAPI filters. Unless you or another admin added some ISAPI filters at some point, the only one you are likely to see is the ASP.NET filter, which is defined in the master properties for all Web sites. If there are others, though, and you don't see any files with that given extension in your Web site pages, then just delete the reference to that ISAPI filter. Code Red looked for an extension `.IDA`; had the ISAPI filter for IDA not been in place, then the virus would have gotten a Page Not Found, and wouldn't have infected that server.

## Detecting Outside Attacks

Windows Server 2003 comes with some built-in tools to make detecting attacks easier. You can do the following:

- ◆ Audit failed logons.
- ◆ Use the Performance Monitor to alert you when logon failures exceed some reasonable value.
- ◆ Periodically log network activity levels. If all of a sudden your network gets really busy at 3 A.M. for no good reason, then look closely into exactly what's going on at 3 A.M.

In addition to these, consider reviewing your IIS log files (found in `\Windows\system32\logfiles`) periodically. If you've been getting 100 hits a day and suddenly it's 10,000 hits a day, something is up. These logs also record source IP addresses for hits; you may be able to identify vulnerability scanning patterns by frequency and by the pages requested, and then notify the ISP or organization that administers the source addresses of any suspicious activity. There are some very good log analyzer tools available for Web servers; some are even free.

## Deterring Attacks

The main steps to take to deter attacks include the following:

1. Don't use obvious passwords.
2. Don't enable Guest accounts on Internet-connected machines.
3. Rename the built-in Administrator account.
4. Don't let the built-in Administrator account access the servers over the network.
5. Lock out users after a certain number of failed attempts.
6. Make passwords expire after a certain length of time.
7. Install a firewall to filter out UDP ports 136 and 137, used for Microsoft networking commands such as `net use`.
8. Install Web, news, and FTP servers on a separate machine in their own domains, with no trust links to other domains. Even better, install each Internet-accessible box as a stand-alone system with no ties to any internal domain. Sure, it's a pain to administer local accounts for FTP users and such, but the system can be locked down more radically since there's no need to communicate with domain controllers. This way, a compromised Web server doesn't have to mean a compromised Active Directory domain.
9. Don't put any services on your DNS servers except for DNS.

It seems to me that only by directly accessing your file servers through the normal `net use` interface, via an NFS interface, or through an FTP service would someone be able to read or write data on your computers over the Internet. I'll assume that you're not going to run NFS, that you'll put the FTP server where compromising it won't matter, and that you'll focus on the file server interface.

In a nutshell, here's the scenario that you should worry about. Suppose I know that you have a server named S01 whose IP address is 253.12.12.9 and that it has a share on it named SECRET. I just create an LMHOSTS file with one line in it, like so:

```
253.12.12.9 S01
```

Now I can type `net use X: \\s01\secret`, and my Internet-connected PC sends a request to 253.12.12.9 for access to the share. Assuming the Guest account isn't enabled on S01, then S01 will first ask my PC, "Who are you?" I'll see that as a request for a username and password. When I respond with a valid username and password from the server's domain, I'm in. Actually, this is how I access my network's resources from across the Internet when I'm on a client site—two seconds' work with an LMHOSTS file, a `net use`, and I'm accessing my home directory from thousands of miles away.

To do that, I needed to know:

- ◆ A valid username on my network
- ◆ The password for that account
- ◆ The IP address of a server on the domain
- ◆ The name of a share on the domain

All right, suppose I want to hack some company with the name **bigfirm.com**. Where do I start? Step one is to find out what its range of IP addresses is. That's easy. Just telnet to **internic.net**, type **whois bigfirm.com**, and you'll get the network number and responsible person for that network. (You can alternatively run a Web-based search page with your Web browser; point it to **www.internic.net**.) You'll also get the IP address of their DNS name servers. The other way to find this information would be to type:

```
nslookup
set type=all
bigfirm.com
```

Bigfirm will dump the names and addresses of their DNS servers and their mail servers. Because there has to be a secondary DNS server to make the InterNIC happy, there will be at least two name servers. Now, bigfirm is probably thinking—the way most of us do—“It doesn't take much CPU power to run a DNS server. Let's put some shared directories there, too.”

As Jane Slimeball Hacker, I'm thinking, “Cool—fresh meat.”

You see, you've got no choice but to publish two of your IP addresses, the addresses of your DNS server and its backup. So don't put anything else on it. Once, I would suggest to firms that they just run DNS on old, slow machines. That's not an option anymore, as we now need dynamic DNS, which means you're running Windows 2000 on a system and DNS on that system. It's a shame to make a server solely a DNS server, but it might not be a bad idea from a security point of view.

Now suppose you're smart and there's nothing else on the DNS servers. So I have to fish a bit, but that's not hard, as **whois** told me your range of IP addresses. I'm a slimeball, but I'm a thorough slimeball (after all, I don't have a life, so I've got lots of time), and I'm willing to try all of your IP addresses to find out which ones have servers. There are even, believe it or not, freeware programs for Windows systems that will scan a range of IP addresses looking for machines attached to those addresses.

Alternatively, it's a simple matter to create an LMHOSTS file that includes a NetBIOS name for every possible IP address. For example, if I know that you have class C network 200.200.200.0, then I can create an LMHOSTS file with NetBIOS named N1, which equals 200.200.200.1; N2 equals 200.200.200.2, and so on. Then I need only do a **net view \\servername** for each name from N1 through N254. The IP addresses that have a computer attached to them running the server service will be the ones that challenge me for a name and password. The ones that don't won't respond at all.

What can you do? Not terribly much, except to be sure that the default Administrator accounts on those systems aren't blank—no sense in making things too easy. And it sure offers some incentive for getting rid of your old machines and applications and getting your enterprise off NetBIOS, doesn't it?

Next, I'm looking for a user account name or two. How can I get this? I don't think you can do a **net user** remotely without contacting the domain controller, which means you'll have to have a domain ID and password to get **net user** to work from the outside—whew, that's one less thing to worry about!

But there is a way to find at least some usernames. When a user logs in to a Windows system, the machine registers not only its own machine name on the network, but the user's name as well. It does that so alerts with that name on them can get to the proper user. For example, suppose you've asked the Performance Monitor to alert you in your username of JILL02 if a server gets low on free space. How does the network know where you are?

It's quite simple. When you log in, the Messenger Service—assuming that it's running—registers your username as one of the NetBIOS names attached to your workstation. Assuming you are logged on to a server whose IP address is 200.200.200.200, anyone doing an **nbtstat -A 200.200.200.200** would not only see the computer's name, they'd see your name as well.

So, supposing that someone named paulad was logged in at the 200.200.200.200 machine (that's physically logged in, not connected over the network), a look at the NBTSTAT output would show me that there's a user named paulad who's logged in.

So now I have a username—and probably the username of an administrative account, since paulad is logged in to a server; good news for Joe Hacker. What can you do about that? Disable the Messenger Service, and the name never gets registered. And, by the way, speaking of NBTSTAT, if you run an **nbtstat -A** and the name MSBROWSE shows up, you've found a browse master. There's a good chance that a browse master is a domain controller, right? So maybe it's a good idea to set **Maintain-ServerList=No** for the domain controllers; you make that change in **HKLM\System\CurrentControlSet\Services\Browser\Parameters**. Just let the other servers handle the browse master part; you'll remove a clue that a hacker could use. Unfortunately, however, all domain controllers have other names registered to them that pretty much identify them as domain controllers.

Now that I have a username, I need a password. Now that's a problem. Even if I could physically attach my computer to your network, I wouldn't get a password with a network sniffer—NT uses a challenge/response approach to password verification. When you try to log in to an NT domain, the domain controller sends your workstation a random number that your workstation then applies to your password using some kind of hashing function, a mathematical function that produces a number when supplied with two inputs. The result is what gets sent over the network, not the password. (As I said earlier, there is one exception to this rule; when you change your password, the new password does go over the network to the server, but that's pretty rare.)

Where do I get the password? I can do one of two things. First, taking what I know about the user, I can try to guess a password. Second, I can run a program that tries to log in repeatedly, using as passwords every word in the dictionary—this is sometimes known as a dictionary hack.

The defense against this should be obvious. First, don't use easy-to-guess passwords. Use more than one word with a character between it, like **fungus#polygon**. Second, don't make it easy for people to try a lot of random passwords: Lock them out after five bad tries.

That leads me to a note about the Administrator account. Windows Server 2003 extends the lockout policy to include the Administrator account. After five bad login attempts, by default, the Administrator account can only be used to log in locally at the domain controllers, not remotely or over the network. If the lockout policy didn't apply to the Administrator account (and it didn't in Windows 2000, not without a Resource Kit utility called **passprop.exe**), then no matter how

many times you tried to log on with a bad password, the Administrator account wouldn't lock. The slimeballs on the Internet could spend all of their free time trying to figure out your Administrator password. To protect the Administrator password further, rename the account. Don't leave it as Administrator. Second, limit its powers. You cannot delete the Administrator account, nor can you disable it. But you can remove its right to access the server over the network. By removing this right, you force someone with the Administrator password to physically sit down at the server in order to control that server. Unfortunately, that won't be easy, because the ability to log in to a server locally is granted to the Administrators group, and the Administrator account is a member of that group. You aren't allowed to remove the Administrator account from the Administrators group, so all you can do, I suppose, is to remove the entire Administrators group's right. Then just grant the individual administrative accounts the Log On over the Network right. Now, these measures—disabling Guest, renaming Administrator, removing Administrator's right to log in over the network, locking out repeated penetration attempts, setting Performance Monitor to alert you to excessive failed logon attempts, using well-chosen passwords—may be sufficient, and you've no doubt noticed that they're all options that don't cost a dime. But if you want greater security, then look into a firewall. The firewall doesn't have to do much, but it has one really important job: to filter out two ports on UDP.

UDP (User Datagram Protocol) is the sister protocol to TCP; just as there is a TCP/IP, there is also a UDP/IP. TCP is connection oriented, whereas UDP is not connection oriented; it just drops messages on the network like messages in a bottle, hoping that they'll get where they should go. Whenever you execute a Microsoft networking command, such as `net use` or `net view`, you are running an application that sends commands to a server using UDP and UDP port numbers 136 and 137. Ports are software interfaces that are used to identify particular servers; for example, when you send mail from your desktop, you usually use TCP port number 25, and when you receive mail from your desktop, you usually do it on TCP port 110. Web browsers listen on TCP port 80, in another example.

Firewalls are powerful and sometimes complex devices. Once you install them, they have a million setup options and you're likely to wonder if you've caught all the ones you need. Running NetBIOS over IP services happens on UDP ports 136 and 137; tell your firewall to filter those and it's impossible for someone to access normal file server services.

### SECURING ACCOUNTS

Since an account is required to perform most actions on a Windows Server 2003, it would make sense that the accounts database should be the first line of security for any publicly connected server. Try starting with the following suggestions to harden your accounts database a bit more:

- ◆ Set a minimum password length of 8 characters. This one should be pretty straightforward: short passwords = easy to guess, long passwords = harder to guess. On any publicly connected system, a minimum password length of no less than 8 characters should be enforced.
- ◆ Set a minimum password age of 2 days. Microsoft's secure Web server recommendations call for setting a minimum password age of 2 days. This means that if someone—authorized or not—changes a password, that password cannot be changed again until 48 hours have passed. This is designed to catch situations where an attacker might know a user's password and attempt to change it temporarily for a specific purpose, with the intention of changing it back immediately afterward, going unnoticed.

- ◆ Set a maximum password age of 42 days. Again, common sense security practices dictate that no password should be kept forever. Therefore, setting a maximum password age of no more than 42 days is a good security precaution. Depending on your specific needs, you could set this to an even shorter interval if necessary.
- ◆ Keep the last 24 passwords. When used in combination with the maximum and minimum password ages, this prevents anyone from reusing any of the last 24 passwords used for an account. This is designed to defeat a common habit by some administrators of simply flipping back and forth between a few different passwords each time a change is required.
- ◆ Set an account lockout policy. If I could only make one recommendation for securing a publicly connected system, it would be that there must be an account lockout policy in place. In other words, if  $x$  number of invalid login attempts occur within  $y$  minutes, then the account should be locked out for a duration of  $z$  minutes/hours/days. You can use your own values for  $x$ ,  $y$ , and  $z$ , but this is one of the most valuable security precautions you can take!
- ◆ Require complex passwords. You read how to do this in Chapter 9.
- ◆ Assign the Deny Access to This Computer from the Network right to the Administrator account. Windows servers know whether an account is logging in from over the network or from the keyboard or mouse (or through a Terminal Services session). If you have physical access to your IIS server whenever you need it, you should strongly consider removing this right from your Administrator account. By default, most any hacker is going to know that Administrator is the default account to go after on any system, so removing this right will make it impossible to connect to the server over the network as the Administrator. This will restrict you to managing your system at the console only (or through a Terminal Server session), but it's a small price to pay for making sure that no one connects to your server over the Internet as Administrator. For more information on granting/revoking user rights, please see Chapter 9.
- ◆ Rename the Administrator account. As I mentioned in the last paragraph, everyone knows that the Administrator account is the default account on any Windows Server 2003 with the most privileges. Hackers want to "get Admin," so make it more difficult by renaming your Administrator account to something else—maybe something like "God," "root," "ToothFairy," or something equally obscure. Some people have commented to me that this is not useful advice because it's relatively simple to actually find out the default administrator's name, and I'd have to agree that it's easy for a determined hacker to get that information. But there are many attacks that rely on very simply built scripts or programs, and many of those programs aren't built to be very sophisticated—they assume that your home Web directory is `Inetpub\wwwroot`, that your administrator is named Administrator, and the like. Renaming the account will slow those guys down.
- ◆ Create a "bait" Administrator account. If you do decide to rename your Administrator account, an additional step you can take is to create a bait Administrator account on your system. Start by renaming your Administrator account to something else. Then create a new account and call it Administrator. Give it an extremely obscure password, disable the account, and make the account is a member of the Guests group only. That way, hackers can spend (and waste) their time hacking away at an Administrator account that won't yield anything if they do get the password.
- ◆ Disable the Guest account. By default, Windows Server 2003 will disable the default Guest account that is installed. It's worth double-checking this account to make sure that it is still disabled.

### SECURING FILE AND PRINT SHARING

By default, Windows Server 2003 assumes that you'd like to enable file and print sharing on each of the interface cards installed in your server. If you have a server with multiple NICs (one for the public Internet and one for your internal network), you can disable file and print sharing on the public interface very easily.

To disable file and print sharing, start up Control Panel/Network and Dial-Up Connections and find the icon for your public interface. Right-click the public interface, then uncheck the box for File and Print Sharing for Microsoft Networks. You can test to make sure this works by mapping to a share on your server before changing this setting and then mapping to a share on your server after changing this setting. Just for kicks, if you wanted to try to “decoy” someone who might compromise your system, you could put in decoy `winnt` and `inetpub` directories and if anyone hacked into your system, they'd simply be hacking at a dummy installation.

### Don't Forget Hazards from Within

Finally, remember that, all too often, the bad guys aren't outside the walls; they're right inside the company with you. Here are a few thoughts to consider about internal attackers.

#### INTERNAL USERS CAN EASILY GET A LIST OF USER IDS

Earlier in this book, you learned how to configure a set of home directories. First, you create a share called `USERS` on an NTFS volume, giving the Everyone group or, better, the Domain Users group, full control permissions. Then you set the top-level directory permissions to read and execute, and assign Domain Users no file permissions at all. Users need to read and execute to navigate from the top-level directory to their individual home directories. Then you set the file and directory permissions for each directory to full control for each particular user.

The problem is that there's no way to keep a user from moving up to the top-level directory and seeing the names of all of the users' home directories. Result: Now that user has a list of all of the users' IDs, hacking is made a bit easier.

Additionally, any user on an NT Workstation, Windows 2000 Professional, or XP Professional machine can type `net user/domain` and get a list of users in the workstation's domain. Again, these are mainly things you're concerned about for internal users, but inside hacking is probably more prevalent than outside hacking.

#### INTERNAL USERS CAN EASILY CRASH SHARED VOLUMES

If you haven't enabled disk quotas, any user with write access to a volume can, either accidentally or purposefully, write as much data to a shared volume as the volume can hold. The result is that now there's no space left for other users. Worse yet, if that's the volume that holds the pagefile, then the pagefile can't grow in size, which might crash Windows altogether.

It wasn't SMB file and print sharing that built the Internet or that builds e-businesses—it was and is the Web. Almost anyone working with servers will find herself the proud administrator of a Web server or two—whether she wanted to be or not. Just a bit of work can make those servers run well and run safely.

## Chapter 18

# Tuning and Monitoring Your Windows Server Network

IF A SERVER ISN'T performing well—if it seems unresponsive or if you're getting funny error messages—then you could install more memory or add another processor and hope for the best. Alternatively, you could try to find out what was going on and address that question specifically. Why is the server slow? Is it running short of memory? Has someone tapped into your computer and is running unauthorized processes on it? If you ask the right questions of the tuning and monitoring tools, then you may find out the answers.

Whether you use the graphical tools or write scripts to reach performance or event monitoring data, the trick to using performance monitoring tools effectively is *asking the right questions*. These tools are not omnipotent gods, but more like slightly dim-witted genies. Like such genies, performance monitoring tools are very literal-minded little cusses. They may be able to give you the answers if you ask—depends on what you want to know and whether that information is exposed by the tools—but only if you ask correctly. If you ask the wrong questions you'll drown in a sea of irrelevant data. (Somewhat less metaphorically, if you ask indiscriminate questions you'll slow down your servers and/or clog your network's bandwidth with unimportant queries, not to mention get a bunch of information that you can't use and which can cloud the important stuff.) Thus, in this chapter I'll talk about the genies—er, performance monitoring and event viewing tools—that come with Server 2003 and give you background to help you figure out which questions to ask the oracle. Once that's done, I'll discuss the tuning you can do based on the information you gathered.

**NOTE** This chapter will focus on how to gather and evaluate performance information using the graphical and command-line tools built into Server 2003. However, the performance monitoring tools accessible from the MMC are Windows Management Instrumentation (WMI) providers, meaning that it's also possible to gather performance information through one of Server 2003's supported scripting languages—VBScript or JScript.

## Roundup of Tuning Support Tools and What to Do with Them

Before I get into a description of how to use these tools, here's a quick tour of the monitoring tools that come with Server 2003:

- ◆ System Monitor
- ◆ Performance Logs and Alerts
- ◆ Event Viewer
- ◆ Task Manager

**NOTE** *Server 2003 also has a Network Monitor tool that's a crippled version of the one included with Microsoft System Management Server. Unfortunately, it can only monitor data traveling between the monitored computer and the rest of the network, not network traffic in general.*

### System Monitor

The System Monitor in Server 2003 is very similar to the tool by the same name in Windows 2000. When you open the System Monitor, you'll see that it has two components: a Performance Monitor–like tool called the System Monitor that displays real-time performance statistics and Performance Logs and Alerts, which is the System Monitor's logging function.

**TIP** *To open the System Monitor quickly, type **perfmon** (the executable name of the System Monitor) into Run. Server 2003 will start the Performance tool with the System Monitor screen active.*

With the System Monitor, you can do the following:

- ◆ Provide a simple, visual view of your servers' vital signs (one that looks great on a PowerPoint presentation of why you need more hardware) in charts or reports
- ◆ Output real-time system monitoring information to a browser
- ◆ Keep an eye on how processes are using processor time, memory, disk space, and other server resources
- ◆ Log network data over time and export that data to a file that you can import into a spreadsheet for further analysis
- ◆ Open saved logs to review historical data

### Performance Logs and Alerts

The other half of the Performance tools is the Performance Logs and Alerts, which takes over the logging functions of NT 4's Performance Monitor. You can do the following using the logging function:

- ◆ Monitor system stress and performance over a period of time, instead of watching the current output
- ◆ Automatically keep track of minimum, maximum, average, and current values of critical system values
- ◆ Send alerts to the Event log, notify someone, or run a program when counters exceed the tolerances you set or when important events occur

## Event Viewer

The Event Viewer (located in the Administrative Tools program group) maintains several separate event logs on the server:

- ◆ System log
- ◆ Security log
- ◆ Application log
- ◆ DNS Server log
- ◆ File Replication Service log
- ◆ Directory Service log

**NOTE** *The Event Viewer for member servers in the domain displays only the Application log, System log, and Security log.*

The System log records the starting and stopping of services and any system-related events. This is where you'll find out that time synching isn't working, that the DHCP server has successfully cleaned up its database, or that a print job was successfully completed. If you see a message box telling you that something didn't work and to check the Event Monitor for more details, the System log is the first place to look. If there are noninformational messages here, don't ignore them!

The Security log records any audited events that relate to security issues, such as users accessing files or changing the Security Accounts Database. In Windows 2000, you had to explicitly turn on security logging. In Server 2003, it's turned on by default.

The Application log records application-specific events that aren't far-reaching enough to make it into the System log. The name of this log might be misleading. It's not about user applications so much as about licensing, the BINL service used to back Remote Installation Services (see Chapter 20, "Installing and Managing Remote Access Service in Windows Server"), backups, the successful (or unsuccessful) application of security policies, performance library issues, and the like.

You'll find the System, Application, and Security logs on any Server 2003 computer. The remaining logs only apply to computers that need them because of their role in the network. The DNS Server log (found, as you'd expect, on the DNS server) records events associated with resolving computer names to or from IP addresses. The File Replication Service log lists events relating to the File Replication Service, and the Directory Service log records events related to domain controllers keeping up with the security database.

## Windows Task Manager

The Task Manager gives you a way to monitor the general state of the server without going to the trouble of creating a customized chart with the System Monitor. In Server 2003, the Task Manager has five tabs:

**Applications** Displays the applications separate from the core OS that are running on the server and shows whether they're running or not responding.

**Processes** Lists the image names of the processes running on the server, including those processes that are part of the core OS, and shows statistics about the resources allocated to those processes.

**NOTE** For those not familiar with the distinction between an application, a process, and an image name, allow me to digress for a minute. The executable name of an application (e.g., MYAPP.EXE) is known to Server 2003 as its image name. A process is a collection of resources allocated to some executable portion—a thread—of that image. An image may have one or more processes supporting it, depending on how the developer split the code up.

**Performance** Displays current processor and memory usage.

**Networking** Displays the current network utilization for the server's connection to the network.

**Users** Lists the current local and remote Desktop sessions connected to the server.

You can use the Task Manager not only to gather information about a server, but to interact with it and resolve some problems. For example, if the server seems sluggish, you can open the Task Manager and turn to the Performance tab to get a real-time view of processor usage. If the chart there indicates that the processor is running full-time, you can turn to the Processes tab to see which process is taking up all the processor time and find out from the Applications tab whether an application has stopped responding and needs to be shut down.

## Observing Performance Patterns with the System Monitor

If you can't measure it, you can't tune it.

As noted earlier, the System Monitor is the graphical display tool in Server 2003's collection of monitoring tools. To use it, you'll need to be familiar with objects, instances, and counters.

**Object** Any system component that possesses a set of measurable properties. An object can be a physical part of the system (such as the memory or the processor), a logical component (such as a disk volume), or a software element (such as a process or a thread).

**Instance** Shows how many occurrences of an object are available in the system.

**Counter** Represents one measurable characteristic of an object. For example, the Processor object has several counters, including the percentage of processor time in use and the percentage of time the processor spends in Privileged and User modes.

Written out, the object name comes first, then the counter name. For example, System Monitor opens with a sample chart of three commonly monitored object counters: Memory: Pages/sec, Physical Disk: Avg Disk Queue Length, and Processor: % Processor Time. Server 2003 contains hundreds of counters to track system data, such as the number of network packets transmitted per second, the percentage of time a processor spends in User mode versus Kernel mode, and the number of pages swapped in and out of memory per second.

You'll also need to be familiar with the various types of output that the System Monitor can produce—graphs, histograms, and reports—to know when each would be most useful.

**Graph** By default, System Monitor displays its output in a line graph. This way of presenting data makes it easy to identify spikes in the data and show trends over time. Graphs always show current values, whether working from real-time or logged data.

**Histogram** Histograms display current values for counters in a bar chart. They're very useful for visually comparing values—say, the percentage of time that the processor on three separate servers

is busy. By default, histograms show current values when working from real-time data and average values when working from logged data.

**Report** Reports display the objects and counters being monitored and their current value (in text). They're useful for getting an exact value, since you don't need to interpret a graph or histogram to find out what the current value is—you can just read the text on the screen. By default, reports show current values when working from real-time data and average values when working from logged data.

## NEW TO SERVER 2003: COMMAND-LINE PERFORMANCE LOGGING TOOLS

Windows 2000 offered only graphical tools for working with performance logs. In Server 2003 (and Windows XP), you also have command-line performance logging tools. Logman lets you create and manage performance logs from the command line, and relog allows you to take existing performance logs and change the sampling rate and file format. You can monitor performance data and create new counter logs with typeperf. And, using tracerpt, you can convert trace logs into a CSV file and/or summary report.

## Creating a Chart

Every System Monitor chart is a custom collection of counters to monitor. To add a counter to the chart, open the Add Counters dialog box by clicking the button in the toolbar that has a plus sign (+) on it or right-clicking in the chart display window and choosing Add Counters from the context menu. This will open the dialog box shown in Figure 18.1.

**FIGURE 18.1**

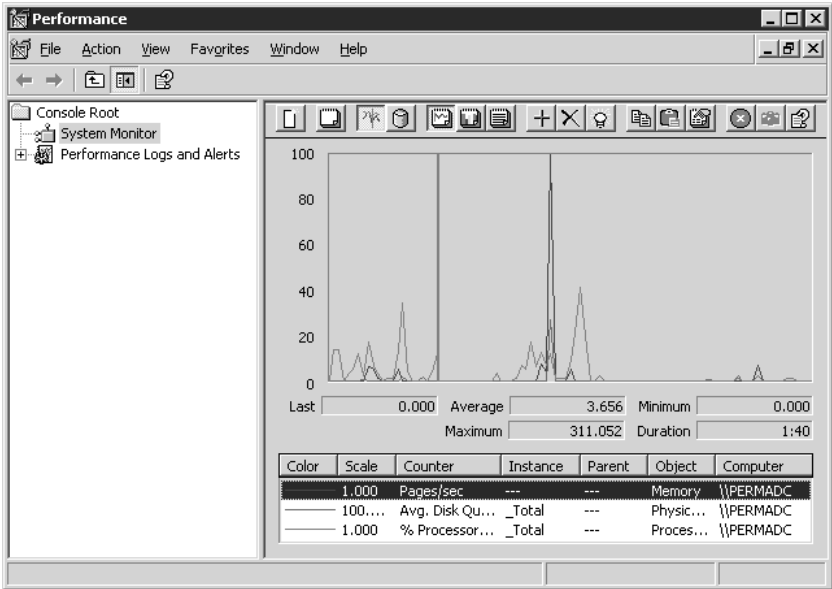

Add counters to the System Monitor.

Adding counters to a chart is easy. Choose a performance object, then pick one of its performance counters. If there's more than one instance of the object (for example, if the server has more than one processor), then you'll have the choice of monitoring counters for all objects of that class or only a specific one. Click the Add button, and that counter will be added to the chart and will show up in the System Monitor, as in Figure 18.2.

**NOTE** Installing some software on servers may add performance objects and counters to the list. For example, installing MetaFrame (helper software used to enhance the capabilities of a Server 2003 application server) adds objects and counters for monitoring remote sessions using MetaFrame.

**FIGURE 18.2**  
System Monitor  
output

Adding counters may be easy, but *choosing* the counters to add and interpreting what you’re seeing requires a bit more work. Let’s take a look at how you could pick counters to monitor.

**NOTE** The System Monitor’s Add Counters dialog box has an Explain button you can click to show more information about the currently highlighted counter. However, the information that’s displayed isn’t always all that useful—especially for the counters new to Server 2003—and not always strictly accurate. Use the information in the Explain text box as a starting point for further research if you need details about what a counter’s monitoring, not as the final word.

Incidentally, I’ve described here how to add counters to monitor on the current computer. As I’ll explain a little later in this chapter, you can also—and you frequently should—monitor other computers with the System Monitor. The procedure for adding the counters is identical to adding counters to monitor locally, however.

### CHOOSING OBJECTS AND COUNTERS TO MONITOR

When you first open the Add Counters dialog box, it’s easy to get information overload. I haven’t yet been bored enough to count all the counters for all the objects, but there must be thousands. Even if you just look at the objects, how do you tell which of the dozens available is the one you want? It’s not easy, and to make the performance monitoring useful at all, you’ll need to be selective. Monitoring all the counters would give you more information than you could possibly handle. You need to know what to look for.

Let me set the following scenario: You have a network up and running. But with time, the network seems to be slowing down. People are complaining. The Powers That Be start applying pressure on you to find out what's wrong and to find it out *now*. What can you do? Well, the obvious thing to do is to throw hardware at the problem, right? Go buy more memory, an extra processor if the servers support multiple processors and have slots available; get a faster network card; get a faster disk.

Jacking up, say, the processor speed *may* get you a faster server. But if the problem is lack of memory, getting a faster processor won't really help. You tune a troubled server by locating and removing its bottlenecks as much as you can. Eventually, you will bump into the limits of performance improvements, so the trick is to find the most effective performance improvements and apply them. What I want to do next is to (1) introduce you to the art of tuning, (2) point out the most likely causes of problems for file servers and application servers in particular, and (3) recommend a few objects and counters that you can monitor to keep an eye on your server performance with minimum trouble.

A server's job on the network will influence the counters that are important to it: IIS Servers serving Active Server Pages (ASP) or SMTP servers providing e-mail will call on entire object classes that you can ignore on servers not performing those roles. If a server has no printer directly attached, then you needn't monitor the print queue object counters. However, there are four big sources of performance bottlenecks common to any server:

- ◆ Memory
- ◆ Disk subsystem
- ◆ Network card and software
- ◆ Processor

### **Resolving Memory Bottlenecks**

The biggest performance drain on a Server 2003 system is memory. Windows applications are memory-hungry, and the operating system itself is memory-hungry—although, thankfully, the jump in resource demands between Windows 2000 and Server 2003 is nowhere near as dramatic as the jump between NT and Windows 2000—in fact, Server 2003 has changed the way it uses memory to make it more efficient. Still, if you install Server 2003 with the bare minimum of memory and then actually try to use it as a server, you're not going to be happy with the result.

When you're monitoring memory, you're actually monitoring both physical memory and hard disk access. The reason has to do with how Windows operating systems eke the most use possible out of physical memory—some of the apparent contents of that physical memory are actually on disk, in what's called *virtual memory*.

Virtual memory is a result of what Dorothy Parker would have said if she had been a network administrator: you can never be too rich, too thin, or have too much RAM installed. No matter how much you have, it seems, physical memory can't keep up with the data storage needs of Server 2003 and any applications it's running. Therefore, Windows operating systems use virtual memory, a kind of memory simulation that allows the server to support more applications and data in memory than it actually has physical memory to support. Regardless of the amount of *physical* memory installed, Win32 operating systems support up to 4GB of virtual memory space—2GB to be shared among all system-level processes and 2GB for the exclusive use of each user process running on the server. The memory manager is responsible for organizing each process's access to virtual memory so that processes don't write on each other's data in *physical* memory.

**NOTE** One of the reasons Server 2003 needs so much memory is because it uses a big chunk (25 percent or so) of this memory for caching recently used file data. Servers that aren't file servers don't need to do this. In the "Basic Tuning Stuff" section later in this chapter I'll explain how to make a server stop thinking of itself as a file server and start giving you back some memory.

Virtual memory works like this: When an application is loaded into memory, it stores its data in physical memory to store data it needs to run and present user files. As more and more applications (and the operating system) use RAM to store data, things start getting crowded. To allow applications to keep their important data in physical memory where they can get to it more or less instantly, the memory manager shuffles less important data to a file on disk called the *paging file*. The applications don't care whether data is stored in RAM or the paging file, the applications just keep referring to the data according to the virtual address where it was originally stored. Among the memory manager's many jobs is the task of keeping track of how the virtual memory storage area corresponds to the physical memory storage area, since it is almost inevitable that the physical storage area for memory will change.

What kind of data is stored in memory? Several kinds, actually:

- ◆ Each application (and the operating system) has a *working set* that is the sum of all the data that application is currently working with. The memory manager can trim working sets if there's a shortage of physical memory. But the smaller an application's working set, the slower the application will run, because it's going to have to keep requesting data back from the paging file, and paging data back into memory takes time.

**NOTE** If you're using Terminal Services (see Chapter 16), then there will also be a per-session working set.

- ◆ *Page table entries (PTEs)* are structures the memory manager needs to map each user process's virtual address space to an area of physical memory. The memory manager needs this map to see how each process is using its view of the 2GB of user virtual memory addresses and to keep processes from overwriting each other's memory.
- ◆ Some operating system data must remain in memory all the time and cannot be paged to disk. The range of virtual memory addresses called the *nonpaged pool* stores this data. The *paged pool* stores operating system data that can be paged to disk.
- ◆ The *system cache* is the data used by the entire operating system kept in RAM for quick access. The System Monitor Help describes the system cache as though it were synonymous with the disk cache, but it's not—the disk cache of recently used on-disk data and disk data structure is one part of the entire system cache.

The Server 2003 memory manager allocates memory to the system and user processes by first *reserving* it for the process that needs it (defining a range of virtual memory addresses for later use) and then *committing* it (ensuring that a place in the paging file is available to store the data the process wants to put in those virtual memory addresses). Processes can reserve all the memory they want, but when it comes time to commit that memory, some on-disk storage *must* be available to back it. Server 2003 has to assume that all user data will move to the paging file at some time. When a process is done with

memory, it's supposed to give it back to the system to be marked as available for other processes—*free* it. Some processes do the opposite, taking more and more memory even though they're not using it or just not giving back memory that they're not using anymore until you reboot the machine. This is a result of buggy programming and is called a *memory leak*. Memory leaks are frustrating because they starve other processes without giving you any gain at all. Give them enough time, and memory leaks will shut down your server from lack of resources. The only way to reclaim this memory is by rebooting the computer. Processes can't use data that's stored on disk, so when an application calls on data that the memory manager has paged to disk, the memory manager tracks down the data's current location and executes a *hard page fault* to send that data to RAM where the memory controller can retrieve it for the application. Something similar happens if the memory manager moved data from one location in RAM to another, except that retrieving this data—called a *soft page fault*—takes less time than retrieving data from the hard disk. The end result of a soft or hard page fault is the same, however: even if data has been moved to a location other than the one the application expects, the application gets its data with no more than a little finger drumming at the slight delay. To the process, it looks as though the data was in memory all the time, but it really wasn't.

There is one catch to the paging file: disks are slower than RAM. You measure access times (the time required to read or write data) on RAM in nanoseconds (billionths of a second) and on disk in milliseconds (thousandths of a second). So, although you can't escape paging—Server 2003 is designed to use it, and it will, no matter how much RAM you install—you will improve server performance if you seek to minimize the amount of time your server spends on hard page faults.

That's not everything there is to know about virtual memory, but it's enough to make people avoid you. The important memory counters are described in Table 18.1. You can use this information to help you read other memory counters, too.

**TABLE 18.1: IMPORTANT MEMORY COUNTERS**

COUNTER	DESCRIPTION	WHAT THIS TELLS YOU
Memory: Available Bytes	Records the memory currently available on the server.	A low value may indicate that your server is low on memory or that one of the programs is experiencing memory leaks (especially if the number keeps decreasing). You should always have 4MB or more available. If you don't, then check for memory leaks or add more memory.
Memory: Commit Limit	Records the amount of memory that can be committed without extending the paging file. You can increase the paging file up to the limit of available space on the volume.	Extending the paging file is an expensive procedure (and requires processor time), so it's a good idea to do this as little as possible. Make the paging file as large as you think you'll need—at least 2.5x the size of RAM you have installed.

*Continued on next page*

TABLE 18.1: IMPORTANT MEMORY COUNTERS (continued)

COUNTER	DESCRIPTION	WHAT THIS TELLS YOU
Memory: Committed Bytes	Records the amount of memory committed to processes running on the server.	Records the amount of used RAM that requires space in the paging file in case the data must be paged to disk. Therefore, this is memory in use and unavailable to other processes, not just reserved in case a process needs it.
Memory: Pages Input/sec	Records the rate at which pages of data are written to RAM from the paging file to resolve page faults.	As this value describes hard page faults (the Page Faults counter includes soft page faults, which pull data from another area of memory and don't incur much of a hit), it's a good measure of how often you're having to pull data back from disk.
Memory: Pages Output/sec	Records the rate at which pages of data are written to the paging file to free RAM.	If the server seems to be running more slowly than it used to, monitor this counter. A high rate may indicate that the server doesn't have enough RAM to support all the data that the running applications need to keep handy.
Memory: Pages/sec	Records the current rate at which pages (4KB chunks of data on an x86 system, 8KB on an Alpha system) are read from disk back into physical memory to satisfy a hard page fault or are written to disk to free RAM.	A value of more than 20 pages per second implies a lot of paging and suggests that your server needs more memory.
Paging File: % Usage	Records the percentage of the paging file currently in use.	If this value approaches 100 percent, then you need to reduce the pressure on the paging file, either by enlarging the file or adding more RAM. Although the memory manager will make the paging file larger if necessary, doing so takes up processor cycles, and the memory manager will only increase the paging file's size as needed immediately. It's better to increase the size of the paging file manually.
Paging File: Usage Peak	Records the peak size of the paging file.	If this value is close to the maximum size of the paging file, you need to either enlarge the paging file or add more RAM. A high value implies that the paging file isn't big enough to hold all the data it must.

Continued on next page

**TABLE 18.1:** IMPORTANT MEMORY COUNTERS (*continued*)

COUNTER	DESCRIPTION	WHAT THIS TELLS YOU
Physical Disk: % Disk Time	Records the percentage of time the disk spends servicing read or write requests.	Monitor this value for the physical disk that the paging file(s) are located on. If this amount seems to be increasing, check paging file usage and consider adding more memory.
Physical Disk: Avg Disk Queue Length	Records the average number of read and write requests waiting for the disk during the selected interval.	If this number is increasing at the same time the number of Memory: Page Reads/sec is increasing, that indicates that a lot of paging is going on. Monitor this value for the physical disk that the paging file(s) are located on.
Physical Disk: Avg Disk sec/Transfer	Records the length of time it takes the disk to transfer data to or from disk.	Monitor this value for the physical disk that the paging file(s) are located on to find out how responsive those disks are. This information may encourage you to move the paging file to a faster disk.
Process: Private Bytes	Records the virtual memory committed to that process.	This counter shows you how much memory a process (for all practical purposes, an application) is using. Especially if you're monitoring a terminal server, consider moving demanding applications to the client side or to a server dedicated to those applications, to prevent other processes from being starved for memory.
Process: Working Set	Records the amount of RAM that the process is using to store data. The larger the working set, the more memory the process is consuming.	If a process's working set increases over a period when you're not doing anything with it (for example, over a weekend), the process may be experiencing a memory leak.

**NOTE** Notice that not all the counters you'll be monitoring for memory usage are in the Memory object.

Memory is complicated. Examining other potential server bottlenecks is, thankfully, a bit simpler.

### **Resolving Processor Bottlenecks**

If you look at the counters available for the Processor object, you'll see a lot of counters for DPC and APC objects, some percentages of User and Privileged execution time, and so forth. Most of these won't help you much with server tuning. The DPC counters refer to *deferred procedure calls (DPCs)*, functions that perform a system task that is less essential than the currently executing system task, but

which can grab a little processor time while the more important task is waiting for information that isn't yet ready. The APC counters refer to *asynchronous procedure calls (APCs)*, which provide a way for user programs and system code to execute code using the memory allocated to a specific application, and at a low level of priority. Basically, APCs interrupt an application that's using the processor to make it do something else without going through the usually necessary rigamarole of shutting down the application's access to the processor. In a broad sense, the counters for User and Privileged time refer to the percentage of time that the processor is spending executing instructions for user applications and system functions, respectively. Again, this isn't information you can use for a lot of system tuning unless you're interested in the time that Server 2003 spends executing system code in contrast to user code.

The information you *can* use for system tuning lies in the % Processor time and the Interrupts counters. Processor: % Processor Time tells you the percentage of time that the selected processor is doing something other than executing its "marking time" thread, the system Idle thread. Ideally, the processor is supposed to spend most of its time executing the Idle thread, because if that's the case, then the processor is available when it's needed. If Processor: % Processor Time rises above 75 percent on average, then that processor is working pretty hard and the server might benefit from a faster processor or an additional processor—and from you tracking down whatever it is that's using up all those processor cycles.

Interrupts/sec and % Interrupt time tell you how much time the processor is spending interrupting itself to handle requests from its hardware (network cards, video cards, keyboards, and so forth). If the value of Interrupts/sec exceeds 3500, then more than likely something's going wrong, either a buggy program or a board spewing out spurious interrupts. One common cause of excessive interrupts is badly designed device drivers. Are you running any beta device drivers? I've seen beta video drivers that spew out thousands of interrupts per second. You can test this by running the standard VGA driver and comparing the interrupts before and after. Another source of excessive interrupts is timer-driver programs. Some years ago, one network manager I know was seeing 4000 interrupts/second on a fairly quiet 486-based file server. After some playing around with the system, he realized that he was opening Schedule+ in his Startup group. He shut it down, and his interrupts/second dropped to a normal rate.

**NOTE** *I'd like to tell you that there's a System Monitor counter that lets you track interrupts/second on a program-by-program basis, but there isn't—much of this is just trial and error. Now and then I see a board that sends out a blizzard of interrupts if it's failing or, sometimes, when it's just cold. You might see this when you turn a workstation on Monday morning and it acts strangely for half an hour, then settles down.*

### **Resolving Disk Bottlenecks**

The hard disks on your servers represent another potential sticking point for server production. For file servers, the bottleneck is obvious: the whole point of a file server is to grab data and pass it to the network for distribution. For application servers, the disk problem is more related to paging because of the memory burden that applications incur. If you're running SQL Server or Exchange or supporting terminal server sessions, it's easy to run up against the amount of memory installed in the server—and when that happens, the server goes after your disk drive to support virtual memory.

There are a lot of counters for physical disks, but most of them don't tell you much in diagnostic terms except to help you see whether the disks are living up to their specifications. A couple that *do* are in Table 18.2.

**TABLE 18.2: IMPORTANT PHYSICAL DISK COUNTERS**

COUNTER	DESCRIPTION	WHAT THIS COUNTER TELLS YOU
Physical Disk: % Disk Time	Reports the percentage of time the physical disk is busy.	If it's busy more than 90 percent of the time, then it's too busy—you'll improve performance if you get another disk or do less with that one.
Physical Disk: Current Disk Queue Length	Reports the current number of data transfer operations waiting for the specified physical disk (or all disks, if you choose) to handle them.	This value should be as small as possible. A high value indicates that disk waits are impacting users.

The counters in Table 18.2 can also apply to logical disks (C: drive, E: drive, and so on, as opposed to Disk 0 or Disk 1, which identify physical disks). However, you may not *need* the logical disk counters for the performance monitoring described in Table 18.2. You've already got counters telling you how many jobs are waiting in the physical disk queue at any given time and how often the disk is busy; monitoring logical disks instead of physical disks won't really tell you anything you didn't already know, since what you're looking at is disk stress. Logical disk counters are more useful when it comes to performance metrics such as Free Megabytes, which shows the amount of free space remaining on the selected disk. Another logical disk counter you might find useful for logical disks is Split IO/Sec, which keeps track of the number of split input/output actions on the disk. This counter is useful because a high number of split writes or reads (meaning that the disk controller is having to read from or write to more than one place on the disk during a single I/O action) can indicate a fragmented disk.

### **Resolving Network Bottlenecks**

Your network's apparent speed (not what it's rated at, but how responsive it is) is a function of how much traffic there is on the network and how quickly the server can process user requests.

First, how busy is the network? You'll need to monitor the transport protocols you're running on the server. Recall that TCP/IP has several different parts—it's a suite of protocols, not a single one like NetBEUI—and the parts do different things. So, for example, a lot of IP datagrams tells you that your network card is getting a lot of regular (that is, data-related) traffic. A suddenly large number of ICMP datagrams could signify problems—or suggest that someone is pinging the heck out of your server. Look for differences in traffic levels, both on the protocol level and for the entire network card (you can monitor both). Are you getting transmission errors for inbound or outbound network traffic? How busy is the local network segment?

Second, how busy is the server? Is it seeing logon errors? How quickly are people logging in at different times of day? How many files are open on the server? If it's a terminal server session, how many users is it supporting? If it's an FTP server, then how many connections are you having to maintain? Is the server experiencing nonpaged pool failures, failing to allocate memory to components that need nonpaged memory because there's too little RAM installed on the system?

**NOTE** *You can only get accurate network segment data if you have the Network Monitor for SMS installed. The Network Monitor that comes with Server 2003 only monitors data going to and from the monitored server. Therefore, you can get pretty much the same information from Network Interface that you can from Network Segment.*

Lots of questions. I'd suggest that you poke around the performance objects a bit to look for specific counters you want to monitor for your server, but Table 18.3 includes some of the more common counters you should watch.

TABLE 18.3: IMPORTANT NETWORK-RELATED COUNTERS		
COUNTER	DESCRIPTION	WHAT THIS COUNTER TELLS YOU
Server: Bytes Total/sec	Reports the rate at which the server is sending and receiving network data.	The total of bytes going in and out of the server per second gives you a pretty good indication of how busy the server is. If you do something to change the server load, like adding another server of that kind or added load balancing to the network, you can monitor this value to see whether the change actually did any good.
Server: Files Open	Reports the current number of files open at the moment of reporting. This is a current total, not a total of all the files that have been opened during a given time.	This counter indicates the traffic load a file server is experiencing. Sadly, there's no way to monitor file openings on a per-user or per-file basis.
Server: Pool Non-paged Failures	Reports the number of errors the server is reporting as it tries to allocate nonpaged pool.	Nonpaged pool is an area of virtual memory whose contents cannot be paged to disk because they must be ready immediately when called on—no time for page faults. Lots of errors suggests that the server is running low on RAM and you'll need to add more.
Server: Server Sessions	Reports the number of current connections to the server.	This counter may not tell you how <i>busy</i> the server is, but it can tell you how popular it is—especially if it's popular at an hour when no one should be accessing the server at all.
Network Interface: Bytes Total/sec	Reports the rate at which the network card is sending and receiving network data.	If this rate is significantly lower than what you'd expect, given the speed of your network and network card, it's time to do a little investigating to see whether something's wrong with the card.

**TIP** *If your server is an Internet server of some kind (e-mail, FTP, Web, etc.), be sure to monitor the counters appropriate to its function.*

Be sure to also monitor installed protocols for error conditions or heavy traffic at odd times.

## Remote Performance Monitoring

There's one big problem with running the Performance Monitor on a server: the Performance Monitor *itself* consumes resources, and thus skews the resource-usage reports on a server. Consider monitoring servers remotely. If you do, then you'll use a little network bandwidth but fewer resources on the monitored machine—and you'll get a more accurate reading, because you're not stressing the server by running the monitor on it.

**TIP** *The only time it's to your benefit to run Performance Monitor locally is when you're monitoring counters related to network traffic. Monitoring remotely will increase network traffic and skew the results.*

Setting up remote performance monitoring is quite simple. When you're adding a counter to the monitor, you have a choice between adding the counter for the local machine or another one. You can monitor any generation of NT computer, so if you've got a mixed environment it doesn't matter. When you connect to a remote computer, the counters available to that computer will be visible, so it doesn't matter which counters are available on the computer from which you're running Performance Monitor. You can even use Win2K Professional or Windows XP workstations to do the monitoring, so you don't have to tie up a server for this task.

Make sure you've selected Select Counters from Computer, and type in the name of the computer you want to monitor with two preceding backslashes, like this: `\\Serpent`. (There's no Browse feature, so you have to know the name of the server you want to monitor. Annoyingly, Performance Monitor doesn't consistently "remember" the names of remote servers that it has monitored previously. Sometimes it does, and sometimes it develops amnesia. However, it is generally able to find servers across trusted domains, even if you can't specify a server's domain.)

**WARNING** *Type server names carefully. If you mistype, it takes the System Monitor a while to discover that the server you've specified does not exist on the network.*

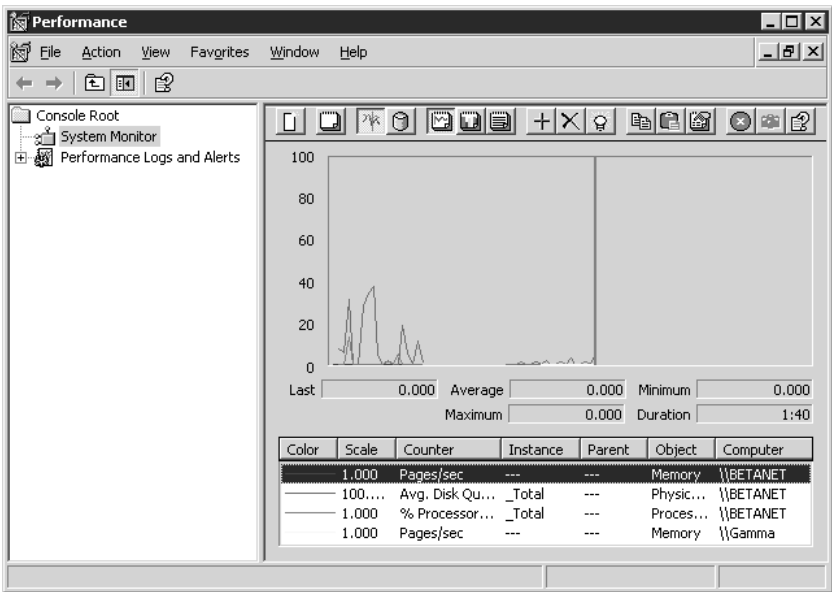

When you're done choosing the counter you want to monitor, add it as you normally would and close the dialog box. The remote computer's counter will be added to the list and identified by the computer name (see Figure 18.3).

One of the cool things about doing remote performance monitoring is that it lets you compare server stress easily. If you select the same performance counter on two servers, you can compare the stress on those two servers.

**WARNING** *As explained in Chapter 16, Server 2003 supports remote server administration using Terminal Services. Do not try to run the Performance Monitor from a Remote Administration session. You're still running the monitor on the server and consuming server resources—you're just watching from a different computer.*

**FIGURE 18.3**

Performance counters to remote computers will be displayed alongside local ones.

**Saving Chart Data**

When you’ve identified the counters you want to monitor, you can save that information and reuse it later, either to monitor again (on the principle that what you need to monitor once, you almost certainly will need to monitor again) or to make them into an HTML file that you can display in a browser. To save chart settings, right-click somewhere in the Performance Monitor’s display of current counters. From the context menu that appears, choose **Save As** to save the data, and you’ll be prompted for the name of the HTML file. (This data will always be saved as a hypertext document.) The default folder is the **My Documents** folder for the person currently logged in, but you can browse for another folder as you would with any **Save As** operation. Type a name for the file, and it’s saved.

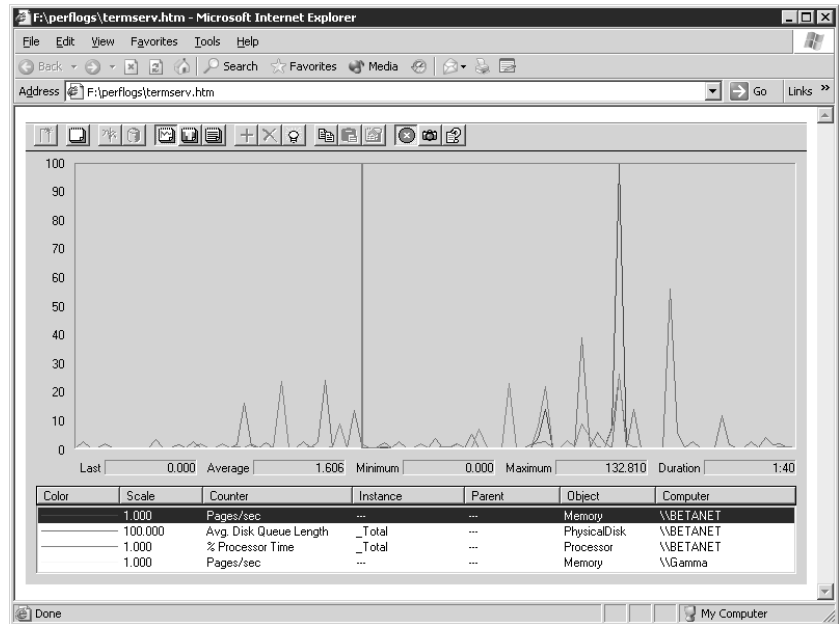

If you open the file, it will open in your browser as shown in Figure 18.4.

The cool part about this is that the file you’re opening here will continue to display the monitored data. So long as the System Monitor is still running, you can dynamically update the output in this HTML chart. Why do it this way rather than just running the System Monitor? Mostly so you can streamline the UI. As you can see in Figure 18.4, the HTML view shows only the monitor, not the entire System Monitor tool.

To update the view steadily, click the **Freeze Display** button (the red button with the white X on it) in the browser to disable it. You’ll see a warning that all current data will be cleared from the display; click **OK**. The display will clear and the browser will fill with the updated Performance Monitor data. To manually update the data (perhaps if you’re making a presentation and don’t want people to be distracted watching the updates to the output), then keep the **Freeze Display** button activated and click the **Update Data** button (the camera between the **Freeze Display** and **Help** buttons). After the first freeze/unfreeze action, the chart data will remain displayed in the browser.

**FIGURE 18.4**

A saved Performance Monitor chart opened in Internet Explorer

What about reusing this data in a later Performance Monitor session? I'll talk more about how to use this data in the next section, "Logging Performance Data."

## Logging Performance Data

Knowing how the server is performing now is useful, but knowing how the server was performing last week or two months ago can also be useful, since previous records can give you a reality check for current performance. The Server 2003 Performance Logs and Alerts section of the System Monitor works much like the tool of the same name in Windows 2000. Using a combination of comma-delimited and tab-delimited files and HTML documents, you can pass information between the Performance Monitor and the Logs and Alerts—or even pass it to another application that can accept comma-delimited or tab-delimited files, such as Excel.

The System Monitor supports three types of logs: counter logs, trace logs, and alert logs. *Counter logs* record data from local or remote computers about hardware usage and system service activity. *Trace logs* are event driven, recording monitored data such as disk I/O or page faults. When a traced event occurs, it's recorded in the log. *Alert logs* take counter and trace logs one step further. They monitor counters that you specify and wait for them to exceed user-defined tolerances. When this happens, the event is logged. You can also set up an alert log to *do* something when the event happens, like send a message alerting someone to the situation, or run an application. You'll often use logs in combination—for example, using a counter log to develop a "normal" baseline for a server and then creating an alert log to notify you when the server's activity falls outside that normal range.

**NOTE** You can either set up perpetual logging or log only for a preset period of time so you aren't overwhelmed with data.

## Creating Logs

To create a log, turn to the Performance Logs and Alerts section of the System Monitor. Open the folder for the type of log you want, so that its contents (or lack thereof) are displayed in the right details window. Right-click empty space in the Details window and choose an option for creating a new log from the shortcut menu that appears. What happens from here depends on the type of log you're creating: a counter log, a trace log, or an alert log.

**NOTE** *As an administrator, you'll use counter logs and alert logs most often.*

*Counter logs* record system counters, like static versions of the performance logs we've discussed so far in this chapter. You can save the log data in a binary file that will open in System Monitor (looking like real-time data) or in a text (comma-delimited or tab-delimited) file that you can open in a spreadsheet application.

*Trace logs* keep track of data according to the part of the operating system that collects it. Unlike counter logs, which just record at regular intervals, trace logs are event-driven. They also provide a more general and less granular view of system activity than counter logs do—for example, rather than monitoring Physical Disk object counters, a trace log will monitor disk input and output. Trace logs can also draw information from nonsystem providers such as the Local Security Authority or the Active Directory Service to get information. To log some information (such as kernel monitoring information), you must either be logged in as the server's local administrator or use RunAs—accessible while setting up the trace log—to do the logging in the appropriate security context. To read a trace log without writing an interpreter or getting the TRACELOG tool from the Windows 2000 Resource Kit, you'll need to process it with the tracerpt tool found in Server 2003 and Windows XP.

*Alert logs* are like counter logs but taken one step further. Counter logs just collect data. Alert logs monitor performance object data for selected counters, using the same UI used for monitoring performance objects, but they assess those counters against tolerances that you set when creating the log. In other words, with an alert log you don't collect *all* the data for the selected counters; alerts are only logged when the performance data falls outside the acceptable range. Alert logs are kept in the Application log of a server's Event Viewer.

### COUNTER LOGS

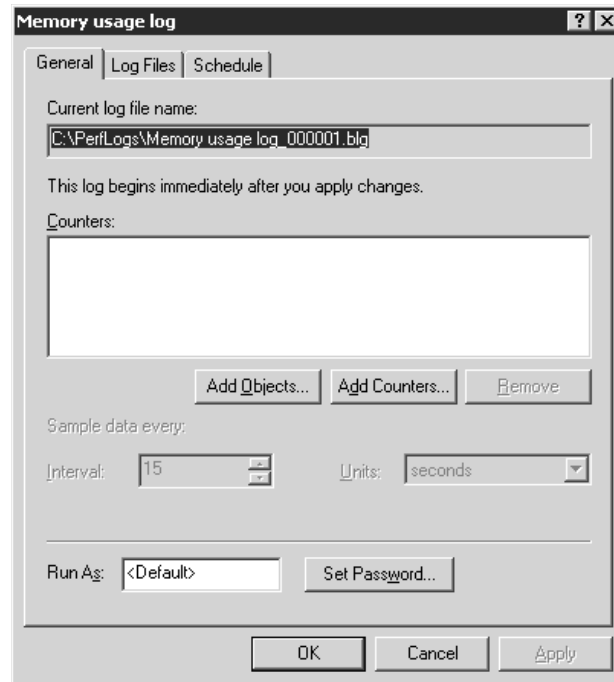

If you're starting from scratch, choose the New Log Settings option. Provide a unique descriptive name for the log in the box provided. Click OK, and you'll see the General tab of the log property sheet as shown in Figure 18.5.

**TIP** *It's acceptable to put blanks in the names of performance logs, but if you plan to manage those logs from the command line you'll simplify your life if you don't. Including blanks in the log name means that you'll need to put the filename in quotes.*

You aren't yet monitoring anything. You have two options for adding counters to the log. To add individual counters, click the Add Counters button to open the same window you used to add counters to the System Monitor. To monitor *all* the counters for an object in the log, click the Add Objects button to see a list of all available objects for the selected server (see Figure 18.6). If you choose one of these objects, then you'll record activity for all counters associated with that object.

**FIGURE 18.5**

When you create a new log, it will contain no counters to monitor.

**FIGURE 18.6**

Adding objects and all their counters to a counter log

To begin, click the Add button, and you'll open the same Select Counters dialog box you used to add counters to a Performance Monitor chart. Make sure you've selected the computer that you want to log. As with charting, logging takes up resources on a server, so consider running logs remotely. Whichever option you go with—most often, you'll probably want to add individual counters—the counters you selected will now be added to the Counters list on the General tab.

Back in the General tab, you can edit the sampling interval from its default of 15 seconds. The Sample Data Every box will accept an integer between 1 and 10,000, and the drop-down list of time units supports seconds, minutes, hours, or days. Pick an interval based on the duration of your expected logging time—the longer the period you're logging for, the wider you'll probably want the interval to be so you can see trends. The shorter the sampling interval, the more processing time the sampling will take and the more datapoints you'll have.

**NOTE** You can reuse Performance Monitor counters that you've previously saved as an HTML file. If you plan to do so, start the creation process by choosing *New Log Settings From* from the context menu. You'll be prompted to provide the name of the saved file. After that, the process will work exactly as it does for creating a new counter log file from scratch. The General tab will display the counters used in the saved Performance Monitor file.

Turn to the Log Files tab (see Figure 18.7) to edit file settings for the log.

**FIGURE 18.7**

Edit file settings to control file type, size, and name.

Most of these options are fairly self-explanatory, but let's take a quick tour:

- ◆ By default, logs are stored in a **PerfLogs** folder on the server's boot partition. Unless you regularly back up this location, you might want to put the logs somewhere else for safekeeping.

- ◆ The name of the log is the filename. It must conform to the naming convention of the file-system where you're storing the log.
- ◆ The auto filename suffix is an extension to the log filename that allows you to identify logs by their name, if you maintain more than one log with the same filename. The *nnnnnn* naming means that the files will be numbered in order (the first serial number determines the first number that will be used). Other options identify the file by the date it was created, whether by year; month, day, and hour; or some other mechanism. Open the drop-down list to find the naming convention that works best for you.
- ◆ The log file comment will appear next to the list of log names in the folder, so add a comment if the log file requires further description.
- ◆ Unless you specify otherwise, the file is a binary file that will open in System Monitor, but you can also save the data as a binary circular file, comma-delimited file (CSV), or tab-delimited file (TSV). CSVs and TSVs can both be opened in text editors or spreadsheet applications such as Microsoft Excel for analysis. The only limitation to CSV and TSV logs is that they must log all at once—they can't accommodate logs that start and stop. Binary and binary circular files (both of which have *.BLG* extensions) are for recording data intermittently, when data collection may stop and then resume while the log is recording data. The binary files create sequential lists of all events, while the binary circular files record data continuously to the same log file so that previously written records are overwritten when new data is available.
- ◆ Choose whether to limit the log file size. If you're planning to log for only a certain period of time (specified on the Schedule tab), then you may not want to limit the log's size, so you don't lose any of the data you choose to save. However, if you don't plan to choose an automatic ending time, it might not be a bad idea to limit the log size so you don't get more data than you can usefully examine.

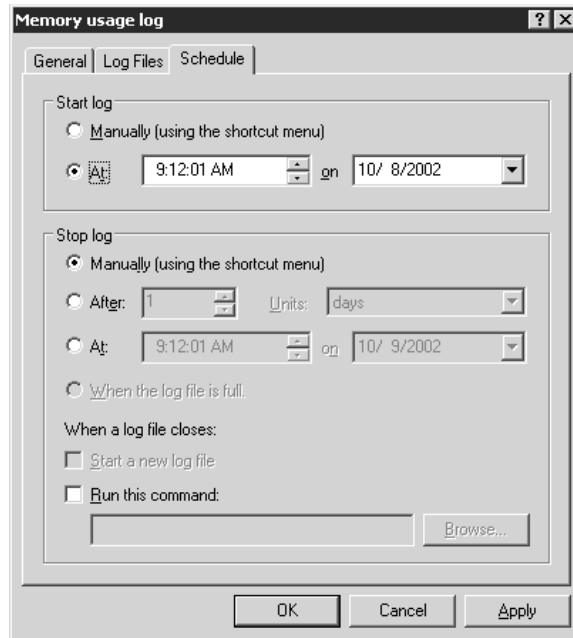

When you've edited all the file settings, turn to the Schedule tab (see Figure 18.8) to finish creating the counter log file.

Normally, the log is set to start as soon as you finish—that is, it's set to start automatically at the time you started creating the log, which means it will begin logging as soon as you finish setting up options. If you're trying to gather information about server information under circumstances that you know will apply at a specific time, you can choose to either manually start the log or specify a specific date and time the log should start.

Unless you specify otherwise, the log will keep collecting data until you shut it off manually. To schedule a stopping time or logging duration, select the After radio button and specify the time or period for which you want to log. In this same dialog box, you can also tell the System Monitor to restart the log when the preset period is ended (as you might do if you wanted to compare data from several different times of day) and provide a command or batch file to run when the log is completed. Click OK, and the new log will appear in the Details side of the **Counter Logs** folder. Its icon will be red until the log starts collecting data, either at the time you specified on the Schedule tab or when you right-click the log object and choose Start from the context menu.

**FIGURE 18.8**

Editing scheduling settings for the log file

You can also monitor performance data from the command line, using `typeperf`. In its most basic form, it's another form of System Monitor, spitting out performance data into the command window from which you initiated the logging. For example, typing this on computer BETANET

```
typeperf "\Processor(_Total)\% Processor Time"
```

gives you output like this:

```
"(PDH-CSV 4.0)", "\\BETANET\Processor(0)\% Processor Time"
"10/01/2002 17:24:28.272", "1.000000"
"10/01/2002 17:24:29.274", "9.000000"
"10/01/2002 17:24:30.275", "2.000000"
"10/01/2002 17:24:31.277", "0.000000"
"10/01/2002 17:24:32.278", "0.000000"
"10/01/2002 17:24:33.279", "4.000000"
"10/01/2002 17:24:34.281", "1.000000"
"10/01/2002 17:24:35.282", "0.000000"
"10/01/2002 17:24:36.284", "2.000000"
"10/01/2002 17:24:37.285", "8.000000"
"10/01/2002 17:24:38.287", "0.000000"
"10/01/2002 17:24:39.288", "1.000000"
"10/01/2002 17:24:40.289", "1.000000"
"10/01/2002 17:24:41.291", "0.000000"
"10/01/2002 17:24:42.292", "1.000000"
```

**WARNING** You must watch the command syntax very carefully. Yes, you really need that underscore before “Total”, but if you’re specifying a particular processor (0, to monitor the first one) then you should not have the underscore. If you leave out a space—or add an extra one—when naming the counters, you’ll see a warning that the counter isn’t accessible and there are no valid counters for the monitoring you proposed.

You can monitor more than one counter by enclosing both counters in quotation marks:

```
typeperf "\Processor(0)\% Processor Time" "\Processor(0)\Interrupts/sec"
```

The counters will be displayed in the order you gave them to typeperf, like this:

```
"(PDH-CSV 4.0)", "\\BETANET\Processor(0)\% Processor
Time", "\\BETANET\Processor(0)\Interrupts/sec"
"10/01/2002 17:41:17.594", "9.000000", "109.830447"
"10/01/2002 17:41:18.595", "0.000000", "105.844672"
"10/01/2002 17:41:19.596", "0.000000", "108.843920"
"10/01/2002 17:41:20.598", "0.000000", "110.840128"
"10/01/2002 17:41:21.599", "0.000000", "109.838443"
"10/01/2002 17:41:22.601", "2.000000", "167.760419"
"10/01/2002 17:41:23.602", "0.000000", "122.818836"
"10/01/2002 17:41:24.604", "0.000000", "125.822315"
"10/01/2002 17:41:25.605", "0.000000", "107.850406"
"10/01/2002 17:41:26.606", "0.000000", "108.841461"
"10/01/2002 17:41:27.608", "0.000000", "130.810447"
"10/01/2002 17:41:28.609", "2.000000", "117.829948"
"10/01/2002 17:41:29.611", "6.000000", "107.844991"
"10/01/2002 17:41:30.612", "0.000000", "106.846337"
"10/01/2002 17:41:31.614", "0.000000", "105.847418"
"10/01/2002 17:41:32.615", "0.000000", "109.840925"
"10/01/2002 17:41:33.617", "0.000000", "108.844831"
"10/01/2002 17:41:34.618", "0.000000", "114.838308"
"10/01/2002 17:41:35.619", "0.000000", "116.827087"
"10/01/2002 17:41:36.621", "0.000000", "108.842918"
"10/01/2002 17:41:37.622", "0.000000", "111.839624"
```

You can also monitor a remote computer by including its name in the counter argument. For example

```
typeperf "\\Gamma\Processor(0)\% Processor Time"
```

will monitor Processor: % Processor Time on the server named Gamma—even though Gamma is running Windows 2000 and therefore does not locally support typeperf. To stop monitoring the selected counters, type Ctrl+C. Stopping the monitoring may take a minute, especially if you mistyped the instance identifier and are therefore getting weird output suggesting that the processor is busy –1 percent of the time.

As you are probably beginning to suspect, the real value of typeperf is not in its ability to send performance logging output to a command window. It’s much more useful as a shortcut to making counter logs without using the GUI. Table 18.4 lists the switches for this command.

TABLE 18.4: SWITCHES FOR THE TYPEPERF COMMAND-LINE LOGGING TOOL

SWITCH	MEANING
-f <CSV TSV BIN SQL>	Output file format, with the default of CSV (comma-delimited file).
-cf <filename>	The file containing the performance counters to monitor. Each counter must be on its own line.
-si <[[hh:]mm:]ss>	Time between samples, with a default value of one second.
-o <filename>	Path of the output file or SQL database. If you don't specify an output file, the output is displayed in the command window from which you launched typeperf.
-q [object]	List installed counters (no instances). To list counters for one object, include the object name, such as Processor.
-qx [object]	List installed counters with instances. To list counters for one object, include the object name, such as Processor.
-sc <samples>	Number of samples to collect. Unless you specify otherwise, typeperf will keep sampling until you press Ctrl+C.
-config <filename>	Settings file containing command options.
-s <computer_name>	Server to monitor if you don't specify a server in the counter path. You do not need to specify a server if you are monitoring the local computer. To log counters on more than one server, you're best off including the server path with the performance object to monitor.
-y	Answer yes to all questions (such as whether or not to overwrite files) without prompting.

These switches make typeperf much more useful and a lot simpler to work with. First off, let's skip that pesky parameter bit—it's too hard to type accurately. Rather than type the counters you want to monitor as part of the command, collect them with the `-qx` switch and write them to a text file with the `-o` switch. For example, the following will write all instances of the LogicalDisk object into `f:\perflogs\diskcount.txt`:

```
typeperf -qx LogicalDisk -o f:\perflogs\diskcount.txt
```

The file now contains neatly formatted counters for all instances of the LogicalDisk object, nicely formatted (one per line) in the way that typeperf requires. However, you don't need to monitor *all* these counters, so delete the ones you don't want. You'll need to do that manually, but when you've edited the file and saved it as `diskcounted.txt`, you can point to that file with the `-cf` switch and then create a printed log (called `output.csv`) of the results of monitoring those counters, like this:

```
typeperf -cf f:\perflogs\diskcounted.txt -o f:\perflogs\output.csv
```

**NOTE** Writing output to a file not only makes it easier to keep and format the log data, but it makes Server 2003 more responsive when you press Ctrl+C to end the logging. While typeperf is writing to the file, the command window will show a spinning cursor.

Finally, you can refine this logging a bit further to use a different file format (-f), change the sampling rate (-si), stop monitoring after collecting 50 samples (-sc), and direct typeperf to another server to collect performance data (-s). The following example will save the log as a tab-delimited file, take a sample every 5 seconds, stop logging after 50 samples, and check data for server \\Gamma:

```
typeperf -cf f:\perflogs\diskcounted.txt -si 5 -sc 50 -f tsv -o
f:\perflogs\Goutput.tsv
```

## TRACE LOGS

Trace logs are more of an application or database developer's tool, testing to see how often a selected event occurs and logging the time, the thread ID that initiated the event, and the user data. To create a new trace log, right-click the Trace Logs icon in the right pane to open the context menu. As with counter logs, you can choose to either start from a saved Performance Monitor chart (New Log Settings From) or create a new log from scratch (New Log Settings). Type a unique name for the trace log when prompted (in this case, I've named it NetLogon), and click OK. When you do so, you'll see the General tab in Figure 18.9.

**FIGURE 18.9**

Choose counters for the TraceNetLogontrace log.

As you can see from this figure, you can collect data from two different types of providers. (A *provider* is just what it sounds like: something that provides information to an external application. In this case, the external application is the trace logging tool.) Services such as Kerberos can also send data to a trace log. The available nonsystem providers are visible when you select nonsystem providers to log and then click the Add button. From the list in the box that appears, you can pick available providers, such as the Active Directory service or Kerberos.

**TIP** File I/O and page faults are not normally included in the trace log because of the very high values they're likely to register—a lot of I/O and page faults happen on a server operating normally. Microsoft recommends limiting the log to two hours if you want to include that data in the log.

The Log Files tab of the trace log creator works the same way the one for counter logs does, except that your options are between a circular trace file (one that starts writing over itself) and a sequential one (where all data is appended to the end of the file). So does the scheduler—pick a time and date for the trace log to begin, or choose to begin it manually.

**TIP** If you can't start a trace log, check the Application log of the Event Viewer. Some providers require a local administrator's account name and password to let their data be logged.

The trace log creator includes one tab not in the counter log creator: Advanced (see Figure 18.10). Trace logs don't log data in real time; they store it in buffers until the buffers are full. Edit the settings here to make the buffers smaller or larger or to force the buffers to write to the logs at a definite interval. (Since trace logs are event driven, buffering the events before putting them into the log shouldn't matter.)

**FIGURE 18.10**

You can edit the size of the buffers reserved for a trace log.

When you've edited all the trace log settings, click OK to return to the System Monitor. The log file will appear in the list. Its icon will be red until the log is running, then it'll turn green when it starts automatically or when you start it by right-clicking it and choosing Start.

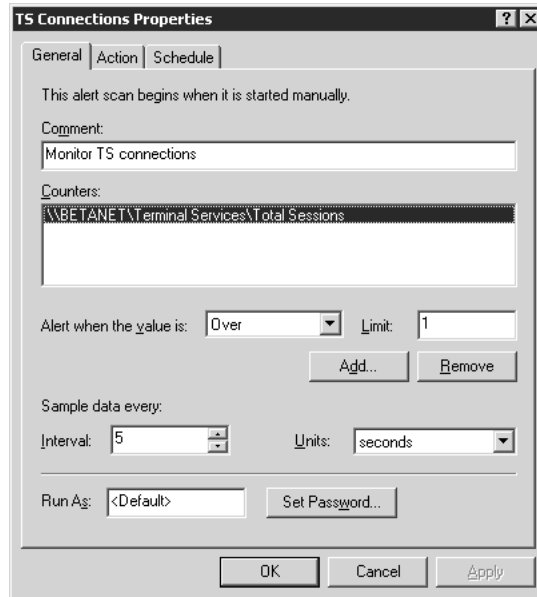

### ALERT LOGS

Finally, you can use Performance Monitor to keep track of failed logon attempts (Server: Errors Logon), file access attempts, and other types of attempted access that can indicate someone's trying to break into the network. That's what alert logs are for. After all, you don't just want to know about this stuff after the fact, you want to know when it's happening.

The initial stages of creating an alert log are much like those of creating a trace or counter log. Open the **Alert Logs** folder so that its contents are displayed on the right side of the System Monitor tool. Right-click anywhere in the blank area on the right of the display and choose **New Alert Settings** to define new counters to log or **New Alert Settings From** to open a saved Performance Monitor file and use its counters. Choose a name for the new alert, then click **OK** to open the alert log's property sheet (see Figure 18.11).

**FIGURE 18.11**

General tab of the alert log's property sheet

Assuming you're creating this log from new data, you'll need to add counters to the log as you did for a counter log. Click the **Add** button to open the **Add Counters** dialog box, and choose the computer and performance counters you want to monitor. When you're done making selections (remember, you can add as many counters as you like by clicking the **Add** button), click **Close** to return to the **General** tab. The counters will show up in the list.

So far, creating an alert log hasn't been any different from creating a counter log, but we haven't yet gotten to the good stuff. Below the list of added counters, you'll need to specify tolerances for each counter you choose. When the counter exceeds those tolerances, Performance Logging will add an entry to the alert log. For example, say that you added **Terminal Services: Total Sessions** to the log so you know whenever someone logs onto a server via RDP. In that case, you'd set the upper tolerance to 1—or 2, if you want to be able to log into the server yourself.

**NOTE** In this example, the System Monitor will keep sending messages and recording events until the number of remote sessions is below the alert threshold. Bear that in mind when setting up alerts.

Notice that the default sampling interval for alert logs (five seconds) is much shorter than the one for counter logs. This is because of the different nature of the log—it's assumed that you're a little

more concerned about the contents of this one. Use the drop-down lists to edit the sampling intervals if you need to. The alert log will only record events where the tolerances were breached, so you don't have to worry about drowning in data, but more frequent monitoring takes a toll on the server.

The scheduling tab for alert logs works just like the one you used to configure counter and trace logs—just pick a date and time to begin and end the log, or choose to start and stop it manually—but the Action tab (see Figure 18.12) is something new. From this tab, you'll need to tell the System Monitor what you want it to *do* when it generates an alert.

**FIGURE 18.12**

Edit alert log action settings.

Normally, System Monitor just adds an entry to the Event Viewer's application Event log. If the alert isn't something that you need to know about right away, then you can leave it at that. More important alerts, however, like those generated by unauthorized logins in a pattern that suggests that the network is being hacked, or a severe shortage of memory, may require immediate action. From the Action tab, you can tell System Monitor to send a message to your computer when writing an entry in the alert log or even to have it run a specific application that you can use to resolve the problem. Use this tab to send arguments to the application.

Once again, when you're done editing the alert log's properties, click OK to add it to the Alert Logs folder. When it's running, its icon will be green.

## Editing Log Settings

You can edit any log's settings by right-clicking its icon and opening its properties sheet in the same way that you created the log in the first place. However, in Server 2003 you can also edit log properties from the command line, using the new `relog` tool that allows you to change the sampling rate and file format of existing logs.

`Relog` allows you to take existing performance logs and change the sampling rate and file format.

## Viewing Log Data

Setting up the log data is the easy part, once you know what you want to monitor. Reading and interpreting that data is harder. The method of viewing log output depends on the type of log and its file format.

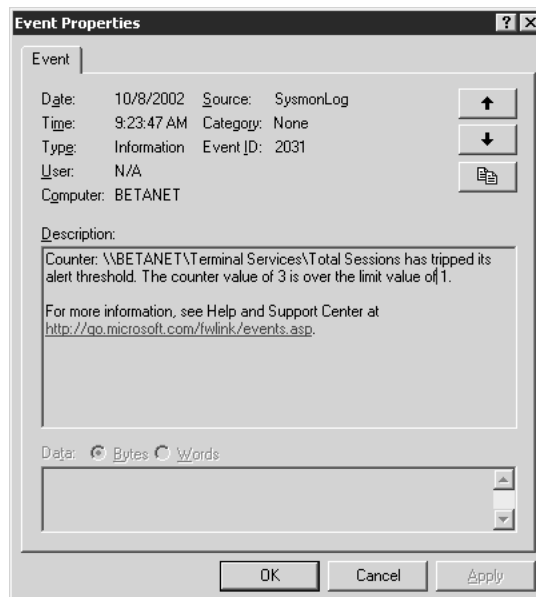

### COUNTER LOGS

Recall that when you're creating counter logs, you have a choice about how to present the data. The default option is to save the data in a binary log file (BLG) that you can examine from System Monitor. To see this data, click the icon on the System Monitor that has the database symbol (a cylinder) on it and browse to the location where you saved the log file when setting it up. This will open the contents of the log like a static performance monitoring chart, so you can see what performance was like at a given time without having to be on the spot at that moment. Charts are nice, but there will also be times when you want to view the information in a spreadsheet so you can manipulate the way it's presented. To do so, save the log data in a tab-delimited (TSV) or comma-delimited file (CSV) that you can open with a spreadsheet application such as Microsoft Excel. To view the data, just open the file with Excel. If the log is still active, you'll see an error message telling you that another user or application is using the data, but you can open it as a read-only document or click the Notify option to open the file—you just can't save it to its current name while the log is still writing to the file. From there, you can use Excel's charting tools to massage the data to make a good presentation.

### ALERT LOGS

Alert logs don't go into a regular file but directly to the Event Viewer's Application log (see Figure 18.13). When the counters exceed the tolerances you've set up, Server 2003 will add an Information record to the Application Event log.

**FIGURE 18.13**  
Output of an alert log

Of course, for more serious alerts, you'll have to set up the alert log to e-mail you or send a message to the location on the network where you're logged in so that you know that the alert occurred.

**TRACE LOGS**

Server 2003 (and other Windows Server operating systems) doesn't come with any program that can read the ETL files created when you make a trace log. You *can* view the contents of a trace log without writing an interpreter, but to do so you'll need to use `tracertp` to convert the output to comma-delimited file (CSV). Luckily, it's a pretty simple tool, with only the switches in Table 18.5.

TABLE 18.5: SWITCHES FOR THE TRACERTP TOOL	
-o [filename]	Text (CSV) output file. Default is <code>dumpfile.csv</code> .
-summary [filename]	The name of the summary file for the trace log. The default is <code>summary.txt</code> .
-report [filename]	Text output report file. Default is <code>workload.txt</code> .
-rt <session_name [session_name ...]>	Real-time Event Trace Session data source, used to generate a readable log from real-time data instead of a converted log.
-config <filename>	Settings file containing command options.
-y	Answer yes to all questions (such as whether or not to overwrite files) without prompting.

For example, running

```
tracertp trace1_000003.etl -o tracelog.csv -summary tracesum.txt
```

yields the following output:

```
Input
-----
File(s):
    trace1_000003.etl

Output
-----
Text (CSV):      tracelog.csv
Summary:        tracesum.txt
```

The command completed successfully.

**Troubleshooting Performance Monitoring**

Performance monitoring doesn't always work as expected. The reasons for this vary with the situation.

The descriptions for the counters can be misleading or inaccurate, so you may not be measuring what you think you're measuring—I've pointed out a couple of instances that I've noticed. Since there are thousands of counters, I'm sure that I haven't caught them all.

Be as specific as possible when monitoring particular instances, and make sure that you know which instance you're monitoring—for example, be sure of physical and logical disk identifiers before you begin monitoring disk activity. Similarly, it is very difficult to get any real process or thread information with the System Monitor, because the tool identifies processes and threads by instance, not by PID or TID. (There are Process: ID Process and Thread: ID Thread counters. They don't work. To get PID and TID information, you need to use the Task Manager.) If a server is running more than one instance of the same image, it is very difficult to tell which one you're collecting the data for. You could collect data for *all* instances of a particular image—say, EXCEL.EXE—but that doesn't help you figure out usage patterns for a particular instance.

Since histograms and reports display averages by default when working from logged data, be careful not to let unexpected zeros and spikes skew those averages. A value of zero doesn't necessarily mean that the real value is zero. Rather, it may mean that the service you're monitoring (if applicable) is not running—check the Services tool in Computer Management or the Event Viewer to make sure that a service that should be running but isn't reporting any data hasn't stopped. If you're remotely monitoring a server, make sure that you can get to it—particularly if you're opening a saved console that someone else set up for you; they might have permissions that you do not, and all you'll know is that you can't get any information about the remote server. Similarly, spikes might be part of the normal routine for a server and require investigation, or they might reflect an aberration. For example, say you're trying to find out how stressed a domain controller's processor is during an average hour. If you make that average hour at 8 A.M. when everyone is getting to work and logging in, you'll probably get a result different from the one you see when monitoring at 2–3 P.M. If logged averages are high, check the graph and look for spikes that can throw off the average, and consider lengthening the monitored period to put spikes into perspective.

## Whattheheckhappened? Troubleshooting with the Event Viewer

Server 2003 defines an event as any significant occurrence in the system or in an application that users should be aware of and have the chance to log. Critical events—those that can impact server availability—deserve immediate notifications, which is why you'll see “low on virtual memory” announcements on your monitor without asking for them. Less-critical but still important events are recorded in the Event Viewer, a tool in the Administrative Tools program group. You can log just about any kind of event on a server: file and directory access, services starting (or failing to start), unexpected conditions on the server, or, as discussed earlier, alert logs based on System Monitor data. And you'll *need* these logs. Any time that something strange starts happening on a server, those event log entries are your first key to finding out what went wrong and how to fix it.

### Understanding Log Types

The Event Viewer can display six types of logs. All servers will accumulate system, security, and application events. System events are generated by system components or related services and drivers.

Security events record changes to any security settings or any audited access such as attempts to open files or folders. You can monitor both successful and failed security events. Application logs contain events generated by applications, installed printers, or (as you've seen) alert logs. The Application log is a good place to look for important events not related to the core functioning of the OS or its services, but important nonetheless. If you set up event logging with administrative scripts, the events you record will also be in the Application log.

Three other logs—Directory Service, DNS Server, and File Replication Service—are for keeping track of AD-related events. The Directory Service log entries record information regarding the NT Directory Service (NTDS), problems connecting to the global catalog, and any issues regarding Active Directory in your network. The DNS Server entries record any events related to running the Directory Name Service in your Active Directory. Finally, the File Replication log entries record any notable events that took place while the domain controller attempted to update other domain controllers.

To view any log, open the Event Viewer. From the left pane showing the log types, click the type you want to view. The display in the right pane will change to show the log's contents.

## Viewing Remote Event Log Data

You can connect to any Windows server with an account in your domain (or in another, trusted domain). To do so, right-click the main **Event Viewer** folder in the left pane of the tool. From the context menu that appears, choose **Connect to Another Computer**. You'll see a dialog box that looks like the one in Figure 18.14.

**FIGURE 18.14**

Enter the name of a remote computer to manage.

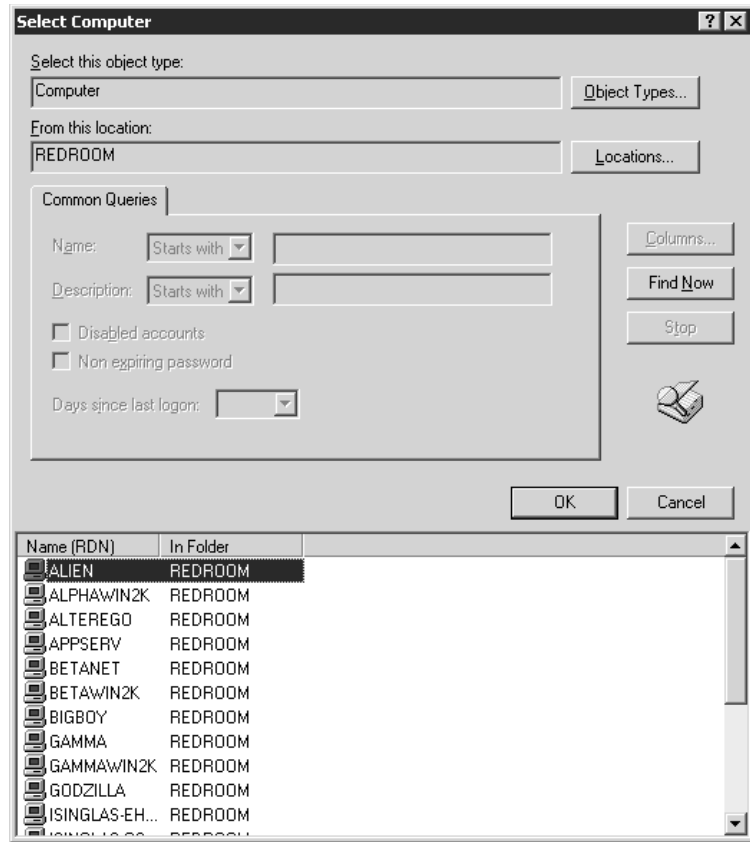

Type the name of the computer you want to monitor (for example, **sandworm**—you don't need backslashes) and then click **OK**. If the new computer is accessible across a low-speed connection, right-click the log you want to view (not the remote server, the actual log), and then click **Properties**. Near the bottom of the **General** tab, check the box for **low-speed connection**.

If you're not sure of a remote server's name, you can browse for it in an NT or Active Directory domain. Instead of typing a server's name and clicking **OK**, click the **Browse** button to open the **Select Computer** dialog box. If you're unsure of a remote computer's name, the first dialog box is unlikely to help you, so click the **Advanced** button to open the dialog box in Figure 18.15.

**FIGURE 18.15**

Browsing a domain for a computer account

From here, click the Locations button to choose a domain, and then click the Find Now button to list the computer accounts in that domain.

**NOTE** You can only connect to the logs of computers that have a computer account in the selected domain and are currently connected to the network. All computer accounts will be listed, even if a particular computer is offline at the moment.

When you've chosen a computer, click OK, and then click OK again back in the Select Computer dialog box. The Event Viewer information displayed will now be the remote computer's. To reconnect to the local computer, just open the Select Computer dialog box again and pick the option for monitoring the local computer.

## Reading Log Entries

There are five categories of log entries, each identifiable by an icon:

- ◆ Information events describe the successful completion of a task, such as the beginning of a service. If you're using Alert logging, information events in the Application log may also indicate that an alert's been triggered, so don't assume that all information events are benign.

- ◆ Warning events aren't necessarily fatal—they describe unexpected behavior that might point to future problems if not corrected.
- ◆ Error events describe fatal errors that mean a task failed. Error events may lead to data loss; they always mean that the server wasn't able to do something you asked it to do.
- ◆ Success events describe an audited security event completed as requested—for example, a machine account's login.

**TIP** *Some third-party services record successful initialization as a success event instead of an information event.*

- ◆ Failed events describe an audited security event that the server could not complete as requested. Failed security events can point to attempts to hack the computer, or may signify that a service does not have the permissions it needs to do something that it's supposed to do.

Each entry also includes the following information pertinent to the event:

- ◆ Date and time logged
- ◆ Object logging the event (such as the service that failed to start)
- ◆ Computer name of the server where the event was generated and, if applicable, the name of the person responsible for generating the event
- ◆ If applicable, the category of event, which won't tell you much—it's for the internal use of whatever server component logged the event
- ◆ Event number describing the event type

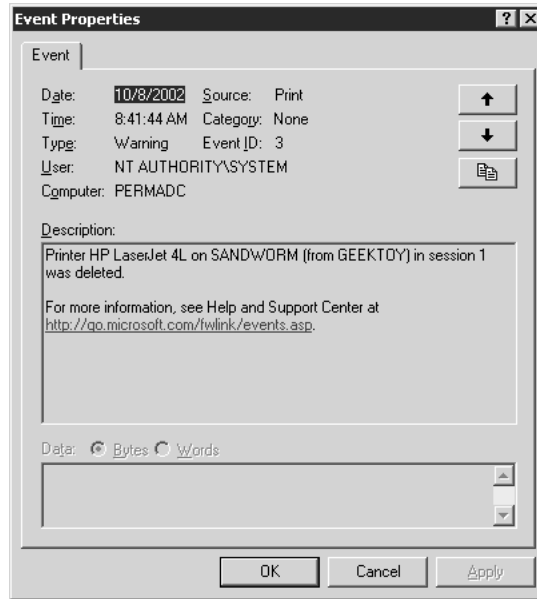

**TIP** *You can search for event numbers at [www.eventid.net](http://www.eventid.net) to find out what a particular event number means, since the descriptions for events aren't always very clear. This Web site doesn't have all event ID information, but it's a good place to start when trying to track down problems.*

Double-click any event in any log to open its property sheet (see Figure 18.16) and see more information about the event. The explanation is sometimes more than a little cryptic or is incomplete, but sometimes—and this gets easier with practice—you can glean useful information from the explanations of the events.

Troubleshooting with the Event Viewer takes a little practice. For best results, you'll need to know what your system looks like when it's running normally so you can more easily identify the events that indicate something is broken. Reading the Event Viewer on a regular basis also lets you find out about problems you may not have known you had, like misconfigured services, undetected because no one's using them much, or a drive running low on disk space. If a server seems to be acting oddly, then check the Event Viewer for warnings or informational messages that may explain what's going on. For example, reading the System log once helped me find a rogue program running on a server that I hadn't properly firewalled. A terminal server refusing connections because of a lack of licenses will also log this information in the System log, as will a service that can't start. (You'll still have to track down *why* the service won't start, but knowing that it didn't will help you figure out why a server isn't acting as expected.) And if a printer isn't appearing in a terminal session, the System log may indicate the reason.

**FIGURE 18.16**

Event details for a  
System log entry

## Managing and Archiving Log Contents

That's what you're looking at in the Event Viewer. *Managing* all that data can be a task unto itself.

### DISCARDING OLD DATA

The Event Viewer logs will keep filling up according to their settings. After a while (and, if you're recording something that happens a lot, "a while" may not be long), they get full. Unless you specify otherwise, an Event log cannot get any bigger than 16384KB (up from 512KB in Windows 2000).

To keep the data fresh, the Event Viewer normally overwrites events as it needs to keep the log under that size, overwriting the oldest data first. To edit this, open the property sheet for a log by right-clicking its icon and choosing Properties. Turn to the General tab shown in Figure 18.17. Most of these settings are pretty clear—from here, you can edit the maximum size of the log, the way in which old entries are overwritten (or not) and whether to clear an existing log and start over.

**WARNING** If you click the *Clear Log* button on this tab, you'll delete all the entries in that log (Event Viewer will prompt you to save them). Save logs before clearing them if you think you might need the data again.

### FILTERING DATA

Normally, the Event Viewer will display all records that it's collected, with the most recent entries at the top of the log. You can simplify the view of all this data by applying filters to the logged data. Filters don't affect what information is logged, only how it's displayed.

To filter a log's events, right-click the log's icon in the left pane and choose *Filter* from the View menu. You'll see the Filter tab shown in Figure 18.18. Choose the filtering options you want, described in Table 18.6. Only event logs with the options you specify (you can apply as many as you like) will appear in the Event log once you've applied the filter.

**FIGURE 18.17**  
Edit the settings governing how data is discarded when the log is full.

**FIGURE 18.18**  
Filter data to display only pertinent information.

**TABLE 18.6:** FILTERING OPTIONS FOR EVENT LOGGING

OPTION	DESCRIPTION
Category	Includes all events within a given category. This filter is most useful for security events, as most system events do not belong to any category and the application categories are numbered, with no keys.
Computer	Includes all events on that particular computer. As the computer in question is the one you're monitoring and you can only display one computer's Event log at a time, it's not clear to me why this filter is part of the Event Viewer.
Error	Includes all error events, which are requested tasks that the server was unable to complete for some reason.
Event ID	Includes all events with the event ID you specify. You can only specify one event ID at a time—you can't, for example, filter the Event log to display both event ID 7000 and event ID 4002.
Event Source	Displays events stemming from a source you specify (a driver, system component, or service).
Failure Audit	Displays failed security events such as opening a file or changing a security setting. The events this will include depend on the security and auditing settings for the domain or computer.
Information	Displays information events. Information events typically mean that everything worked as planned, but you can use information events to reassure yourself that yes, that service started as planned, so it couldn't be a problem there.
Success Audit	Displays successful security events such as opening a file or changing a security setting. The events this will include depend on the security and auditing settings for the domain or computer.
User	Displays events that are associated with a particular user, generally the user working at the console when the event was generated. Not all events have a user associated with them—this is mostly a system log thing.
View From and To	Use these boxes to specify a range of events to display. Unless you tell it otherwise, the Event log will display all events in the log from the oldest to the newest, but you can provide starting and finishing dates and times.
Warning	Includes warning events, which tell you that something didn't go as expected (or, for alert logs, that a counter exceeded the tolerance you set up) but that the problem isn't immediately critical.

Filters work like Boolean AND statements, not OR statements. That is, if you specify event ID 7000 and check the Error box, then the log will only display entries that are errors associated with event ID 7000, not all errors and all entries with event ID 7000.

**TIP** Want to view all data of a certain type but aren't sure how to filter the Event log? Click the column heading that corresponds to the type of data you want to view, and the log will sort its entries based on that type. For example, if you want to see all the entries associated with the Browser service, click the header for the Source column. All entries related to the Browser service will be grouped together.

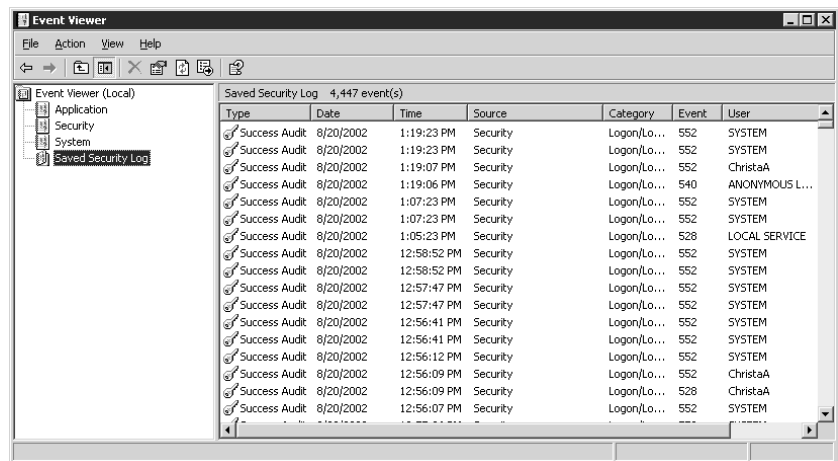

### SAVING AND RETRIEVING LOG DATA

Like I said, logs get full. You may want the data in them for future reference, however, so you don't necessarily want to just clear all log file entries. To save a log file, right-click the log's icon in the left pane of the Event Viewer. From the context menu, choose **Save Log File As**. A dialog box will open; type the name of the log, click **Save**, and you're done. You can now clear the file to begin logging afresh.

To open a saved log, right-click the Event Viewer icon in the left pane and choose **Open Log File**. Browse for the EVT file containing the saved log, choose a log type (this isn't an option) and a display name, and click **Open**. When you've loaded the saved Event log, it will appear alongside the other event logs as shown in Figure 18.19.

**FIGURE 18.19**

Loaded event logs don't replace existing log files of the same type, they supplement them.

## Quick Looks: Using the Task Manager

The tools we've talked about so far are good for gathering information for the long term, but setting them up and finding the relevant data takes a little time. When you want to get a quick view of the State of the Computer, the Task Manager is the way to go. It requires almost no preparation, gives you an easy way to determine which applications are hogging resources—as well as providing a short-cut to shutting down runaways—and generally offers you an instantaneous look at how the server is operating. You can't save or log data with the Task Manager, but you can see how the server is performing without having to set up performance counters. I use the Task Manager frequently on both servers and workstations. Just keep in mind that you cannot use the Task Manager to monitor a remote

computer, and this tool uses server resources. I will leave it running on a not-too-stressed workstation, but I won't leave it running on a server.

To get to the Task Manager, press Ctrl+Alt+Del to bring up the Windows Security dialog box, and click the Task Manager button. This tool has five tabs: Performance, Applications, Processes, Networking, and Users.

**TIP** If you're remotely administering a server using RDP, press Ctrl+Alt+End to open the Windows Security dialog box.

## Processor and Memory Usage

Graphically, the Performance tab in Figure 18.20 is pretty easy to interpret.

**FIGURE 18.20**

Get a visual snapshot of the server with the Task Manager's Performance tab.

Processor-wise, the server was recently very stressed but is now better, and it's using a moderate amount of memory at the moment—overall, the server's in pretty good shape. This graphical data is collected from the time I open the Task Manager, so it will take a minute or two to get much of a snapshot of current processor and memory usage. The text on the bottom of the page takes a little more interpretation. In the Totals section in the upper left, the Processes count is a rough estimate of the number of executable files (not just user applications, but any executable file, including service images and files supporting the operating system) running on the server. The Threads count represents the number of executable threads that are using those process resources and contending for processor time. The Handles count represents the number of connections that the processes have to system resources such as internal timers. Moving to the right, the Physical Memory section gives you a little

more useful information: how much memory is available on the computer and how much of it is currently in use. This memory count includes only the installed RAM in the computer, not the paging file. The Kernel Memory section on the bottom right shows how much memory kernel processes are using, and how much is paged to disk. Finally, the Commit Charge section in the bottom left shows how much memory is committed to particular processes and is not available to other processes.

## Application-Specific Information

The Applications tab of the Task Manager shows (some of) the executable files running on the computer, along with the data files they have open (if applicable). As you can see from Figure 18.21, you can use the buttons on this tab to navigate to running applications or end runaway applications—a hung program will show a status of Not Responding. You can also right-click individual applications to change their window state (maximized or minimized), switch to them, close them, or find their process on the Processes tab.

**NOTE** *If an application crashes and is in the middle of being debugged, you can't end it until the debugger is done gathering information, and if closing the application causes the application to open a window prompting you for information (perhaps to save a file) then you'll need to either answer the prompt or choose the End Now option when prompted to override the application's prompt. Generally speaking, you're better off closing the application normally if you can.*

**FIGURE 18.21**

The Applications tab shows running applications and any data files they have open.

## Process-Level Information

The Processes tab in the Task Manager (see Figure 18.22) takes the basic information presented with the Applications tab and significantly expands on it. The Image Name column shows the

executable files associated with the applications on the Applications tab and displays all the operating system executables—that CSRSS.EXE file is the Win32 subsystem. The PID column shows the process ID for that executable, the identifier for the process created to support the needs of that executable. The OS identifies running processes both by the name of the executable file they're supporting and by their Process ID. The CPU column shows the processor that each executable is using; in a single-processor system this won't tell you anything you don't already know, but in a multi-processor system could be useful. The CPU Time column, which you can add as described below, on the other hand, shows you useful information—you can tell which executables are using the most CPU time. If all is going well, then the System Idle Process should be at the top of the list when you're sorting for CPU time. The Mem Usage column shows the size of the working set for each executable. However, since this total includes shared pages, you can't add all these numbers up to get a complete count of the RAM installed in a particular computer.

**FIGURE 18.22**

Use the Processes tab to find out how much memory or processor time an executable file is using.

**TIP** To sort the data displayed on the Processes tab, click the appropriate column head.

This is only a small sample of the data available to you when it comes to getting a current snapshot of the computer. When the Processes tab is in the foreground, the View menu in the Task Manager has a Select Columns option. Pick this menu item, and you'll see a dialog box like the one in Figure 18.23. The selected boxes will be listed on the Processes tab.

For example, notice that my Processes tab does not have a Session ID column, whereas yours may. (This option will only be available if you install Terminal Services.) This column is used on servers

with Terminal Services enabled, whether in Remote Administration or Application Server mode, to identify the session in which a particular executable file is running.

**FIGURE 18.23**

You can choose additional per-process information to monitor.

**NOTE** By default, the Task Manager will display processes only for the console session (Session 0), but it can display process information for all connections to the server, whether from the console or via RDP. Clear the check box on the Processes tab to get a more streamlined view of the server, or select it if you want to know what executables are running in all sessions, whether visible to you or not.

I find myself using the Processes tab most often of all the parts of the Task Manager. It's a very easy way to find out what's active on your server quickly, without mucking around with adding counters or checking the Event log. If you see something that looks like an ongoing problem, then you can set up logging in the System Monitor. You can also kill processes from this tab—just right-click the process and choose End Process—or End Process Tree to kill a process and every other process it spawned.

## Network Information

The Networking tab in the Task Manager (see Figure 18.24) displays the current state of all virtual network adapters in the server, whether they're responding, and how much of their network capacity is currently in use. This network information applies only to traffic going to and from the currently connected server, so it's not much of a tool for general network diagnostics. It can help you track down server-specific network problems, however.

## User Session Information

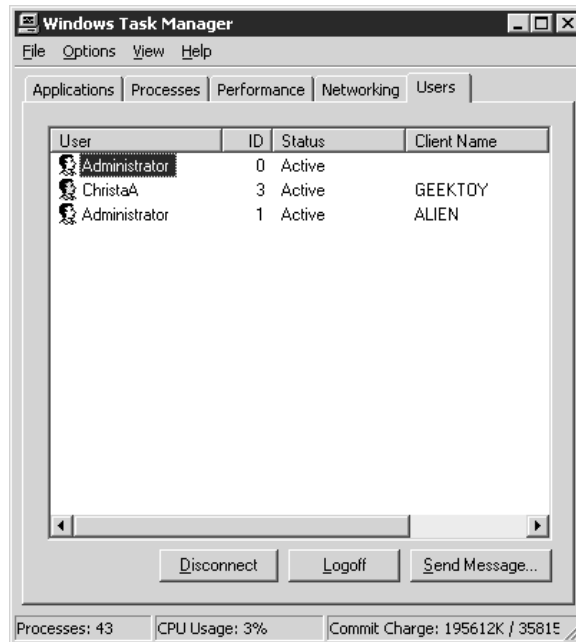

Because Terminal Services is enabled on all Server 2003 computers, the Task Manager now includes a Users tab that you can use to keep track of those remote sessions. From this tab (see Figure 18.25) you can see the session ID for each session (including the console, which will have Session ID 0), the username for the person who's logged in, the status of that session (Active or Disconnected) and the name of the computer they're running the remote session from.

**FIGURE 18.24**

The Networking tab displays connection status for all virtual networks on a server.

**FIGURE 18.25**

Use the Users tab to monitor and manage remote connections to the server.

This tab will come in handy in several ways. First of all, a Server 2003 only supports a maximum of one console and two remote administrative sessions—and disconnected sessions count toward that total. This tab can show you how many remote connections are currently running on the server and show you their status, as well as let you communicate with those sessions.

You can send a message to an active session by right-clicking the session and choosing Send Message from the context menu. A dialog box opens, in which you can type a short message—perhaps asking one administrator to log off the console because the server has accepted the maximum number of connections and someone else needs to log on. When you send a message to a session, it will immediately pop up on the screen of that session.

If another administrator is having trouble with the server, you can take over their session from the Task Manager. Right-click their active session, choose Connect from the context menu, and type their password, and you'll take over that session. (Doing this will kick the other user out; to shadow a session, you'll need to use the Remote Control tool in Terminal Services Manager.) Because connecting to a session disconnects your own session, you cannot connect to a session from the console; you must be working from a remote administration session yourself. You can, however, connect to the console session—you'll just lock it.

Finally, if someone has disconnected from their session and you need to reclaim the session, you can log them off their session. Right-click the session and choose Log Off. The Task Manager will ask if you're sure about logging off the selected user. Click Yes, and you'll boot that person off the server.

**NOTE** For more information about working with terminal sessions (including more options for sending messages to remote sessions and connecting to them), see Chapter 16.

## Basic Tuning Stuff

So far, we've talked a lot about how to *collect* information from a server using the System Monitor, the Event Viewer, and the Task Manager, but not so much about how you can exploit this information to make your servers run more efficiently. Let's open the Control Panel and see what settings you can edit now that you know a little better what state of health your servers are in.

### Optimizing Server Processing Power

Windows NT Server 4 and NT Workstation had several obvious differences, but one of the major differences wasn't obvious. The core files required to run NT Server and NT Workstation were and are the same, but at boot time the OS looks in the Registry key HKLM\System\CurrentControlSet\Control\ProductOptions. Run REGEDT32 and look in that key, and, among other information, you'll see a value for Product Type. That value was (and is—this hasn't changed) since NT 4: WinNT for workstations (e.g., Windows XP), LanmanNT for domain controllers, and ServerNT for server computers.

Why does this value matter? Based on the value of this key, NTLDR makes some decisions about how to configure the system, including runtime policy decisions such as how operating system components and user processes contend for memory and even how the processes contend for CPU time.

The most obvious result of this is that server operating systems give a little more time to the application in the foreground than the ones in the background, but they generally assume that all applications on the server need more or less equal time. But workstation operating systems give a *lot* more time to the application in the foreground, on the premise that the application you're directly interacting with is the one you want to be most responsive. If you ran, say, Microsoft Word from a Server 2003 machine, it would run rather less efficiently than if you ran the application from XP Professional. This is because even when you were typing into Word, the server would be a little distracted, checking with any other running processes to make sure they were happy and getting enough processor time. Windows Server 2003 is meant to be a *server*, not a workstation supporting the needs of one person.

**NOTE** *You could edit the Performance settings in the System applet of the Control Panel, but I'm talking about the way the operating systems were set to run under normal conditions.*

Ah, but what about Terminal Services? It's a server, but a server of a very special kind, since it's providing computing resources to a bunch of client machines. For that reason, Terminal Services should give more time to foreground applications than to background applications and services, as the foreground applications are the most important to the overall performance of the server. If Terminal Services is running and you've set up the application server role, then the operating system is optimized for running foreground applications. (You've got another option of installing Terminal Services only for remote administration of the server, in which case the server is optimized for fulfilling server functions.)

Under rare circumstances, however, you may want to give equal time to all running applications even when the server is supporting user applications. To do so while still running Terminal Services in Application Server mode, open the System applet in the Control Panel. Turn to the Advanced tab, click the Settings button in the Performance area, and turn to the Advanced tab to open the dialog box you see in Figure 18.26.

In the Application Response section, make sure the Background option is selected. This tells the server to give all running applications equal access to processor cycles. This may make your foreground applications a little more jerky, but other applications will respond to user requests more smoothly.

**WARNING** *Generally speaking, you should not edit the Application Response options setting; this is for the exceptional case. When you use Terminal Services in Remote Administration mode, processor time will remain equally distributed among running applications, so you won't need to edit this setting then.*

**FIGURE 18.26**

Edit performance options.

## Editing Virtual Memory Settings

While you're in the Performance dialog box of the System applet, click the Change button in the Virtual Memory section to take a look at the paging file settings (see Figure 18.27).

The default location for the paging file is on the root of the same logical drive where you installed Server 2003. This isn't always the best place for it, however. Generally speaking, your server will be happier if its paging file is on a separate disk from the operating system files. Paging files are good candidates for disk fragmentation, and a fragmented disk is not a fast disk—not good when you're trying to use an operating system from that disk.

To move the paging file from its original location, open the dialog box shown in Figure 18.26 and select the local drive where you want the paging file to go. Type in a minimum and maximum size for the paging file in the boxes provided. Also, select the drive where the paging file *was* and zero it out. For what should be obvious reasons, you can't put the paging file on a network-accessible drive. And although removable drives will show up in the list of local drives that you could put a paging file on, they're displayed with a free space of 0MB, so you can't put the drives there.

**TIP** Try to make sure that the paging file is as large as it needs to be from the beginning. Although it will get bigger as needed, the process of making the file get bigger is resource-intensive. You'll get better performance if you make the minimum size of the paging file something resembling its necessary size.

**FIGURE 18.27**

Virtual memory  
settings for  
Server 2003

When you finish, the size of the new paging file should be shown in the Paging File Size column next to the right drive, and that space in the original drive should be blank. Click the Set button to establish the paging file. You'll need to restart the server, but once you do, the paging file will be moved to the new location.

What if you zero out the original page file but forget to specify the location of a new one? You'll be prompted to reboot the computer as usual for changing the size of the paging file. However, when you reboot, the server will be extremely unresponsive. You must follow the instructions here (and also provided on the nastygram) for creating a new paging file on the appropriate disk. Your server will work until you do this, but it will start with no virtual memory. The new paging file will grow slowly as needed, probably causing you to run low on virtual memory from time to time, and using a ton of processor cycles to grow the paging file. In other words, don't delete the paging file without creating a new one unless you want to see how the server will operate in low-memory conditions.

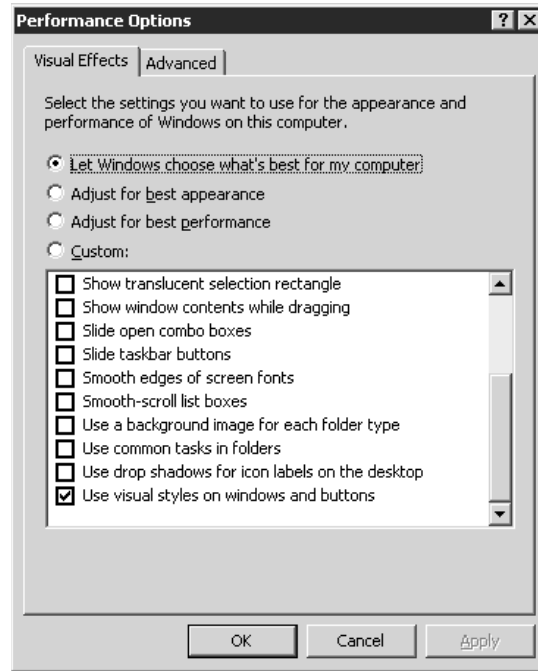

## Turning Off Silly Visual Effects

Okay, maybe this is just me being a Luddite, but in my view a server needs to be *fast*, not spending cycles on fancy visual effects when opening and closing windows. (Fancy visual effects will also impact performance in remote administration sessions.) Therefore, I keep visual effects to an absolute minimum—even easier, now that Server 2003's picked up better command-line support. By default, Server 2003 is actually pretty smart about visual effects. If you stick with the defaults, it only uses one effect. In case someone turns on more bells and whistles, you can turn this off from the Visual Effects tab, which is available on the same Advanced tab that let you reach Application Response. In

the dialog box shown in Figure 18.28, make sure that the server is tuned for Adjust for Best Performance and keep those boxes unchecked.

**FIGURE 18.28**

Keep visual effects to a minimum on servers.

## Tuning the System Cache

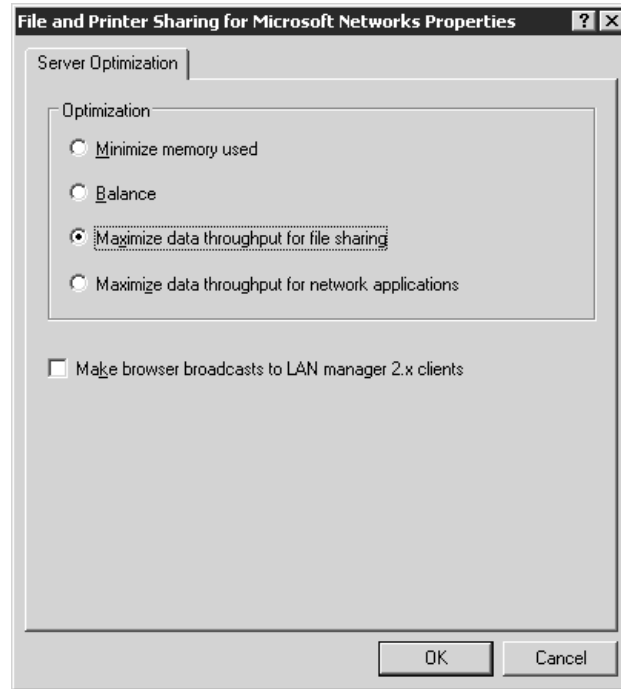

Server 2003's default memory settings reflect NT's legacy as a file-sharing NOS. By default, it's set up with a large *system cache*, which is a range of virtual memory addresses reserved for holding recently used data related to file sharing, whether from hard disks, CD-ROMs, or network-accessible drives. The cache includes any data related to file reads and writes, including file contents, read and write activity to a file, or the metadata that describes a drive's structure and organization. The system cache has a range of virtual memory addresses dedicated to it, with the exact size of the range depending on the amount of physical memory installed in the server. Just as the size of the paging file increases as you install more physical memory, the system cache does, too.

**NOTE** You can see how much physical memory your server's system cache is using by monitoring the value of *Memory: System Cache Resident Bytes*. Although the System Monitor has a counter called *Memory: Cache Bytes*, this counter doesn't actually reflect just the System Cache working set. It reflects the entire system working set, including paged pool and any driver code and kernel data that can be paged to disk. System Cache memory usage is also visible from the Performance tab of the Task Manager.

If a server's supporting file sharing, then it needs this big reserved virtual memory space. However, caching all that data may cause a lot of disk thrashing as the data goes in and out of physical memory.

If a particular server isn't doing file sharing, you can save yourself some physical memory by changing the memory usage parameters for network use. To do so, open Network Connections from the Control Panel. Right-click Local Area Connection and open its property sheet. Select File and Printer Sharing for Microsoft Networks, and open that service's property sheet as shown in Figure 18.29.

**FIGURE 18.29**  
Server Optimization  
options

The default setting is Maximize Data Throughput for File Sharing. If you're not using the server to share files, change this setting to Maximize Data Throughput for Network Applications, or to Balance. (The Minimize Memory Used setting is only a good idea for servers serving a very few users, like fewer than 10.) This should reduce the amount of paging to disk that your server's doing.

## Chapter 19

# Preparing for and Recovering from Server Failures

COINCIDENCE, GREMLINS, OR INCENTIVE from The Powers That Be to do my homework?

The day I planned to start working on this chapter, one server on my network stopped booting. I'd been out of town for a few days and so I'd shut all the computers on the network down (power in Virginia is notoriously chancy during the summer months). Came back, booted up the server, and it worked fine. Added support for an additional transport protocol, and rebooted as required. This time, the system couldn't find a bootable device.

Uh-oh.

Why did this happen? Dead hard disk? Something disconnected? NetBEUI ate my hard disk when I installed it? (Geez—when Microsoft makes TCP/IP the default transport protocol, they're not kidding around, are they?) The initial question, however, wasn't "What happened?" but "How badly is this going to screw me up?" Regardless of the reason *why* the machine didn't boot, the fact remains that it didn't. Had this been a production server instead of a test machine, I would have been in a world of hurt. Or could have been, if I hadn't been prepared for this kind of eventuality.

There's nothing quite like that sinking feeling when a server dies. You can't always prevent this from happening; sometimes, you're just stuck with the whims of the malignant forces in the universe. What you *can* do is either fix the problem or recover from it. That—and how to prevent problems when you can—is what I'll talk about in the course of this chapter. In this chapter, I'll cover the following:

- ◆ The importance of redundancy in a fault-resistant server and network
- ◆ Some basics of preventing preventable disasters
- ◆ How to use the Windows Backup tools to create manual and automatic backups
- ◆ How to use the System Information tool to isolate hardware problems
- ◆ What's going on when your computer boots
- ◆ The use of the recovery tools found in Server 2003
- ◆ Disaster recovery tips

Let's start with some ways to avoid some disasters in the first place.

## Preventing Stupid Accidents

Deliberate external attacks on your network are frustrating, but at least they allow you to get mad at someone else. It's the *preventable* infiltrations or server crashes that lead to the most gray hair. To keep your servers running and secure, you need to do the following:

- ◆ Keep multiple copies of important data and important server roles such as domain controllers.
- ◆ Physically secure your network. If the bad guys (and the careless good guys) or Mother Nature can't get to your network hardware, it's a lot harder for them to damage it. The degree to which you can physically secure your network varies—not all of us have the option of running our fiber cable through concrete pipe—but you can, at least, keep the servers behind a locked door.
- ◆ Protect your network's user and system data with a good backup strategy.
- ◆ Prepare for the worst with a point-by-point disaster recovery plan that anyone in your organization can follow. Don't depend on one person knowing how to return the network to working order—that one person may be unavailable when the time comes to restore the network.
- ◆ Understand how your server works so you can troubleshoot problems and perhaps prevent more problems in the future.
- ◆ Install the service packs and patches that Microsoft issues. I know this may shock you, but Windows products have flaws. (Other operating systems also have flaws, but we're talking about Windows here.) Microsoft issues patches for these flaws, but if you never install these patches, they're useless.

When something goes wrong with your system, think *noninvasive*. Step 1 is *not* popping the top on the server. Three of your most valuable troubleshooting implements are the OS installation CD, data and system state backups, and your notebook, in which you record every change you make to the network and record resolutions to problems. (The brain is Tool 3A. Sometimes it shuts off in times of stress, so you rely on the notebook.) When the time comes for troubleshooting, that notebook will be an invaluable diagnostic tool and a cheat sheet for “I know I've seen this before. How did I fix it last time?”

A basic concern in any computer security system is the need for physical security, a blanket term for the many ways in which you can protect your server and network from physical harm: stupid accidents, environmental—er—“incidents,” and theft. Entire books have been devoted to the question of how to physically secure a network, so I'm not going to cover everything here. What follows is an outline of the kinds of protection you should be looking for, both physical and logical.

**NOTE** *Protecting your network is a never-ending process; every safeguard has a counter. You can't protect yourself from every possible disaster, so you have to come up with a balance between how much it would cost you to recover from a disaster, how likely it is that you'll be hit by that particular disaster, and how much the protection costs. If protecting your data costs more than the data is worth, then it's time to relax a little.*

## Redundancy: The First Line of Defense

This is a theme that has come up several times in the course of this book, but it's worth repeating here: a redundant server—or network—is a fault-resistant server or network. You can be redundant at several layers.

On the server, protect important data with fault-tolerant volumes, whether with software, as discussed in Chapter 10, or in hardware. The pros and cons of the various RAID types supported in Server 2003 are also discussed in Chapter 10. As you'll see there, RAID 5 gives you the most protected storage space for the number of disks involved, but mirroring is less processor-intensive than the RAID 5 protection supported in software. Do *not* put important data on any multidisk volume that is not fault tolerant unless you are backing it up early and often. Although multivolume disks can improve performance and make a larger single volume, if one disk in the volume dies, the entire volume is inaccessible. Since having more disks increases the chance that any one disk will die at any given time, multidisk volumes are more vulnerable to disk failure than single-disk volumes. To protect data from complete server failures, not just disk failures, you can choose to replicate it across the network.

The same principle of redundancy applies to the network. As you'll see in this chapter, having multiple domain controllers can simplify your restore process if you lose a DC. Rather than having to restore the domain structure from backups or completely rebuild it, you can let the usual replication take care of the restoration for you. Of course, if you're restoring a more recent version of the directory structure, you can choose to propagate those changes to the other domain controllers, but the bottom line is that having more than one domain controller allows you to keep the domain working while getting a failed domain controller back on line. The same principle applies to WINS servers (for name resolution) and DHCP servers. You don't want two DHCP servers actually dispensing IP addresses, but you do want a backup of the scope. See Chapter 7 for more about WINS and DHCP.

Finally, if you're using Windows Server 2003, Enterprise Edition (or a third-party clustering solution) you can use clustering to keep vital servers from going down. There are two main types of clustering. Load-balancing clustering distributes requests among clustered servers to keep the—well, to keep the server load balanced so one server isn't hammered while another one is standing idle. Fault-tolerant clustering can actually transfer connections from a failed server to one that's standing ready for new connections.

## Power-Protect Servers

*Always* use a UPS to power-protect servers and network hardware such as hubs and routers. This will protect the backbone of your network from power surges and dirty power. Power protection also will help prevent data loss and will let you shut down the servers in an orderly fashion (or shut down the servers automatically). Personally, I've had very good luck with APC's UPSes (strictly speaking, SPSes) for workstations and test servers, but the Web server that *cannot* go down is protected with a true UPS (a Powerware Prestige XT, if you're interested). For those who don't know, a switched power supply has a very short (under 4ms) break when switching from line power to battery power—not enough to be noticeable for most computers. An uninterrupted power supply cycles all power through the battery even if line power is available, so if the line power fails there is no switching time. Most devices you see sold as UPSes are SPSes.

**WARNING** *Don't ground only the server room, ground the entire office. Grounding only the server room is equivalent to putting a giant "KICK ME" sign on your servers, as they'll be the easiest path to ground.*

What about client-side power protection? At one time, UPSes were so expensive that it wasn't cost-effective to protect each client station. These days, you can get a low-end UPS for less than

\$100, so think about the investment to give user machines power protection and a little bit of time to save documents and shut down. Power strips with surge protectors don't do the trick. Because of their high tolerance for voltage—they'll pass jolts that will damage a PC—power strips are a convenient way of plugging several devices into one outlet, but not a power-protection mechanism.

**TIP** *Don't plug a printer into a UPS designed for a computer only. First, it won't hurt the printer to lose power suddenly and if the power goes out, printing documents is probably not a vital concern. Second, laser printers draw far more power than a PC and will drain the battery life too quickly. Do plug a monitor into the UPS. Although the monitor draws power, you'll need it to shut down the computer gracefully.*

Speaking of client power protection, one advantage to running Terminal Services instead of a traditional desktop environment is that you don't have to worry about power-protecting a Windows terminal—at least not for reasons of protecting data. If a Terminal Services client computer loses power, the client's session is disconnected, not terminated. That is, all client applications and data remain active and in memory on the terminal server so long as the server is running. When you power the client back up and reconnect the session, it will be exactly as it was when it was disconnected. In other words, a power outage on the client will cause no data loss as long as the terminal server is protected. For more information about Terminal Services in Server 2003, turn to Chapter 16.

For extreme quick-and-dirty power protection for network client machines, tie five knots in each computer's power cord, as close to the wall as you can. If lightning strikes the wiring, the concentration of current within the loop of the knot will kill the cord and thus break the lightning's path to the client machine. I know that this one is hard to believe, but it really works. As Mark tells it:

*During the summer of 1990, a massive electrical storm hit Washington, D.C. (where Mark lived at the time). I had tied knots in the cords of all of the computers in the house beforehand but hadn't thought to do this to the television. During the storm, one of my neighbor's houses took a direct lightning hit and a huge power surge hit my house's wiring. The cords of all the computers were warmed up a bit, but the power surge never touched the computers themselves. The television was another matter. The surge traveled straight through the cord to the TV's innards and rendered the television DOA. I couldn't have asked for a better test, although at the time I wasn't in a mood to appreciate the benefits of having had a control group.*

## Environmental Concerns

Reduce the likelihood of Bad Things happening to your servers by keeping them away from potential problems. Look for evidence of old leaks in the ceiling, and keep equipment away from them—an old leak could become a present leak. Make sure that the server room is climate-controlled. The air conditioning used for the rest of the office might not be sufficient in an enclosed room, given all the heat that computers emit. And don't position *any* computer in direct sunlight.

Finally, avoid introducing new contaminants around the servers. Although it may be impossible to keep people from eating or drinking near their workstations, you can—and should—keep food out of the server room. If your office permits smoking, don't smoke or let other people smoke around the servers or workstations. Smoke particles inside a hard disk can chew up its surface.

## Limit Access to Servers

Most people using the network don't have a valid reason to do anything to a server (except a terminal server, of course, and then they're only using it remotely). One way to keep people away from your

servers is to lock said servers in a separate room to which only trusted people have access—and you can make that even more secure by using a card-key system that records the identities and in-and-out times of the people entering the locked room, if necessary. If people can't get near the servers, they can't:

- ◆ Reboot or shut down the server manually.
- ◆ Steal data-containing hard disks from the server.
- ◆ Reinstall the OS and thus have the chance to create a new Administrator account with full access to the server.

User permissions that prevent a person from shutting down a server from the console don't prevent that same person from shutting down a server with the Big Switch. Therefore, if locking up the servers isn't an option, you can physically disable the Reset button and/or the A: drive so that people can't just shut down the server unless they have permissions to do so.

**NOTE** An OS-dependent protection utility such as `floplock` (in the NT 4 Resource Kit) doesn't prevent people from using the floppy drives from another operating system or from booting from a floppy, because the OS isn't yet loaded when you're booting. If you want to disable the floppy drives for all operating systems, edit the BIOS to remove support for floppy drives (this setting is typically in the Standard BIOS setup) and password-protect the machine for booting. Alternatively, use a keyboard-video-mouse switch with long cables so you can keep the monitor isolated from the server to which you're providing access.

## Use Passwords Effectively

Server 2003's security is built on user authentication. When you log in to a domain, your username and password are compared with the information stored in the Active Directory on the domain controller. Once you're authenticated on the network, you're assigned a security token that contains a list of your rights and permissions based on your user identity and group membership. Whenever you try to do something—read a file, install an application, whatever—the security manager compares your rights and permissions with what you want to do, and permits or denies access based on the results of that comparison.

The only thing that keeps people from impersonating each other, therefore, is the password on their accounts. Once someone has an account's password, they can use that account and all the rights and permissions associated with it. Passwords are the biggest port of entry into your network.

### WHY PASSWORDS ARE VULNERABLE

Previous editions of this book included some tips on creating hard-to-crack passwords. The widespread availability of password-cracking programs such as L0phtCrack (now more innocuously known as LC3) renders most of these tips semi-obsolete for stopping anyone who *really* wants to break in and who can get physical access to the server because they give anyone with access to the network an extremely powerful tool for cracking passwords. LC3, for example, can retrieve password hashes from the Registry or even from the network. Once the tool has the password file, it extracts the password hashes (encrypted passwords) and performs a series of three attacks to decrypt the hash:

**Dictionary attack** In a dictionary attack, LC3 tests all the words in a dictionary or word file (the tool itself comes with an optional word file) until it finds a match.

**Hybrid attack** If the dictionary attack doesn't produce results, the next step is to see whether the user took a known word and added numbers or other characters to it, so as to foil a dictionary attack.

**Brute force attack** The final stage is a brute force attack, in which the password hash is compared against every key combination possible. Brute force attacks take much longer (sometimes days—depends on how fast the computer doing the cracking is) than either of the other two attacks, but they can eventually crack just about any password using characters found only on a standard keyboard.

Just about any password is vulnerable to a brute force attack if given enough time. “Enough time” may mean a couple of days even on a fast computer, but if the cracker has the password hashes, then the delay won't stop the cracker unless people change their passwords during the cracking process.

**NOTE** *The longer and more complicated a password is, the longer it will take to crack it—and the more likely that your user base will write down passwords. You'll need to balance the need for complex passwords with the reality that if you make them too complex they'll be unusable or compromised by people writing them down.*

All that said, passwords are far from useless. You'll notice that using a tool such as LC3 requires physical access to the server or to the network. The answer? *Keep untrusted people off the network.* Protect the Administrators account, only giving Administrator rights to the most trusted people. If your network is connected to the Internet, close TCP/IP ports that you don't need, and audit failed attempts to connect to the gateway from the Internet. For the people on the inside who *do* have access to the network, institute a zero-tolerance policy for password-cracking tools for anyone without a really good reason to have them, and don't set up e-mail to execute attachments automatically, since some malicious software will execute not only with the permissions of the person currently logged in (as software normally does) but can give itself *elevated privileges*, allowing the software to execute as though a member of Administrators or Domain Administrators was logged in—and thus wreak all kinds of havoc.

**NOTE** *Although servers would seem to be safe from an elevated privileges attack (since users are not likely to be logged in at the console, and administrators won't pick up their e-mail there), terminal servers, in particular, are vulnerable to them because ordinary users do effectively log on locally.*

### KEEPING OUT THE IDLE CURIOUS

Your network's security is threatened not only by the actively malicious, but also by the idle curious. Password-choosing schemes are best for keeping out those people who aren't interested enough to get serious about breaking into someone's account, but will go poking through Joe Blow's files in his private home directory if Joe makes it easy for them. To keep these people out of other people's accounts, follow the guidelines for choosing passwords below. They won't foil LC3, but they'll foil someone guessing passwords.

**Impose Password Policies** Passwords must be of a minimum length, changed regularly (but not too regularly, to avoid people reusing passwords too often), and shouldn't be reused often. Set policies to require passwords to include numerals and other nonletter characters, and take advantage of the fact that passwords are CasEs3nSitiVe (hint, hint).

**Don't Let People Use Easy-to-Guess Passwords** No personal names, spouse's names, dog's names, or other easy associations. Ideally, passwords should not reflect that person's job, either. A few years ago, a friend of mine doing network security for one department of the Pentagon told me that he'd had to institute this rule after discovering that the analysts in his division had all chosen passwords based on the names of battleships—words directly related to their division's mission.

**Don't Write Down Passwords** The most difficult password in the world will do no good if it's on a sticky note on the base of the monitor or under the keyboard. This is the dilemma inherent to all password protection. If you make passwords easy to remember, they're often easy to guess. Make them too hard to remember or require too many of them, and users will start writing them down.

**Delete or Disable Unused Accounts** An unused account is an account that isn't getting its password changed regularly and doesn't have someone using it who might notice something strange going on. If you'll need an account later, but not now, disable it so as to retain its security ID while making it impossible to use at the moment. If you'll never need an account again (perhaps for someone who has left the company), delete it.

**NOTE** *If you delete an account and then re-create it, the account will have a new security ID even if it has the same username and password as the original account. You'll have to re-create all user rights and permissions from scratch.*

If passwords don't supply enough security, you can replace or supplement them with other means of validation. Biometric devices can scan retinas or (less intrusively) fingerprints and provide a second layer of security that confirms the person supplying the password is the person authorized to do so. Another alternative is the token-generating tools that create a token (with a smart card or similar device) to be supplied along with the password; the password won't work unless it's the proper token. In short, passwords are a good start, but you needn't rely solely on them.

## Backup Programs and Approaches

Security from intrusion is important, but so is security from data loss. Backups are your first line of defense against server failures and your last recourse when all else fails. When it comes right down to it, the data on your servers is the important part. The box is replaceable, and you can reinstall the operating system if you need to. What you can't replace is the data on the drive. And if you lose that data and can't get it back, your company's life is probably over.

To help you protect your company's most important asset, Server 2003 comes with a version of Windows Backup, complete with support for a wider array of backup destinations and an integrated scheduler.

Using this backup program, you can back up either to files or to tapes or create files for system recovery.

### Basic Data Backups

Backup is in the System Tools section of the Accessories folder. Open the Backup application, and you'll begin the Backup or Restore Wizard. Let's start with a backup.

After the opening screen, you'll see the screen shown in Figure 19.1, asking you whether you'd like to back up or restore files. Choose to back up.

**FIGURE 19.1**

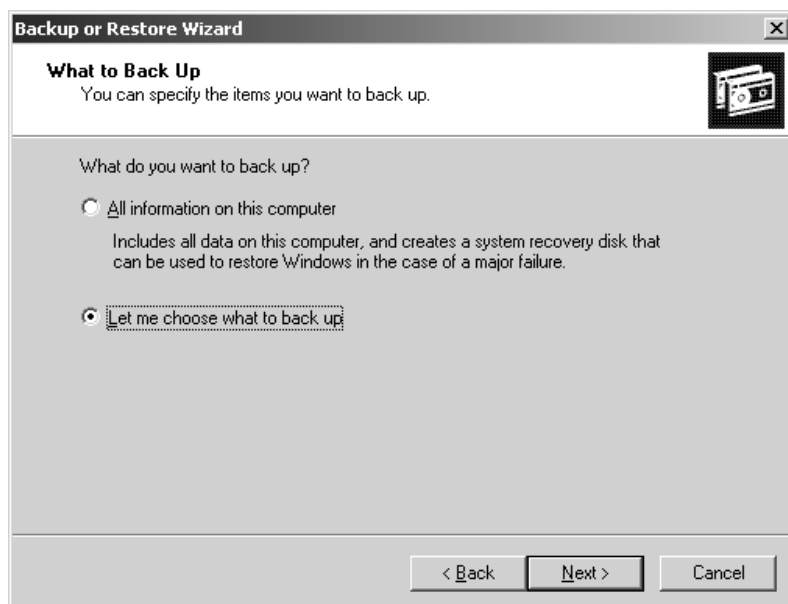

The simple wizard can accommodate either backups or restorations.

Next, you'll need to choose the range of data to back up. As you can see in Figure 19.2, in Server 2003, you've got two options—to back up everything and make a system recovery disk, or choose the individual files you want to back up. (Domain controllers will have a third option—backing up only the System State data.) For now, pick the option that allows you to choose the files.

**FIGURE 19.2**

Backing up selected files

In the next window, you can drill down to find the files and folders you want to back up, whether on the local computer, the network, or even in trusted domains (see Figure 19.3). This is a list of the assigned drive letters of all partitions. The drives listed are *logical* drives, not physical drives. You can sort the available drives by clicking the headings of the Name, Total Size, or Free Space. This list includes all drives on the server, not just fixed or local drives.

**FIGURE 19.3**

Backing up the contents of the Win2K folder

You may have to do a little exploring to find the files you want to back up. Perhaps you *think* that the Applications drive (drive D:) is the one with the data you want to protect, but you're not sure. You can find out for sure by double-clicking the drive to see its folders. If you want to, you can drill down yet further within those folders to expose the subfolders, all the way down to file level. When you find the appropriate folder, you can deselect any object within this folder and prevent it from being backed up. If you do so, the check mark in the folder's box will be gray, instead of the blue that indicates all its contents are selected. Similarly, the box next to the logical drive that a selected folder is stored on will have a gray check mark indicating that part of its contents are selected for backup, but not all.

You can choose as many different files and folders on as many different drives as you like to be part of a backup set. They don't have to be juxtaposed or arranged in any kind of logical form, but they will retain their location on the final backup media. You can't, however, choose to back up all files of a certain type, regardless of location. Backup is organized by location, not by file type. You can't check boxes next to any structures except files or folders—this keeps you from accidentally choosing to back up all the shared files in a domain, for example.

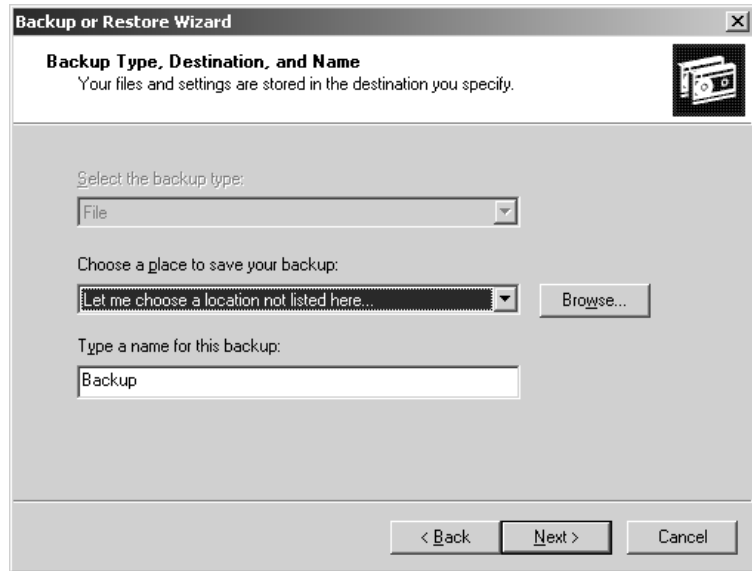

**TIP** If you're backing up network drives or backing up to a network location, make sure this network location is available at the time you run the backup. This is really an issue with scheduled backups, but it can be a frustrating one if it catches you off guard.

Next, choose a location for the backup using the dialog box in Figure 19.4. If you've got a tape drive, you'll be able to back up to tape; otherwise, you'll need to choose a location for the backup file (.BKF).

By default, the backup file is named `Backup.bkf` and stored in `My Documents` for whomever is logged in and performing the backup, but you can click the `Browse` button to choose an alternative backup location. The first time you run Backup, you *will* need to choose a backup location.

**FIGURE 19.4**

Choosing a backup location

Once you've told Windows Backup where to put the backup file, click `Next` to display the final screen that displays your backup options (see Figure 19.5). If you click the `Finish` button, you'll start the backup.

**FIGURE 19.5**

The final screen of the wizard displays the current backup settings.

That's a basic backup, using all the default options. If you want a little more control over how the backup is performed (that is, the options for How and When), click the Advanced button before clicking Finish to start the second part of the wizard and decide on the options listed in Table 19.1.

**TABLE 19.1: ADVANCED BACKUP OPTIONS**

OPTION	DEFAULT SETTING	WHAT IT MEANS
What type of backup should be performed?	Normal	You can choose from normal, copy, incremental, differential, or daily backups. These backup types are described later, under "Choosing a Backup Type."
Verify data?	No	Verifying a backup compares the data on the backup media with the source media to make sure that the data was copied correctly. Verifying a backup takes some additional time, but I'd do it anyway—it's a good way of getting a record that the data was written as expected.
Use hardware compression?	No	This option is only available if you're backing up to tape. If you choose it, then the tape will have a higher capacity than it would have had otherwise.
Append or replace existing backup sets?	Append	If the backup media already contains a backup, you have the option of either replacing that backup or adding the present backup to the catalog. The option you choose depends on which is more important to you: keeping the backup media uncluttered so you can easily find the backup set for restoration or maintaining multiple backup sets. I'd suggest replacing full backups (although you should always archive at least one full backup in case something happens to the current one) and appending incremental and differential backups.
Restrict access?	No	If you've chosen to replace any backup sets already on the media, you can choose whether to restrict access to those sets to members of the Administrators group and the person creating the backups.
What is the name of the backup and the media?	Time and date backup was created	Provide a name for the backup set. If you're using new media, or replacing the data on existing media, you can choose a new name for the tape or file.
When should the backup run?	Now	You can choose to run the backup now or pick a time at which it should run. If you're backing up a server, then you'll almost certainly want to schedule it for later, when people aren't using the data.
Back up migrated remote storage data?	No	This option backs up rarely used files that have been automatically archived in remote storage.
Disable volume shadow copy?	No	Volume shadow copying allows files to be backed up while in use.

The only Advanced backup option that might cause you any trouble is the scheduling tool, which I'll cover later in the section "Scheduling Automated Backups." When you've finished choosing options, you'll see the Finish screen again, showing the updated options.

## Advanced Backup Options

Let's look at these advanced backup options in some more detail. Open the Backup tool in Advanced mode (this will make it look like the Backup tool in Windows 2000) and choose Tools/Options to open the tabbed Options dialog box.

**NOTE** Settings you choose from this tabbed dialog box will apply to all backups. To set advanced options on for individual backups, click the Advanced button on the last page of the Backup or Restore Wizard.

### CHOOSING A BACKUP TYPE

The default backup type for Windows Backup is Normal, which is a not-very-descriptive way of saying that Windows Backup performs full backups (copies all files and resets the archive bit on all copied files) unless told otherwise. If you turn to the Backup Type tab shown in Figure 19.6, you can choose one of the options described in Table 19.2.

**FIGURE 19.6**

Choose a new backup type if you don't want to perform full backups.

**NOTE** The archive bit is a hidden file attribute applied to a file when it's created or edited. It's used to tell a backup or copy utility, "Hey, this file has changed." Resetting the archive bit removes the archive bit from a file; setting the bit adds it.

**TABLE 19.2: SUPPORTED BACKUP TYPES**

BACKUP TYPE	DESCRIPTION
Normal	Copies all selected files and then resets the archive bit
Incremental	Copies all selected files with the archive bit set and resets the bit
Differential	Copies all selected files with the archive bit set but does not reset the bit
Daily	Copies all selected files that were edited the day the backup was performed
Copy	Copies all selected files but does not reset the archive bit

You can use these backup types in combination to back up files completely and efficiently. The longest interval you'll want to have between backups is probably a day—lose more than a day's worth of work, and you're in big trouble. (Losing a day's worth of work is bad enough, which is why companies with really critical data use RAID to protect their data, as discussed in Chapter 10.) Running a normal backup every day takes up a lot of time and space, so you can run a normal backup at regular intervals, perhaps once a week, but supplement this weekly full backup with a daily differential or incremental backup. Running a daily differential backup gives you a daily copy of all the files that have changed since the last full backup; incremental backups copy all the files that have their archive bit set. Either differential or incremental backups work well as a supplement to a regular normal backup. I find differential backups easier to perform and restore because restoring a server becomes a matter of restoring the most recent normal backup and the last differential one. Restoring incremental backups is a slower process, as you must restore each incremental backup made since the last full backup individually. However, incremental backups take less time to perform than differential backups.

Daily backups aren't really a method of preserving data, but more a way of quickly finding files that you're currently using and transferring them to other media. You might find it useful to run a daily backup on a user's files to copy the ones he needs to a laptop for a business trip, if the client isn't using Win2K Pro or Windows XP (or they're using a common computer) and so doesn't have the option of using Offline Files. *Copying* files is only useful if you want to make a complete copy of all selected files without resetting the archive bit. A copy action like that is a way of copying files to a new location.

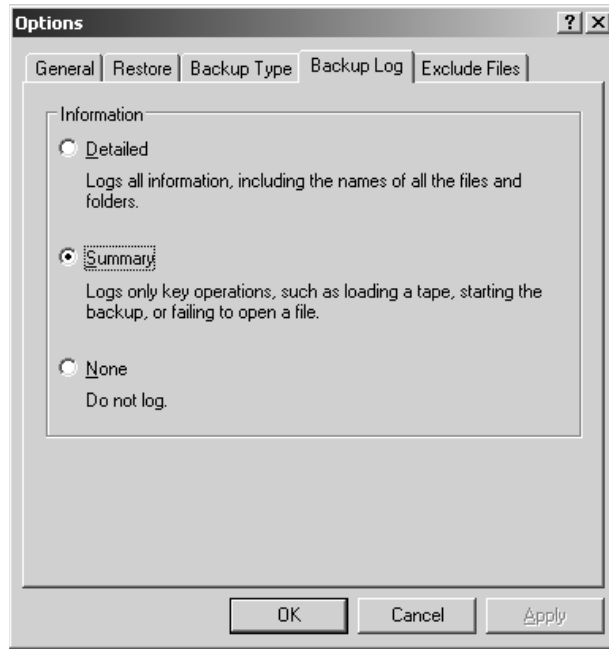

### CHOOSING A LOGGING TYPE

Backup logs are a useful troubleshooting tool. If something goes wrong with the backup, then you can inspect a text-based log to see *what* went wrong. In fact, it's a good idea to at least scan the backup logs produced after each backup to make sure that the procedure went as expected.

How much information do you log? Normally, Backup logs only errors and important events, but if you turn to the Backup Log tab of the Options dialog box (see Figure 19.7), you can choose not to log (bad idea, as that disables a troubleshooting tool) or to log *everything* (also a bad idea for anything other than a daily or perhaps incremental backup, as it will make your logs so big that it will be hard to find errors). Unless you need a complete record for some reason, the summary log option (the default) is probably your best bet.

**FIGURE 19.7**

Choose a logging option.

### WHICH FILES DO YOU WANT TO BACK UP?

Even if you're running a full backup, you don't necessarily want to save *everything*. For example, do you really need to preserve the contents of the paging file? Probably not. For this reason, Windows Backup does not normally back up any files that don't contain real data—a user cache, a page file, temporary Internet files for the person running the backup, and the like. You can edit this list from the Exclude Files tab of the Options dialog box (see Figure 19.8).

The Add New and Remove buttons on this tab are pretty self-explanatory. Unless you have real reason to remove one of the already excluded files from the list, I suggest that you leave them alone, as the files listed are not really anything you need to back up.

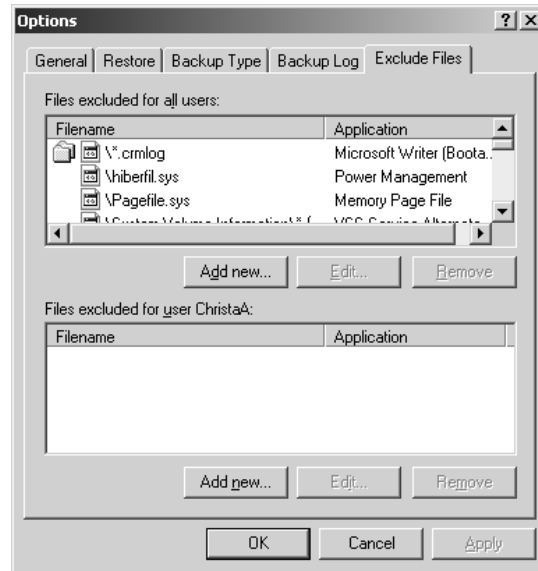

To add files to exclude from the backup, click the upper Add New button to display the dialog box shown in Figure 19.9. The list in the upper half of the dialog box contains all the file types recognized by the server. You have to know the extension for the type of file you want to exclude from the backup, but many of the extensions are labeled so you can be sure that you've got the right one. (If an extension isn't labeled and you don't recognize it as an application file extension, files of that type are probably part of the operating system and can be reinstalled. Just be sure to check before you exclude the files from the backup.) In the Registered File Type list, click the file type that you don't want to back up, Ctrl+clicking to select more than one option at a time. When you click OK, you'll see your selection(s) added to the list of excluded file types. For example, if you don't want to back up any application files (on the principle that you can reinstall the applications if necessary), then you'd find `.exe` in the list, highlight it, and click OK.

The Custom File Mask text box is for extensions that aren't registered file types (ones you've created yourself for certain files) or for filtering files by name. The syntax for this file mask depends

on whether you're filtering by filename or extension. If you want to eliminate all files *named* `abc.*` from the backup, then type `abc` in the box—no asterisks necessary. To eliminate all files with the *extension* `.abc`, then type `.abc` (note the period) in the box.

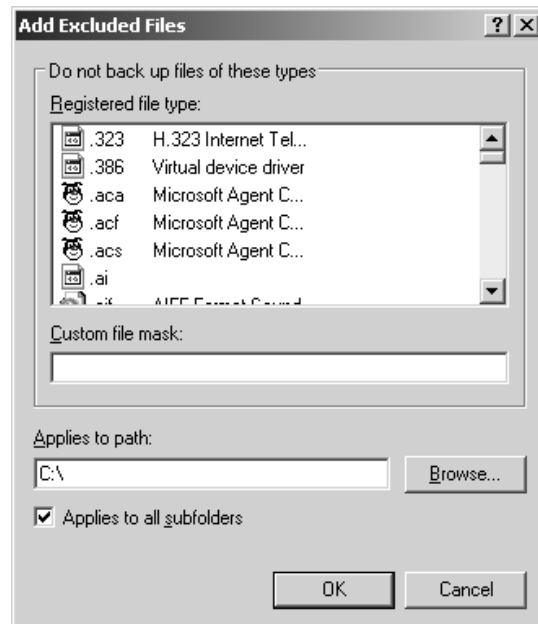

**FIGURE 19.8**

Change the files to exclude, or edit the settings for excluded files.

**FIGURE 19.9**

Choose from registered file types, or type in custom extensions.

**NOTE** You must enter each custom file mask separately. If you enter two at once—say, for `.abc` files and `.def` files—then you’re telling Backup to skip all files with the extension `.abc.def`. Using semicolons or other punctuation to separate the entries doesn’t work.

By default, your file mask will apply to the entire C: drive. To edit this to apply to a different drive or only a specific folder, type in a new path or click the Browse button to open a file tree (see Figure 19.10) from which you can choose the path you want the mask to apply to. You can choose drives either on the local machine or on network-accessible drives.

**FIGURE 19.10**

Browse for the path to apply a file mask to.

When you click OK to exit the Add Excluded Files dialog box, the path information will be listed with the file types to be excluded on the Exclude Files tab.

The file types you’ve excluded will apply to all users. If you’d like to exclude file types only for the person currently logged in (there’s no way to specify another user or a group), then click the Add New button for the bottom window of the Exclude Files tab. You’ll enter the same Add Excluded Files box that you saw previously, and it works the same way. The only difference is that the files you exclude will only apply to the ones you own. For example, if I chose to exclude `.doc` files for myself, then everyone else’s `.doc` files would be backed up, but mine (the ones I created and own) would not.

**TIP** The per-user masking depends on current file ownership, so if a file was created by Joe but Jane took ownership of it, the file would still be backed up if Joe added it to his personal file mask, but not if Jane did. It doesn’t matter whether Joe, Jane, or Fred is running the backup: So long as Jane owns that file, then it’s excluded from the backup.

Notice that the exclude tool really only excludes files—you can’t use it to include only files with certain extensions in the backup. Sadly, there doesn’t seem to be any way to specify that only certain files should be backed up. Even the command-line utility NTBACKUP (which I’ll discuss a little later in the “Scheduling Automated Backups” section) doesn’t accept wildcards.

## GENERAL BACKUP OPTIONS

The General tab of the Options dialog box contains the options explained in Table 19.3. These options control the settings that really don't fit anywhere else in the categories of options.

**TABLE 19.3: GENERAL OPTIONS FOR BACKUP AND RESTORE OPERATIONS**

OPTION	DEFAULT SETTING	WHAT IT MEANS
Compute selection information before backup and restore operations.	Enabled	This is a confusingly worded way of saying that Backup will count the files and folders to be backed up or restored before actually performing the operation. I'd leave this enabled; it doesn't add much to the time required to run the operation, and this information can save you from backing up or restoring the wrong volume or backing up to media that's too small.
Use the catalogs on the media to speed up building restore catalogs on disk.	Enabled	This is the fastest way for Windows Backup to create a list of all the files and folders in the backup. You should only disable this option if you're restoring data from several tapes and don't have the one with the catalog (the first tape) or if the catalog is damaged. With this option disabled, Windows Backup will scan the entire backup set and attempt to build its own catalog. Since reading tapes is a slow process, this could take a long time for a large backup set—perhaps hours.
Verify data after the backup completes.	Disabled	This compares the data on the disk with the data on the backup media after the backup has been completed and records any differences. Although verifying adds some time to a backup, I'd recommend doing it. It's a good way to be sure that files were written correctly.
Back up the contents of mounted drives.	Enabled	Normally, mounted drives (logical drives mapped to a path on another logical drive—read Chapter 10 to learn more about them) can be backed up like other media. If you check this box, the data won't be backed up—just the path information.
Show alert message when I start Backup and Removable Storage Management is not running.	Enabled	If the Removable Storage Management (RSM) service isn't running, you can start it from the Services object in the System Tools folder of Local Computer Management. This service must be running for you to back up files onto RSM media such as tape drives.
Show alert message when I start Backup and there is compatible Import Media available.	Enabled	If this box is checked and you add new RSM storage media, Backup will display a message on startup saying that it's found more media for the Import pool (to which files can be archived).

*Continued on next page*

**TABLE 19.3:** GENERAL OPTIONS FOR BACKUP AND RESTORE OPERATIONS (*continued*)

OPTION	DEFAULT SETTING	WHAT IT MEANS
Show alert message when new media is inserted into Removable Storage.	Enabled	If this box is checked, Backup will display a dialog box when it detects new RSM media.
Always move new import media to the Backup media pool.	Disabled	If this box is checked, Backup will assume that any new media it detects should be added to the Backup media pool, and thus be available for backups.

**NOTE** *Removable Storage Management is used with tape drives and other archiving media. If you normally back up to a file on any kind of disk (including a removable disk like a Jaz drive) instead of tape, you don't have to worry about the Removable Storage Management settings.*

### SAVING BACKUP OPTIONS

You can define settings for a backup job and save them to be used later or reused at your discretion. To do so, make sure that you've chosen the files to back up. Then, in the Advanced view of the Backup utility, choose Job/Save Selections. You'll see a Save Selections dialog box prompting you to save the backup script (normally saved in %systemroot%\Documents and Settings\%username%\Local Settings\Application Data\Microsoft\Windows NT\NT Backup\data).

If you load a saved backup script when you have files and folders selected for backup, Backup will ask whether you want to use the currently selected folders or clear them. Clear them to load the backup script, and you'll be ready to run the backup job.

### Scheduling Automated Backups

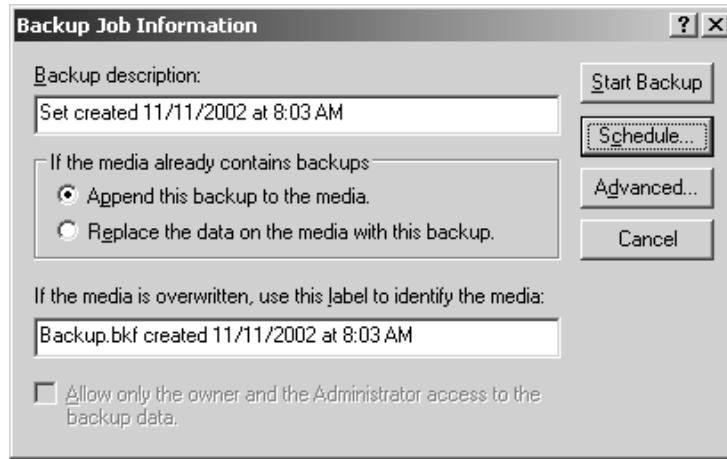

To be safe, you should back up data servers at least once a day. Trouble is, the best time to back up is late at night when everyone's off the network. With NT 4, you could use the AT command or WinAT utility to schedule backups created from the command line. Beginning with Windows 2000, you had the choice of two backup-scheduling methods, one using the GUI, and one using the AT command for running scripted backups created with an updated command-line version of NTBackup.exe.

There are a few ways you can schedule jobs from Windows Backup:

- ◆ In the Backup Wizard one of the Advanced options asks whether you want to run the backup you've created now or schedule it for later. If you choose to schedule it for later, you'll be taken to the Schedule Job dialog box, which I'll discuss in a minute.
- ◆ In Windows Backup, when you create a backup job from the Backup tab and click the Start Backup button, you'll see a dialog box that prompts you for the name of the backup and allows you to start the backup now or schedule it for later (see Figure 19.11). If you click the Schedule button, you'll be taken to the Schedule Job dialog box. If you're creating a new backup job, you must save the backup and provide the username and password of the account used to run it before you can save the backup settings.

**FIGURE 19.11**

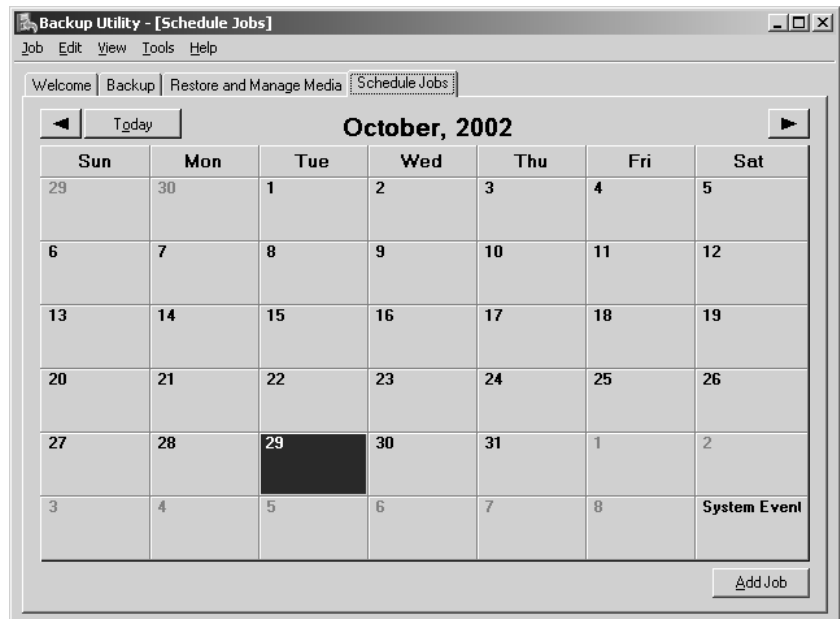

When creating a backup job, you have the option of running it immediately or running it at a later time.

- ◆ If you're creating a new backup job, you can turn to the Schedule Jobs tab, where you'll see a month calendar like the one shown in Figure 19.12. To create and schedule a backup job from the Schedule Jobs tab, click the Add Job button in the lower-right corner of the screen to start a Backup Wizard similar to the one described earlier under "Basic Backup Procedures"—the only difference between the two wizards is that this one includes the advanced options in the main wizard, rather than through the Advanced button on the wizard's final screen. One of the options you'll be presented with is the choice of running the backup now or later, with the default time for "later" being midnight of the day you set up the backup job. To schedule a job, select Later and click the Set Schedule button to open the scheduler.

**FIGURE 19.12**

The Schedule Jobs tab of Windows Backup

No matter how you get to it, the Schedule tab of the Schedule Job dialog box looks like Figure 19.13. The basic options are pretty straightforward. Choose the interval at which you want the backup job to run (once, daily, weekly, monthly, at system startup, at logon, or when the computer is idle) and the starting time and date. If you select the Show Multiple Schedules check box at the bottom of the screen, a new drop-down list will appear at the top of this dialog box, showing the varying intervals and starting times that you've chosen for this job.

**FIGURE 19.13**

Choose a time and frequency for the backup job.

**TIP** If you want to run a backup job biweekly (once every two weeks), show multiple schedules and create two monthly backup jobs that start on different days.

The Advanced button takes you to the Advanced Schedule Options (see Figure 19.14), which apply only if you want to repeat the backup job, apart from any interval that you set in the main scheduling screen. Most often, you won't need to touch these options. You don't need to use them for scheduling jobs at regular intervals; this set of options would be more useful for a shorter task and one that might actually need to be run every 10 minutes or so. (Frequent backups are a Good Thing, but let's not get carried away.)

More likely, you'll use the Settings tab back in the main Schedule Job dialog box (see Figure 19.15). From here, you can specify how long the job should run (a backup job that lasts more than 72 hours seems suboptimal) and whether the job should be deleted from the list of tasks when it's done unless it's supposed to run again. The Idle Time settings apply to interaction from the console—keyboard or mouse input—so they shouldn't prevent a backup job from running on a server being accessed from the network.

**FIGURE 19.14**  
Advanced backup  
scheduling options

**FIGURE 19.15**  
Configure job  
settings for the  
scheduled backup.

**TIP** With the volume shadow copy service, Backup can now back up open files.

The final options in the Settings tab, on battery use, aren't likely to apply to a server unless you frequently use laptops as servers. These settings help you conserve battery power by not running non-essential tasks when your power supply is limited. Accessing the hard disk takes a lot of power, so backups are an especially draining task when the power is low.

When you've finished adding jobs to the scheduler, they'll appear on the Schedule Jobs tab's calendar, as shown in Figure 19.16.

**FIGURE 19.16**

Scheduled jobs appear in the calendar.

You're not stuck with the options for a scheduled job once it's created. To edit the settings for a scheduled job, just click its icon in the calendar to open the Scheduled Job dialog box shown in Figure 19.17. To delete the job, just click the Delete button.

**FIGURE 19.17**

You can edit all job settings even after the job is added to the task list.

Click the Properties button to edit the timing and settings for the backup job. The Schedule and Settings tabs that appear are the same ones you saw when scheduling the job. The Task tab that also appears, however, is new. Here, you can choose a different job to run at the scheduled time, specify a different user account in whose context the job should run, and create some identifying information for the job.

## Backing Up to Tape

Windows 2000 introduced a whole new layer of software called the Removable Storage Manager (RSM). You wouldn't think that you'd need to know anything about RSM to do backups, but RSM is the basis of Windows 2000's and Server 2003's backup and archival capabilities. A backup program needs both drivers for the storage devices it works with and the intelligence to control those devices. NT 4's backup program directly managed the tape drives it worked with (as you may recall, NT 4's backup program only worked with a tape drive—you couldn't even *start* the program unless you had a tape drive installed). So long as you were happy with NT 4's choices, this was fine, but NT 4 was designed in a day when hard disks were a lot smaller than they are now. For example, NT 4's backup program did not support DAT *autoloaders*, systems where there's usually only one tape drive (although there can be more) with a built-in capacity to store and automatically load or unload several other tapes. If you wanted to use a DAT autoloader, you needed a third-party backup program that knew how to handle it.

**NOTE** *If it's not clear why you'd want an autoloader, a tape drive that can automatically insert and eject a stack of tapes, then you've never done regular backups on a hard disk (or a group of disks) whose capacity is greater than your tape drive's. For instance, 4-mm DAT drives are pretty good, fairly fast, and reliable. . .but only store about 8GB. To back up an entire 40GB hard disk using DAT drives, you'll need to baby-sit a backup program that prompts you every now and then to "please insert tape 4. . . ." I'll pass.*

One way to make NT 4's backup program more flexible about its storage would be to create special tape-emulating drivers that would make *any* storage appear to be a tape drive. That is, even if the storage were, say, a CD-RW drive, then it could accept tape-related commands such as "rewind" and "retension" even though it can't use them. However, to my knowledge no such drivers exist. RSM performs a similar function by abstracting the interface not just to tape drives but to all removable storage. Backup doesn't manage its storage, RSM does.

**NOTE** *Even though they're not RSM aware, NT 4-era backup programs will generally run on Windows 2000. However, they won't back up anything that employs the new features of NTFS: encrypted files, Single Instance Store volumes, or sparse files.*

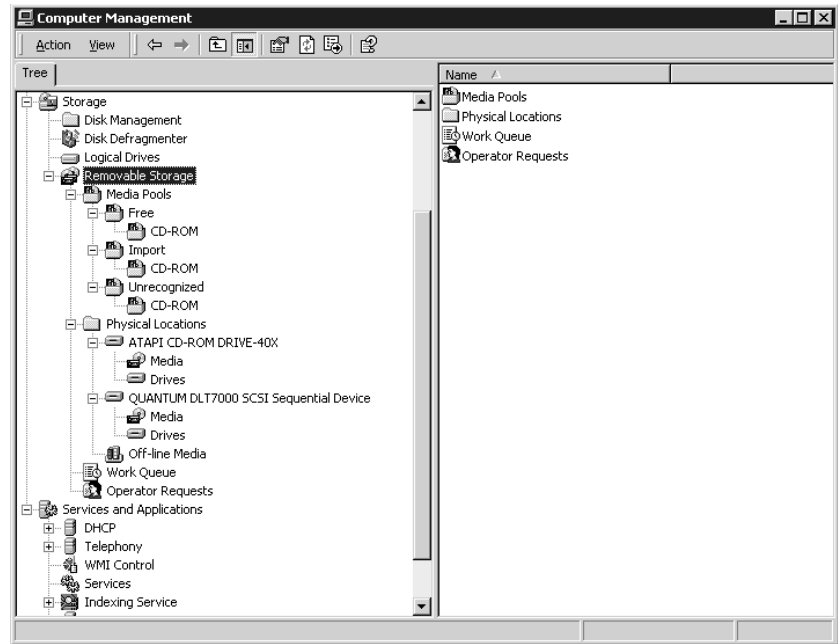

Although it's an intrinsic part of Backup, RSM also supports *any* program that uses removable storage, such as the archiving capabilities that back hard disk space with offline storage. In other words, RSM is not just about making backups work, but that's the part I'll focus on here.

### RSM CONCEPTS: PHYSICAL LOCATIONS, LIBRARIES, DRIVES, MEDIA

To use the RSM-enabled features of backup, you'll need to know a physical location from a library from a drive from media. You can see the GUI interface for the Removable Storage Manager in Manage Computer. Right-click My Computer and choose Manage, then open up the icon labeled Storage, and you'll see something like Figure 19.18.

**FIGURE 19.18**

RSM before any backups

This computer has just two removable storage devices—a standard EIDE-connected CD-ROM drive and a DLT1 tape drive. There are no tapes in the DLT1 drive and NTBACKUP has never run on this system (you’ll see why I mention that in a minute). Notice that under the **Removable Storage** level, there are four objects:

- ◆ Media Pools
- ◆ Physical Locations
- ◆ Work Queue
- ◆ Operator Requests

I’m going to skip the last two and just focus on the first two because they apply to backing up.

### ***Physical Locations = Mechanical Drives***

Of these two, **Physical Locations** is the easier to understand. In Figure 19.18, I expanded it, so you can see three objects—a drive icon representing the CD-ROM (ATAPI CD-ROM DRIVE-40X), one representing the tape drive (QUANTUM DLT7000 SCSI Sequential Device), and one labeled **Off-Line Media**. **Physical Locations**, therefore, are the drives that RSM can manage. Not the *media* in those drives, but the drives.

### ***Library = “Autoloader” or “Stand-Alone Drive”***

When I right-click either the CD-ROM or the tape and choose **Properties**, I get a properties page describing not the drive, but the drive’s interface. I’ll also see a lot of references to the device as a

*library*. There is, for example, no button or check box to disable the device; instead, you'd see an Enable Library check box and unchecking it would disable the device. To RSM, a *library* is one or more drives that have an automatic changer for their tapes, cartridges, discs, or whatever. (For shorthand, I'll call them generically *tapes*.)

As you can see, Microsoft has upped the ante on its definition of the "basic removable storage doodad." Where it once was a tape, now it's a *tape library*, one or more tape drives and zero or more *changers*, the little robotic hands. My humble DLT tape drive is, then, a library consisting of *one* tape drive and *zero* changers. (Yeah, it's kind of simple. I couldn't afford that really cool HP autoloader with four drives and capacity to hold 60 tapes—\$46,000 was a bit out of my budget—so I'll stick to DLT for the moment.) Microsoft even has a name for a zero-changer, one-tape-drive library: a *stand-alone library*. That's not just a CD-ROM on your system, my friend, it's an optical stand-alone library. Notice also that in addition to my DLT and CD-ROM "libraries," I have a third one called my Off-Line Media library. *Off-line media* is Microsoft's way of describing wherever you store tapes when they're not in your drives. So tapes sitting in a desk drawer or on a shelf are in a library.

This may sound odd, but it kind of makes sense once you adopt the RSM way of thinking. RSM's main job actually seems to be a kind of database that lets you keep track of your tapes. As you'll see, this database keeps track of the following information about tapes:

- ◆ Where they are physically located—on a shelf, in an autoloader waiting to be inserted into a drive, actually in a drive
- ◆ What program wrote them
- ◆ What sort of drive can read and write them
- ◆ What data is on them

RSM really only *secondarily* concerns itself with the specifics of what sort of drives you have. Calling them all libraries allows you to concern yourself with where your *data* are, not where your tapes or CDs are.

This information is not just available from the GUI; RSM has a command-line tool called RSM.EXE. To get the list of your libraries, just type **rsm view /tlibrary**. That gets a result like this:

```
LIBRARY

Off-line Media
ATAPI CD-ROM DRIVE-40X
QUANTUM DLT7000 SCSI Sequential Device
```

The command completed successfully.

Notice the odd spacing—there is no space between /t and library. We'll use **rsm view /t** again—the /t means "type of thing to view"—and its odd syntax requires no spaces between /t and the parameter describing what you want to view. As with other things in Server 2003, though, those names are just the human-friendly names. Under the hood, the OS *really* identifies things by globally unique IDs (GUIDs), and sometimes you'll need to know what they are, as you'll see later. You can find that out by adding the /guiddisplay switch, like this:

```
C:\>rsm view /tlibrary /guiddisplay
```

LIBRARY

```
Off-line Media D49F02AE9CEA46BFB58E51AB6C7FE262
ATAPI CD-ROM DRIVE-40X 6043C178219841208E034076D0566885
QUANTUM DLT7000 SCSI Sequential Device E30ADF03E8014BA4BB824AD69B39FBE7
```

The command completed successfully.

```
C:\>
```

**Media = Tapes, Cartridges, CD-ROM Discs, Etc.**

Within the CD-ROM and tape drive objects there are then, in turn, two objects, Media and Drives. *Drives* of course refers to the physical drive. But *media* needs some defining. To RSM, media means anything that you put into a drive. Tapes go in tape drives, so tapes are media. CD-ROMs go into CD-ROM drives, so they’re media. But media doesn’t mean a *type* of media, it means particular *instances* of media. As I suggested before, RSM’s job seems to be to maintain a database that keeps track of every single tape that you ever shove into one of your tape drives.

The folder labeled **Media** under a drive’s icon in the **Physical Locations** object will contain an object representing the particular tape, cartridge, or disc sitting in your drive at that moment. For example, if I insert a CD into my CD-ROM drive and click the **Media** folder under **ATAPI CD-ROM**. . . then I’ll see something like Figure 19.19. Notice that under **Loaded Media** it says **STREETS9**. That refers to a piece of software, as this is the installation CD for a mapping program.

**FIGURE 19.19**  
CD-ROM as media

**NOTE** In truth, RSM isn’t very useful for CD-ROMs; this is just an example of how it works that you can try out on almost any system. As I’ve said before, NTBACKUP cannot use CD-R, CD-RW, DVD-RW, or DVD+RW drives.

I can easily use the GUI to see that my CD-ROM drive contains a CD whose label is **STREETS9**, but I’m going to want to be able to retrieve that kind of information from the command line; for that, I’ll use more of RSM.EXE. To get information on a particular tape, I’ll use the `physical_media` option on the `rsm view` command. But just typing `rsm view /tphysical_media` won’t do the job—that will display *every* bit of removable media on the system at the moment. (Admittedly that’s not a real

problem on *this* computer, as it only contains one bit of removable media, the CD. But let's see how to do it on more real-world systems.)

To narrow the scope of `rsm view /tphysical_media`, I'll add a parameter, `/cg` for "container GUID." As I'm trying to find the GUID of the CD-ROM disc sitting in the CD-ROM drive at the moment, the container is the CD-ROM drive. As you saw a moment ago, I get that with the `rsm view /tlibrary /guiddisplay` command. As you can see here, to find out about the media in the drive, I'll just plug the drive's GUID into the command like this:

```
C:\>rsm view /tphysical_media /cg6043C178219841208E034076D0566885
```

```
PHYSICAL_MEDIA
```

```
STREETS9
```

The command completed successfully.

**TIP** If you're wondering how you can accurately type a GUID, don't worry. To type that command, I highlighted the GUID from the `rsm view /tlibrary /guiddisplay` output and pressed `Enter`, which puts the highlighted text into the Clipboard. Then I typed `rsm view /tphysical_media /cg`, clicked the icon in the upper-left corner of the window to drop the Control Menu for that window, then chose `Edit/Paste`.

Note that as with the parameters following `/t`, I typed the GUID after the `/cg` command without any spaces after the `/cg`. Note also that if I needed to retrieve the GUID of the media (which we'll want to do later in with tapes), I could have added the `logical_media` command.

You can drill down even further than a given tape—physical media contain one or more partitions, and partitions contain one or more `logical_media`. In each case, you'd just use `/guiddisplay` to get the GUID of the container and then feed that with `/cg` as the GUID of the container to view.

### MEDIA POOLS: CLASSIFYING TAPES

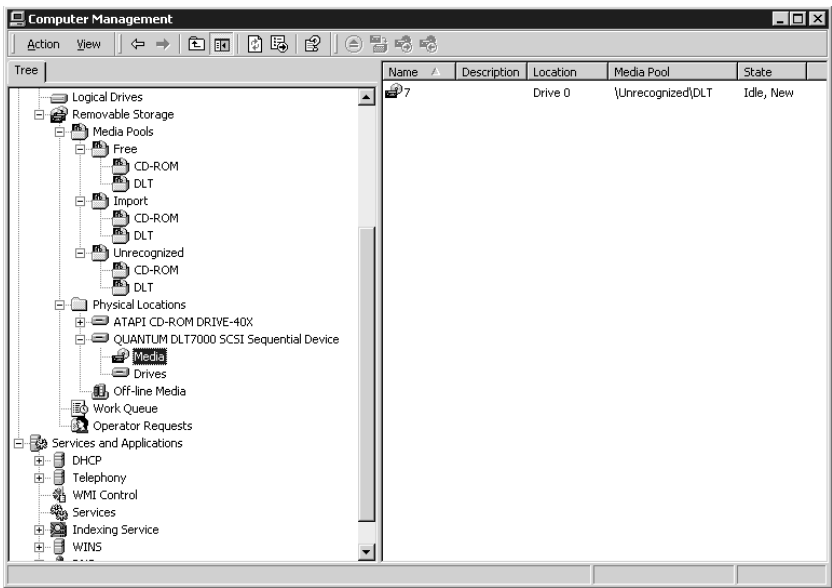

Thus far, I haven't shown you much of anything that has to do with tapes, so let's pop a tape into the drive and see what happens. Note that this is a *new* tape, fresh out of the box. It's never been introduced to this drive, or to NTBACKUP, before.

After inserting the tape and waiting for the tape drive to settle down, I right-click the `QUANTUM DLT7000...` drive and choose `Refresh` to force RSM to reexamine the drive's status. I then click the `Media Pools` folder under the tape and see a screen like Figure 19.20.

Notice that a few things happened. First, the `Free`, `Import`, and `Unrecognized` media pools (I'll get to what they are in a minute) now have a `DLT` folder underneath them, where previously they only had a `CD-ROM` folder there. Second, the `Media` folder for the tape drive now contains something called "7" that is said to be in Drive 0 in a media pool called `Unrecognized\DLT`; its state is reported to be `Idle, New`. And sure enough, clicking the `DLT` folder under the `Unrecognized` folder in the `Media Pools` object shows another item named 7—it's the same tape—in that folder. (If you're not crazy about naming a tape "7," then fear not. The later section "Renaming a Tape" explains how to change a tape's name.)

**FIGURE 19.20**  
Remote Storage  
Manager after  
inserting new tape

Basically, this is RSM-ese for “this tape is unformatted.” That’s not exactly right, as DLT tapes ship formatted, but RSM wants to write a bit of identifying data onto the tape. I can do that by right-clicking the tape’s icon in the right pane; I’ll get a menu that offers Eject, Mount, Prepare, and Dismount. I choose Prepare and see a dialog box that says:

This operation will destroy the data on the media and move it to a Free media pool.  
Are you sure you want to write a Free media label on the selected medium?

I choose Yes and get *another* confirmation message:

Are you sure you want to write a Free media label on 7?

What *are* you, hard of hearing, RSM? I click Yes again and the tape’s media pool changes to Free\DLT and its state goes to Loaded, Unprepared while the tape spins for a few minutes. It finally finishes whatever it does when “preparing” the tape, and the tape ends up in Free\DLT in a state of Idle, Available.

**NOTE** There is not, as far as I can see, a command-line tool in RSM.EXE that will prepare never-before-used tapes. But that won’t be a problem since NTBACKUP has a /um option that automatically erases and prepares tapes before backing up.

Now I can explain the next RSM concept, *media pools*. Remember that RSM is a database of tapes. Even if you just shove a tape into a drive once, prepare it, remove it, bury it in a mine shaft, and never look at it again, RSM remembers that tape. Remember also that the RSM word for a tape is *media*.

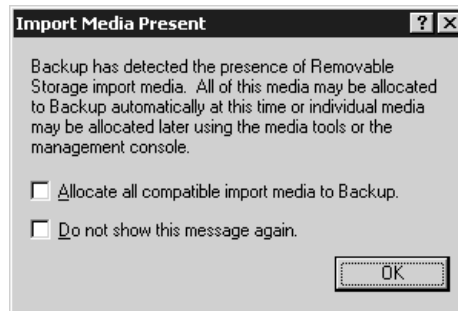

RSM wants to organize the media that it has met into categories and, by default, it categorizes media in one of three ways:

- ◆ *Free media* are tapes that RSM has “prepared” but that don’t have any data on them. They’re waiting to be used by some RSM-aware application such as NTBACKUP.
- ◆ *Import media* are tapes that RSM recognizes as having been prepared by RSM on this or some other machine in the past. They’re RSM tapes, all right, but they’re not blank (so they don’t go into Free). They’re also not associated with a particular RSM-aware application. As you will soon see, RSM-aware applications create their *own* media pools, and RSM will then be able to categorize some media as neither Free, Import, or Unrecognized—they’ll be categorized as Backup tapes, ArcServe tapes, BackupExec tapes, or the like. So Import is a kind of catch-all category meaning, “This tape has been prepared, so it doesn’t go into Unrecognized, it’s not blank, so it doesn’t go into Free, so some application *has* worked with it before, but I don’t remember it, so it’ll stay here in Import until the user decides to drop it into some application’s folder.”
- ◆ *Unrecognized media* have not been prepared to work with RSM. RSM can’t do anything with them until they are.

This will make a lot more sense once we get an RSM-aware application running. When I run NTBACKUP for the first time, that causes it to introduce itself to RSM, and tells RSM to create a new fourth media pool called Backup. Now that I’ve run Windows 2000’s backup program, any tape that NTBACKUP writes to will become essentially the “property” of NTBACKUP. As a matter of fact, if I *had* media sitting in the Import media pool that had been originally created by NTBACKUP on some other system, then the first time that I started up NTBACKUP I’d have gotten the dialog box that you see in Figure 19.21.

**FIGURE 19.21**

Should Backup be able to claim old backup tapes?

Even if you don’t allow NTBACKUP to import the media now, you can do it by hand later; you can just drag any media item out of one media pool and drop it into another. (Of course, if you try to drop it into Free, then you’ll get a warning that dropping it into Free will cause RSM to erase it.)

### MANAGING MEDIA IN RSM

That’s an overview of how RSM works—it tracks particular tapes, giving each one a GUID (which changes whenever you “prepare” a tape) and categorizing it in either an application’s media pool

(Backup on most systems, but if you’ve purchased other RSM-aware apps then you might have more than one application media pool), or one of the “holding tanks”: Free, Import, or Unrecognized. Understand also that you can move media between media pools even if the actual physical tape isn’t currently in the tape drive; the tape doesn’t know and doesn’t care which media pool it belongs to. Tapes *do*, however, carry on them the mark of their associated RSM-aware application, which is why you can take a tape created on one system, pop it into another Server 2003 system, and it will immediately be recognized as having already been seen by RSM *and* NTBACKUP will recognize that this tape contains data written by NTBACKUP.

We’re just about done with RSM and almost ready to tackle NTBACKUP.

### **Renaming a Tape**

As intuitive names for my first tape go, “7” is not ranking high. So how about I give it a more useful name? I intend to use this tape as one of two tapes that I’ll store differential backups on, so I’ll rename it “Diff1.” To do so, I’ll right-click the tape and choose Properties. The General tab has a text field that includes the name of the tape.

For some reason, renaming the tape doesn’t seem to be enough to convince NTBACKUP that the tape has a new name. In my experience, you need to then put the tape in the Free media pool so that it is reinitialized.

**WARNING** *Moving the tape to the Free media pool deletes any data on the tape, so don’t do this if there is any data on the tape that you’d miss!*

### **Moving a Tape to Free**

Sometimes you won’t be able to move a tape from the Backup media pool to the Free media pool. You must first “deallocate” it. Now, *finding* where to deallocate a tape may be a challenge.

You’ve already seen that by right-clicking a media object you’ll get a drop-down context menu that includes four actions—Eject, Prepare, Mount, and Unmount. Below that is a submenu, All Tasks, which on *most* MMCs would just repeat Eject, Prepare, Mount, Unmount. But *this* one includes a fifth option...Deallocate. So to free an existing tape, first right-click it and choose All Tasks/Deallocate, and then drag it to Free. (And along the way, say “yes” to all of the “are you sure?” messages.)

### **Ejecting a Tape from the Command Line**

We’ve been going over RSM to get ready to do backups and command-line backups in particular. Over the years I’ve seen people write batch files for handling backups, and some folks like to end off the backup process with an `eject` command. I guess it makes for a slightly more secure backup because once the tape’s ejected, then there’s no hacker on earth who can convince the tape drive to reinsert the tape. (That’s not true for autoloaders, of course, but it is for stand-alone drives, at least in my experience.) So how do you tell NTBACKUP to eject your tape? With RSM. The command looks like this:

```
rsm eject /pf"name of tape to eject" /ast art
```

Or alternatively:

```
rsm eject /pgGUID /astart
```

In the first case, you fill in the media's name; in the second, you fill in its GUID. Note that if you let NTBACKUP prepare the tape, then it'll have a name like `Media created 1/4/2003 at 5:21 PM - 1`, and for the command to work right, you'll need to type in the media name precisely.

The only real problem with this is that you probably want a fairly generic "eject" batch file, but both versions of `rsm eject` are very tape specific: You've got to either know the name of the particular tape, or know the tape's GUID. Unless you intend to use the very same tape night after night, then this won't be too useful. But consider:

- ◆ The GUID of the tape *drive* won't vary from day to day.
- ◆ If you have the tape drive's GUID, you can use `rsm view /tphysical_media` to get the GUID of the particular tape in the drive at that moment.

Here's how to put all of that together into a batch file that needs only to know the GUID of the drive in order to eject any tape in that drive. If you don't know how batch files work internally, then don't worry about following this—I'll have a ready-made batch file prepared at the end of this section that you can just type in and use (replacing my GUID with the one for your tape drive, of course).

My plan for the batch file will be that I'll use `rsm view` to retrieve the tape's GUID and put it in a variable `%tguid%`. Then I'll just issue the `rsm eject` command with the `/pg` option, specifying the GUID of the tape. I can do all that with just three lines (the second one is broken but should be all on one line):

```
set drvguid=E30ADF03E8014BA4BB824AD69B39FBE7
FOR /F "usebackq" %i IN ('rsm view /tphysical_media /cg%drvguid% /b /guiddisplay')
DO set x=%i
rsm eject /pg%X% /astart
```

In the first line, I'm just filling up an environment variable named `drvguid`. That long value that I'm stuffing in it, `E30ADF03E8014BA4BB824AD69B39FBE7`, is the GUID of *my* DLT drive. Yours will be different, so use `rsm view /tlibrary /guiddisplay` to get the particular GUID for your tape drive and replace my drive's GUID with yours in that line.

In the second line, I'm executing the command `rsm view /tphysical_media /cg` to get the GUID of the tape in the drive. But, as you've already seen, you must provide the GUID of a container for that to work—that's what `%drvguid%` does. You filled in your drive's GUID in the line before and that gets inserted before the command executes. The `/guiddisplay /b` says to display the GUID, and the `/b` option says to show *only* the GUID. That makes life easier, as it's only the GUID that I want. The result of that—the GUID—goes into a variable named `%x`. (The two percent signs are required syntax for the `FOR` command.)

Once I've got the GUID for the tape in `X`, then I can construct the last line, which executes an eject command for the tape whose GUID is in `X`.

Here are the steps to creating and using this batch file:

1. Get the GUID of your tape drive. From the command line, type **`rsm view /tlibrary /guiddisplay`**. You'll see a line for all of the removable devices on your system, including CD-ROMs. The name of the device should make clear which one is your tape drive. Grab the GUID next to that device's name—again, you can copy this value by selecting it and pressing Enter.

2. Open up Notepad and type in the batch file as you see in the previous text. In the first line, substitute your drive's GUID in place of E30ADF03E8014BA4BB824AD69B39FBE7. Note that the single quotes in the second line are *backquotes*. On many keyboards they are on the same key as the tilde (~).
3. Save the file in the WINNT directory as `tapeject.cmd`.

Try it out by opening up a command line and typing **tapeject**. The tape should eject.

***TIP** If you want to run `tapeject` from inside a batch file, then don't just put the line `tapeject` in the batch file; instead, use `call tapeject`, or the batch file will end when `tapeject` ends.*

### **Refreshing a Tape from the Command Line**

Sometimes you'll pop a tape into a drive and try to do something with it from the GUI or the command line, and the command fails—the system acts as if there is no tape in the drive. There are two possible reasons for that. First, remember, you're working with tapes here—they're not the fastest things in the world. When you pop a tape in, the drive may take a minute or two to figure the tape out. Second, RSM for some reason doesn't always automatically figure out that you just put a tape in a drive. The *drive* knows that it's there, it's just RSM that doesn't know. So it never hurts to smack RSM upside the head before trying to do something—that's called *refreshing*.

You can refresh just about any object in the RSM by right-clicking it and choosing Refresh. But if you're about to run a batch job to automatically back up a system, then you want a command-line method to do that. RSM lets you do that with an `rsm refresh` command. It looks like this:

```
rsm refresh /lf"drive name"
```

or

```
rsm refresh /lgdrive-GUID
```

So, for example, my drive could be refreshed either with this:

```
rsm refresh /lf"QUANTUM DLT7000 SCSI Sequential Device"
```

or

```
rsm refresh /lgE30ADF03E8014BA4BB824AD69B39FBE7
```

Notice that the drive name needs quotes and the spelling must be exact; the GUID, on the other hand, must be exact but does not need quotes.

### **Automating Tape Backups**

You've seen that Backup manages tapes through RSM, and you've seen RSM's notions of libraries, physical media, and media pools—and that it assigns GUIDs to everything, and how much it relies upon those GUIDs. That was all necessary preparation for controlling NTBACKUP from the command line.

The basic idea with automating NTBACKUP is simple: Write a batch file that wakes up the NTBACKUP.EXE program and tells it to back up to tape. Then use the Schedule service—the AT.EXE command—to tell the operating system to run that batch file whenever you want it run—daily, every other day, or whatever.

The hardest part is usually writing the batch file. It's typically just one line, a long invocation of the NTBACKUP command. That's what I'm going to focus on here. As you can see in Table 19.4, these options are fairly complex. But I'm going to simplify them as much as possible, starting from a very basic command and then adding things as we go.

**TABLE 19.4: NTBACKUP OPTIONS**

ARGUMENT	FUNCTION
backup	Tells NTBACKUP that you're running a backup operation. You must include this argument.
systemstate	Specifies that all System State data should be backed up and sets the backup type to normal or copy.
bks file name	This is the name of the selection information file in which the backup will be stored (if you're backing up to a file instead of a tape). More than one backup can go in the same BKS file, if you choose to append backups. You must create this file from the GUI before referencing it from the command line.
/j "job name"	Tells NTBACKUP the name of the backup job.
/p "pool name"	Tells NTBACKUP which media pool (a logical grouping of removable media, such as a tape library) to copy the backup files to. If you're using Backup, this will be the Backup media pool. You won't use this option with /g or /t, as those switches specify that a certain tape should be used; with /f, which specifies the name of a file to backup up to; or with /a because you must append backup files to a specific tape, not an entire media pool.
/g "guid name"	Specifies the GUID of the tape that will be overwritten or appended with this backup job. Don't use this switch with /p, as that specifies that NTBACKUP should back up to a media pool instead of a particular tape. The GUID must be in quotes and hyphenated, so that it looks like this: "b471ff3b-101f-43bc-9d15-ffb7176cf2f3"; those demarcations must be respected—8 characters, hyphen, 4, hyphen, 4, hyphen, 4, hyphen, 12 characters.
/t "tape name"	Specifies the media name of the tape that will be overwritten or appended with this backup job. Don't use this switch with /p, as this specifies that NTBACKUP will use a media pool instead of a particular tape.
/n "new tape name"	Specifies the new tape name of the tape that will be overwritten or appended with this backup job. Use this switch to name a tape, but use it sparingly. Don't use this switch with /p, as this specifies that NTBACKUP will use a media pool instead of a particular tape. You also can't use this switch with /a because you can't append data onto a tape that is new or that you're renaming. Finally, it's best not to use this switch with /um since that switch is for unattended tape backups, and it may work best to let Backup name the tape on its own.
/f "file name"	Specifies the path and name of the file in which the backup will be copied. As this switch directs the backup to a file, not a tape or media pool, you can't use it with any of the switches specific to removable media: /p, /t, or /n.

*Continued on next page*

TABLE 19.4: NTBACKUP OPTIONS (continued)

ARGUMENT	FUNCTION
/d "description"	Specifies the description of the backup set, such as “Full backup of SERPENT on 1/20/03.”
/ds "server name"	Backs up the directory service on the specified Microsoft Exchange server.
/is "server name"	Backs up the information store on the specified Microsoft Exchange server.
/a	Appends the backup set to any data on the media. If backing up to a tape, you must use this switch with either /g or /t to specify the tape you want to append to. You can’t use this switch with /p, as you must append to a specific tape, not an entire media pool.
/v:yes or no	Specifies whether the backup procedure should be verified or not. Verifying the data (making sure the data in the backup matches the source) takes a little time, but reassures you that the data was written correctly.
/r:yes or no	Specifies whether the tape should be available only to its owner/creator and members of the Administrators group.
/l:f or s or n	Tells NTBACKUP what kind of log file to create: full (logging every copied file), summary (logging only important events and errors), or none (in which case the backup won’t be logged).
/m backuptype	Tells NTBACKUP what kind of backup to run: normal, copy, incremental, differential, or daily.
/rs:yes or no	Tells NTBACKUP whether to backup the removable storage database that records the location of archived files. If you’re using removable storage, you should back up this database regularly to make sure that you can retrieve archived files.
/hc:on or off	Tells NTBACKUP whether to use hardware compression (available only if you’re backing up to a tape drive, and then only if that tape drive supports it—most do). Go ahead and use hardware compression if it’s available, as it will allow you to get more use out of your tapes.
/SNAP: on or off	Specifies whether or not the backup should use volume shadow copying to back up open files. By default, it will.

Forget all the options for a minute. The basic NTBACKUP command looks like this:

```
ntbackup backup directory tapedrive
```

*directory* is, of course, the name of the directory (or UNC) to back up. *tapedrive* is the name of the tape drive to do the backup to. Leave that off, and the command will just not run—and it doesn’t even tell you *why* unless you look for and read the log files. You specify a tape drive in one of two ways:

- ◆ /t "*name*" as in /t "Tape created on Tuesday"
- ◆ /p "*media-type*" as in /p "DLT"
- ◆ /g "*guid name*" as in /g "b471ff3b-101f-43bc-9d15-ffb7176cf2f3"

By the way, notice that RSM likes to add - 1 to tape names (apparently assuming that you have more than one tape in a set), but that name won't work with NTBACKUP. If you'd created a tape called mytape, then it'd show up in the GUI as mytape - 1—but when you use the /t option, leave the extra - 1 off. That is, use /t "mytape", not /t "mytape - 1". To identify a tape by its GUID, you must use the GUID of the `logical_media` inside the partition inside the `physical_media` that is inside the library.

You'll use /t and /p for different purposes. /t with /a permits you to append new backup sets to an existing tape without deleting the existing ones (which /p doesn't allow) but requires that you know the name of the tape in the drive. /p in combination with /um doesn't need the name of the tape in the drive, as it just tells NTBACKUP, "Whatever's in there, just wipe it clean and start over!"

### A COMMAND-LINE BACKUP STRATEGY

For years, I've used a simple backup strategy for servers: Once a week I do a full backup, and every other day I do a differential backup. It's simple to automate with just a little manual work. I keep two tapes: the differential tape, which I leave in the drive for most of the week, and the full backup tape, which I only leave in the drive over Sunday night. (Yes, I rotate tapes, but I'm simplifying this explanation.) Here's how it works: Every Sunday morning, I remove the differential tape from my server's tape drive and put it aside. Then I insert a tape for a full system backup. On Monday morning, I remove that tape, which now has a full system backup on it, and reinsert the differential tape.

Using the Schedule service, I set up three events:

- ◆ On Sunday night/early Monday morning, I schedule NTBACKUP to back up my server's files (a "normal" backup), but first to wipe clean anything on the hard disk.
- ◆ On Monday night/Tuesday morning, I schedule NTBACKUP to do a differential backup of my server's files, but first to wipe clean anything on the hard disk. (This reinitializes the differential tape each week.)
- ◆ On the other evenings, I schedule NTBACKUP to do a differential backup of my server's files, but tell it to *append* the new backup set to the existing ones on the tape. That way, I have backup sets that represent the state of the network for every day of the week.

Furthermore, let's make this example a bit more complicated—and more useful in the real world—by specifying that the only directories that I want to back up are C:\DATA, C:\USERS, and D:\REPORTS.

### THE WEEKLY BACKUP

For this backup, I want the drive wiped clean. What command does that? `ntbackup backup /p /um`. In its simplest form, that would look like this:

```
ntbackup backup directories /p "DLT" /um
```

Remember that your drive may not be a DLT; other possible values might be 4mm DDS, Travan, QIC, or others. Just look in the folder created under your Backup media pool to find out your drive's type.

But we're not out of the woods yet. How do I specify three different directories to back up?

**Using a Backup Selection File**

You *could* write a batch file that called `ntbackup` three times, but that's too much work. Instead, open up Notepad and type the names of the directories that you want to back up, one to a line:

```
C:\data\  
c:\users\  
d:\reports\
```

Then click Save As and specify that the file's name is `c:\myfiles.bks`, but don't save yet—in the Save As box, go to the Encoding box and choose Unicode.

**WARNING** *This is very important. You don't have to save it in C:\, you needn't give it the extension .bks—but you've got to save it in Unicode, or NTBACKUP simply will not read it.*

Now run NTBACKUP as before, but instead of specifying a directory, specify your backup selection filename prefixed by an `@` sign. If the directory's name includes spaces, then you'll need to surround the name with quotes. The command looks like this so far:

```
ntbackup backup @c:\myfiles.bks /p "DLT" /UM
```

**Choosing Logging Levels**

At least until I'm sure that this thing works, I'd be happier with an extensive log. You can set logging levels with the `/l:` option: `/l:s` provides only summaries (and is the default), `/l:f` provides full logs, and `/l:n` produces no logs at all.

**Hardware Compression**

In theory I can get 80GB of data on this tape if I turn on hardware compression. You control that with the `/hc:` option—it's either `/hc:on` or `/hc:off`.

**Verification**

In general, I find that I distrust computers when it comes to my data. So I don't mind the extra time required to stop, rewind, and verify backups. You control verification with either `/v:yes` or `/v:no`. (Why `/hc` uses `on` or `off` and `/v` uses `yes` and `no` is known only to the Microsoft developers.)

**Append or Replace?**

In this particular case, I want to overwrite any existing backup sets, replacing any on the tape. That's the default behavior, so there's nothing to do. If I wanted the system to append its backup set to any existing sets then I'd add `/a`. You can't do `/a` if you've used `/p`, but you can use `/a` in combination with `/t`.

**Name the Tape**

By default RSM and NTBACKUP name the tape by its date and time of "creation," but you can give it any other name by adding the parameter `/n` followed by a name.

### **Back Up the Registry?**

Adding the parameter `systemstate` will cause NTBACKUP to back up the System State data. The other options can go just about anywhere, but `systemstate` must go after the word `backup` and before the backup selection file's name.

Put it all together and you've got a command like this (all on one line):

```
ntbackup backup systemstate @c:\myfiles.bks /p "DLT" /UM /l:f /hc:on /v:yes
```

### **Create the Batch File**

Finally, let's put the Schedule service to work. Put that line (with your site-specific modifications, of course) into a batch file called `c:\fullback.cmd`. Then open up a command line, type this:

```
at 2:00 /interactive /every:Monday c:\fullback.cmd
```

and press Enter. Now at 2 A.M. every Monday morning, your system will do a normal backup of the directories that you specified in `c:\myfiles.bks`.

### **How Do I Know It Worked?**

NTBACKUP writes ASCII text files called `backup01.txt` through `backup10.txt`, maintaining logs of the last 10 times that NTBACKUP ran. (It starts reusing files once it gets to `backup1.txt`.) You cannot, unfortunately, control either the number of log files that it keeps (it's 10) or where it puts them. NTBACKUP stores the logs in `\Documents and Settings\username\Local Settings\Application Data\Microsoft\Windows NT\NTbackup\Data...` and it's that *username* thing that'll give you fits.

When you're logged in as you, Joeadmin, then the logs go to `\Documents and Settings\joeadmin\Local Settings\Application Data\Microsoft\Windows NT\NTbackup\Data`. But when the Schedule service starts the process—that is, when you're automatically scheduling a backup—it writes the logs to in `\Documents and Settings\Default User\Local Settings\Application Data\Microsoft\Windows NT\NTbackup\Data`. And don't be surprised if you have more than one of those directories—you might find that you've got a directory named `\Documents and Settings\Default User\Local Settings\Application Data\Microsoft\Windows NT\NTbackup\Data` and `\Documents and Settings\Default User\WINNT\Local Settings\Application Data\Microsoft\Windows NT\NTbackup\Data`. Just look in both directories and find the one with the more recent log files—those are the ones you want.

### **THE DIFFERENTIAL BACKUP**

You set up the differential backup basically the same way as the normal backups, but instead of `/p /um` you'll use `/t` and a tape name—we don't want to overwrite the tapes. So you'll need to standardize the name for the tape; I use `diff1`, and append a week's differentials together, so my batch file looks like this:

```
ntbackup backup systemstate @c:\myfiles.bks /t "diff1" /a /l:f /hc:on /v:yes
```

I save that as `c:\diffback.cmd` and tell Schedule to run it every day but Monday morning:

```
at 2:00 /interactive /every:T,W,Th,F,S,Su c:\diffback.cmd
```

And if you wanted to be really snazzy, then you could build a slightly different version that runs only on Tuesday that erases the tape first—use `/p /um` for that one, if you like.

### MAKING RSM AND NTBACKUP SHARE INFORMATION

As I said earlier, RSM and NTBACKUP don't always see eye to eye on how to present data. RSM thinks that all tape sets have more than one tape in them, so it names tapes with a 1 at the end. NTBACKUP won't recognize the name if the 1 is there, so you have to delete the 1 before including the RSM-reported name in a batch file. Similarly, RSM reports GUIDs as unbroken strings. NTBACKUP, on the other hand, is very exacting about the way it wants to see GUIDs: It wants you to type them as 8 characters, hyphen, 4, hyphen, 4, hyphen, 4, hyphen, 12 characters. That is, the GUID RSM reports as `b471ff3b101f43bc9d15ffb7176cf2f3` needs to become `b471ff3b-101f-43bc-9d15-ffb7176cf2f3` for NTBACKUP to use it. Having tired of counting characters and inserting hyphens at appropriate intervals, I wrote a batch file that will grab GUID data from RSM, format it so that NTBACKUP likes it, then starts a differential backup. Just be sure to supply your own GUIDs when using this batch file!

```

differential
```

### ADVICE FOR BUILDING YOUR BATCH FILES

Now, you'll probably end up trying different things in your batch files and will have different needs than I do. So you'll have to craft your own solutions, which means trial and error. There is nothing more frustrating than checking your logs in the morning only to find that for some mysterious reason *nothing seems to have happened at all*.

Here's a methodology for making command-line backups tractable.

**Try everything out from the command line first** Unless you're *really* good, you'll hit a few syntax snags along the way. Trying your commands out on the command line gives you immediate feedback so that you can work out the bugs quickly.

**Build the command line gradually** Start from the most minimal command possible, such as `ntbackup backup c:\testfiles /p "dlt" /um` or the like. Crawl before you try walking and walk before you try flying.

**Keep track of what worked and what didn't** You may have hardware that's cranky about some command and truthfully all tape drives are a bit flaky—something that works today may not work tomorrow unless you clean the tape or restart RSM. When you've got a command that works, make sure you've got its exact syntax saved somewhere. I use Notepad files as my logs when I'm experimenting. I use copy and paste to provide a simple log of the output from my commands.

**Once you have the command line perfect, make a batch file** Just copy and paste the command line into Notepad, save it with the `.cmd` extension and you're a batch file builder. Then invoke the batch file by its name—if you called the Notepad file `c:\dotape.cmd`, then open up a command line and type `c:\dotape.cmd` and make sure that it still works. If it doesn't, then check that any paths needed in the command are there.

**Try the batch file with `at`** Once you've got the batch file running so that it works as expected from the command line, test it with the Schedule service. From a command line, type **`at time /interactive batchfilename`** and press Enter. For *time* just punch in a time a minute or two in the future—you don't want to have to wait forever. (Remember that the Schedule service uses a 24-hour clock, so 3 P.M. should be entered as **`15:00`**.) If it doesn't work, then make sure that you entered the full path of the batch file.

**Once the bugs are out, tell `at` to run the backup regularly** Rerun the `at` command, but add the `/every:` information so that it knows which days to run the command.

## Viewing Backup Logs

Unless you specify otherwise, every time you back up, the Backup application creates a backup log. To see the contents of these logs, you can click the Report button in the dialog box that tells you that the backup is complete. Alternatively, to pick any log to view, choose Report from the Tools menu in Backup. You'll see a list of backups, as shown in Figure 19.22.

**FIGURE 19.22**  
Choose a backup  
log to view.

In the Backup Reports dialog box, find the report you want based on its job name or time and date stamp, and click the View button. The log will open in Notepad and provide output something such as this very simple example:

```
Backup Status
Operation: Backup
Active backup destination: File
Media name: "Backup.bkf created 1/11/2003 at 9:37 AM"

Backup (via shadow copy) of "C: "
Backup set #3 on media #1
Backup description: "Set created 1/11/2003 at 9:37 AM"
Media name: "Backup.bkf created 1/9/2003 at 12:24 PM"

Backup Type: Normal

Backup started on 1/11/2003 at 9:37 AM.
Backup completed on 1/11/2003 at 9:37 AM.
Directories: 4
Files: 2
Bytes: 743
Time: 1 second
```

Notice that in this log you can see what folders and directories were backed up, how long it took to run the backup, and whether any errors occurred. Scan these reports after completing backups so you can identify any problems before you need to restore data from those backups. By the way—there's something new here in Server 2003. The backed-up folder contained an open file. In Windows 2000, this would have netted me an error message telling me that a file was skipped because it was in use. In Server 2003, Backup uses the volume shadow copying service (if you've left it enabled), so it will copy even an open file. (Any changes saved after the file was copied didn't make it into the backup, obviously, but at least I've got the core file.)

## Restoring Data

Backups don't do you a lot of good unless you can put them back on the server from where they came. To restore files, open Windows Backup again. You can either run the Restore Wizard or turn to the Restore tab.

**WARNING** *NTFS 5 uses some file attributes not found in FAT or the Windows NT version of NTFS. You may not be able to restore some data that was originally stored on an NTFS 5 volume to a downlevel volume (FAT, FAT32, or NTFS with NT 4). For example, if you back up encrypted files and then try to restore them to a FAT volume, you'll see an error message telling you that the restore destination doesn't support some system features of the original, so some files (the encrypted ones) won't be restored. What actually happens is that the file's restored, but it no longer has the encryption attribute.*

## BASIC RESTORATION TECHNIQUES

To restore files from the Restore Wizard, start Backup and choose to restore files, or (using Advanced View) turn to the Restore and Manage Media tab of Backup. You'll see the usual Welcome

screen. Click through it, and you'll be prompted to pick the media you want to restore from (see Figure 19.23). The options available will depend on what kind of media you've backed up to.

**FIGURE 19.23**

Available media for restoration

The backup sets on the media will be listed as folders, described according to volume backed up, size, type of backup, and description.

**NOTE** If a backup operation was aborted for any reason—by Windows Backup or by the user—you will not be able to restore it. Such backups will still appear in the catalog but will have a question mark where their size should be. This is one more reason to ensure you can restore backups before you need them.

Double-click a set to catalog it, and you'll be able to browse its contents. Check the boxes next to the files and folders in the backup set that you want to restore. As with selecting files for backup, a checked folder with all contents selected will have a blue check mark; if you've only selected certain files within the folder, its check mark will be gray.

**NOTE** If there are any errors within the folders of a backup set, the folder will have a red exclamation point on it and the corrupted file will have another exclamation point. You will not be able to restore any damaged files.

When you finish picking files to restore, the wizard will display a screen listing the current restore options. Click Back to edit any file or media settings, or click the Advanced button to specify a new restoration location or change the file restoration options for preexisting files and remote storage information.

**WARNING** The Advanced options that you choose will apply to all future restoration operations until you change them again. For example, if you edit the options so that the files on the hard disk are always replaced with the files from the backup, that option will remain in place until you manually change it to another one.

### **Where Should Files Be Restored?**

Unless you tell it otherwise, Windows Backup restores files to their original location. But what if you're restoring data to a new drive with a drive letter that's different from the original? Or you want to put the contents of a daily backup on a Zip disk? From the first screen of the advanced section of the Backup Wizard you can choose from three location options:

- ◆ Original location
- ◆ Alternate location (files and folders will be restored, folder structure intact, to the location you specify)
- ◆ Single folder (files will all be put within a single folder in the folder you specify, and the original folder structure will be lost)

If you tell Windows Backup to restore the files to an alternate location or to a single folder, then the wizard will display a text box where you type (or browse for) the restore path. You can only restore data to an alternate location, not system configuration information such as the Registry. Any system configuration files must go back to their original locations.

***TIP** To edit this option without running the Restore Wizard, turn to the Restore and Manage Media tab of Backup. In the lower-left corner of this tab is a drop-down list of the restoration location options. System State data must always be restored to its original location.*

### **What If a File with That Name Already Exists?**

The second screen in the advanced section of the Backup Wizard tells Windows Backup what to do if a file with the same name as the file being restored already exists on the volume. Normally, Windows Backup will not replace the file on the existing media, on the principle that if you already have the file, you shouldn't need to replace it. However, sometimes you'll want the file from the backup, not the one on the hard disk. For example, a Word document with a macro virus may be present on the hard disk, but you don't want the infected file. To cope with some of the situations in which you might want to replace the file already on the hard disk, Backup supports three replacement options:

- ◆ Do not replace the file on the disk (the default).
- ◆ Replace the file on the disk if it's older than the file on the backup.
- ◆ Always replace the file on the disk with the one on the backup.

Sadly, Windows Backup does not have an option to prompt you if it discovers a duplicate file on the media that you're restoring data to, or to restore the file but give it a new name on the volume if a file with the same name already exists. That would have been handy for those times when you're restoring corrupted files but don't necessarily want to replace *every* file that already exists on disk.

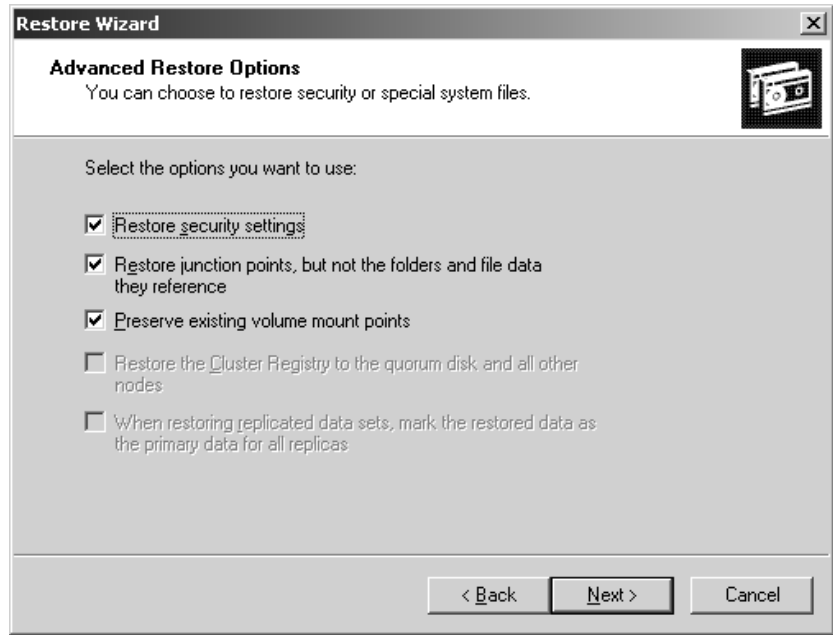

***TIP** To edit this option without running the Restore Wizard, choose Options from the Tools menu in Windows Backup. Turn to the Restore tab and choose the file replacement you want to use.*

### **What Other Data Should Be Restored?**

The next screen in the advanced section of the Restore Wizard asks what non-data information you want to replace (see Figure 19.24).

**FIGURE 19.24**

The non-data information that you can restore depends on the file system the original data was stored in. FAT volumes only let you restore the RSM database.

If you're restoring data backed up from an NTFS 5 volume to an NTFS 5 volume, Backup will normally restore all NTFS-related data: security settings, mount points, and junction points pointing to externally stored data. Replicated or clustered data will also normally have their settings preserved.

What happens if you tell Windows Backup to not restore the settings? Depends on whether the file already exists on disk:

- ◆ If the file exists in the location that you backed it up to, then the security settings attached to the file on disk will be applied, even if you're replacing the file.
- ◆ If the file does *not* exist on disk (if you're replacing a deleted file, for example) and you choose to not restore security settings, then the restored file will give the administrator of the local server and the system account full control—and wipe out any previous settings.

**NOTE** Notice that the way security settings are restored means that if you elect not to restore security settings to a file that *Everyone* had access to, you'll need to explicitly grant that permission again.

*Junction points* are physical locations on a mounted NTFS volume that point to another area of the disk or to another disk. They're used when you choose to mount a new volume to an empty folder on an NTFS volume instead of assigning that folder a drive letter. Normally, Backup will restore both the junction points and the files and folders to which they point. If you check the box that tells it to restore only the points, not the data, you may lose access to the data.

When you've picked all the Advanced settings, click the Finish button on the last page of the wizard. If restoring from a backup file, Windows Backup will prompt you for the name of the file,

then complete the restoration. During the process of restoring the files to disk, Windows Backup will display a Restore Progress dialog box.

### VIEWING RESTORE LOGS

When a restore operation is over, the Restore Progress dialog box will remain open. Click the Report button to open the restore report in Notepad. Alternatively, you can choose Report from the Tools menu and pick the report you want from the list of available reports. The restoration report will be appended to the backup report originally created for that job, so if you don't see the information you're looking for right away, page down for it.

### RESTORING CONFIGURATION SETTINGS

The process of restoring configuration data is much the same as restoring any other data—when prompted to do so, pick the **System State** folder from the backup set and start the restoration.

However, restoring System State data isn't as simple as restoring user data. If you restore System State data to its original location (that is, you don't specify an alternate location for it), then Windows Backup will replace the System State data currently on your computer with the System State data you're restoring. However, if you restore the System State data to an alternate location, only the Registry files, SYSVOL directory files, and system boot files are restored to the alternate location. You can't restore the Active Directory services database, Certificate Services database, or COM+ Class Registration database to an alternate location.

**NOTE** *In order to restore the System State data on a domain controller, you must first start your computer in Directory Services Restore mode, available from the Advanced Start menu when you boot the OS. See the next section “Backing Up and Restoring the Active Directory” for details.*

## Backing Up and Restoring the Active Directory

As I said earlier in this chapter, when you choose to back up the System State data on a computer, the contents of System State depend on the role of the computer you're backing up. If the computer is a domain controller, then System State includes the Active Directory. Backing up the Active Directory is pretty simple—you choose to back up the System State data on a domain controller. Restoring it, however, is not as simple as restoring user data, especially if you need to restore data from a backup that's older than the current data in the Active Directory. In this section, I'll talk about how to back up the Active Directory, how long you can store it, and how to restore it—or pieces of it.

### BACKING UP THE ACTIVE DIRECTORY

You can take a snapshot of the Active Directory at any time by backing up a domain controller's System State data, either from the command line or with the graphical Backup tool. To back up Active Directory, you must be a member of the Backup Operators group, the local Administrators group, or a group that's been given the right to back up the System State data.

### RESTORING THE ACTIVE DIRECTORY

To begin restoring Active Directory information, you'll boot the computer into Directory Services Restore Mode (to do so, press F8 while the domain controller is rebooting and choose this option from the Advanced Options menu that appears). You can perform an authoritative restore on either

all or part of the Active Directory. I'll discuss the Advanced Options boot menu later in this chapter, but because one of its menu items is crucial to restoring the Active Directory, I'm going to leap ahead a bit, returning to this topic later. When you choose this option, it will kick you back to the main boot menu, showing in text at the bottom of the screen that you're in DSRM. The system will boot in Safe Mode with Networking, run CHKDSK on all the volumes, and then present the logon screen for you to log in as the local machine's administrator.

Once you're in, run the Restore Wizard, choosing the backup set containing the system data. Most of the way, this operation looks like restoring any data. However, when you're clicking through the advanced options, you'll come to the screen in Figure 19.25. Don't just blindly click through this screen, as the options you pick here—specifically, the *last* option you pick here—determine what kind of restoration operation you're performing.

**FIGURE 19.25**

Advanced options  
for restoring System  
State data

Let me digress for a moment. A normal file restore operation restores all files, including Active Directory objects, with their original update sequence numbers (USNs). The AD replication system uses the USNs to detect and replicate changes to the Active Directory to all of the domain controllers on the network. The Active Directory replication system updates old data with newer data from other domain controllers.

For normal operations, this is fine. It has one sticking point, though: Normally, any Active Directory data that you restore will retain its original USN used by the AD replication system to detect and spread AD changes among the domain controllers in your domain. Because of this, any data restored in nonauthoritative mode (would that be in “peon mode”?) looks like old data and won’t get propagated to the other domain controllers. Not only that, but the Active Directory replication

system will *replace* that restored data with the “newer” data from the other domain controllers, if any exists. If you’re trying to replace bad current data with good old data, this obviously isn’t what you want to happen. Authoritative restore solves this problem, forcing the domain to accept the older data and overwrite the new.

Before doing an authoritative restore, consider what effect this will have on the domain. When you restore the Active Directory database, you’re restoring the following, among other things (see Chapter 8 for a complete description of what the Active Directory is and what objects it contains):

- ◆ User and machine accounts
- ◆ User and machine account passwords
- ◆ Groups and organizational units
- ◆ Trust relationships (or lack thereof) with other domains

However, what you’re *not* doing is removing any new accounts you created since backing up the Active Directory. The AD isn’t a big lump with a single USN, but a directory of objects, each with its own USN. You can pick and choose pieces of the Active Directory to restore. Also, if you perform an authoritative restore to a domain containing other domain controllers, any objects you created in the naming context (in this example, the domain naming context) after making the backup will remain in the Active Directory. Say, for example, that on Monday you create an account for ChristaA (which is then replicated to the other domain controllers in the domain), then back up. On Tuesday you create an account for Christa—also replicated to the rest of the domain. On Wednesday, you delete the ChristaA account. On Thursday, you perform an authoritative restore from the backup you made on Monday. Both the ChristaA and Christa accounts will exist in the domain, not just the ChristaA account you backed up, because the two accounts have unique USNs—they’re different objects.

### **Types of Restoration Actions**

The way you should restore Active Directory data depends on what kind of restoration you want to complete. Restoring the entire domain from scratch and must therefore replicate the data across all domain controllers? Restoring a single domain controller and do *not* want that data replicated to any other domain controllers? Restoring particular data in the Active Directory? Each of these actions requires a different kind of restoration process.

To restore the entire domain from scratch—to restore the first copy of all replicated data and use that as the basis for further replication—you’ll perform a *primary restore*. From the screen shown in Figure 19.25, choose to mark the restored data as the primary data for all replicas. This will cause all the restored Active Directory data to overwrite any other directory services information in the domain.

To get a domain controller in a working domain back online, restore its System State data, but do *not* check the final box making this domain controller the primary source of replicated data. This is called a *normal restore*. Each object in the Active Directory will keep its original USN number. (In case it’s not obvious why you’re restoring it at all when some of the data may be overwritten from other domain controllers, consider that it’s unlikely that every single object in the Active Directory has

changed since you backed up the System State data, and it's a lot quicker to replicate a few changes here and there than it is to replicate the entire Active Directory.)

So far, we've looked at all-or-nothing scenarios: making the entire restored Active Directory the primary source, or none of it. However, you may need to restore part of the Active Directory; for example, if someone accidentally deletes an organizational unit and with it all the computer or user objects within that OU. To selectively restore parts of the Active Directory as primary replication sources, you'll need to perform an *authoritative restore*. This is a two-part process. First, you perform a normal restore. Next—and before you reboot the server—you run NTDSUTIL, a command-line utility that lets you mark selective pieces of the Active Directory for primary restore.

### **Understanding Tombstone Lifetimes and Backup Lives**

*Tombstone lifetime* sounds like an oxymoron. It's actually a property of the Active Directory Directory Service (NTDS, for NT Directory Service—same thing) object, representing the number of days that a deleted object will exist as a “ghost” in the Active Directory before it's deleted. Tombstoned objects are still replicated but appear in the Active Directory as deleted. A housekeeping process called the *garbage collector* runs every 12 hours on each server to delete objects whose tombstone lifetimes have expired. (Personally, I would have called it the “sexton” to keep the metaphor going—garbage collectors don't normally have much to do with tombstones, or if they do I don't want to know about it.) Left to itself, the default tombstone lifetime is 60 days.

So what does this have to do with the useful lifetime of an Active Directory backup? Simply put, you can't restore data from a backup image older than the tombstone lifetime. If you did, the restored objects would be too old to trigger Active Directory replication and thus never be replicated to other domain controllers, and the restored domain controller would never get the replication data required to delete the objects—the records of those objects being deleted would have been removed by the garbage collector. The result would be an inconsistent Active Directory on the local server, which misses the point of a domainwide database of available resources. In short, don't restore the Active Directory from backups more than 60 days old if you have not explicitly increased the tombstone lifetime.

If you're trying to restore a domain controller and your only backups are older than the 60-day default limit, then you have two choices. If you have at least one domain controller still up and running and its Active Directory information is good, then you have nothing to worry about—just restore the domain controller, and the remaining domain controller with good Active Directory information will replicate its data to the newly restored domain controller. If you're having to rebuild the domain from scratch, then you can pick an outdated backup, restore it to a domain controller, and replicate the other servers from the restored one.

If you *must* restore an older Active Directory backup to a working domain (although I'd hate to think of what could happen to your domain that you had to lose more than 60 days of changes to get it back to working order), then you can force the change by editing the tombstone date. Because `TombstoneLifetime` is a property of the NTDS ADSI object, you can modify it with a script or with an AD editor such as `ADSIEDIT.MSC` or `LDP.EXE`. If you do, then you can make the tombstone lifetime older than the available backup. At that point, you'll need to perform an *authoritative restore* to force the replication of this old backup to the other domain controllers since this information will be stamped as being too old for replication.

### Restoring Part of the Active Directory

As I said earlier, you can use DSRM to restore individual parts of the database, not just the whole thing. For example, you could restore an accidentally deleted machine account for a domain controller. To do so, boot to DSRM and restore the System State data, then run NTDSUTIL for an authoritative restore. This time, though, instead of typing **restore database**, choose to restore part of it, like this (all on one line):

```
restore subtree "cn=domain_controller,ou=Domain Controllers,dc=domain_name,dc=xxx"
```

Here *domain\_controller* is the computer name of the domain controller, *domain\_name* is the domain name the domain controller resides in, and *xxx* is the top-level domain name of the domain controller, such as com, org, or net. NTDSUTIL will ask you if you're sure you want to perform an authoritative restore. When you click Yes, NTDSUTIL will open the directory information tree (DIT), note the last time it was updated and the number of entries that need updating, then read through the restore subtree command backward to find the domain, the organizational unit, and finally the computer name you want to restore. When you're done with this, type **quit** to exit authoritative restore and then **quit** again to exit NTDSUTIL, then reboot the domain controller.

**TIP** If you don't know the name of the part of the Active Directory that you want to restore, use ADSIEDIT.MSC or LDP to find the name. You'll need to enter the name exactly.

## Troubleshooting Hardware with the System Information Tool

If you want current nuts-and-bolts information about the hardware in your servers, you can dig out those PDF files you printed from the Web sites and read all your handwritten notes about configuration changes that you made.

For those less than thrilled about this idea, there's the System Information tool available from the Support section of Help. Using this tool, you can view the following on either the local computer or any Server 2003 or Win2K computer:

- ◆ A system summary showing you the basic hardware and software configuration of the server
- ◆ Hardware resources used on the server
- ◆ Configuration information for the hardware
- ◆ Information about all parts of the server software environment

**TIP** Typing **winmsd** or **msinfo32** from Run will start the System Information tool. For those who don't remember, MSD was the original Microsoft Diagnostics tool, which became WinMSD in Windows.

The System Information tool isn't 100-percent accurate—as I wandered through it, I found a couple of minor pieces of misinformation—but it's close. And it provides a lot more information than WinMSD ever did and in a reasonably organized manner. Read on to learn how to use this tool to inventory and monitor servers.

## System Summary

The system summary information is just that—a snapshot of your system, such as the one shown in Figure 19.26. The information is roughly that which used to be on the Version tab of NT 4's WinMSD, with the addition of BIOS version and some memory information. You can't change the data here, just see what the situation is. About the only information you need pay special attention to is the available memory. You can get memory information in *many* places around the operating system (the Task Manager is another tool that you can use for this), but here it is in black and white: how much physical and virtual memory you have available and have remaining.

**FIGURE 19.26**

System summary information for a Server 2003 computer

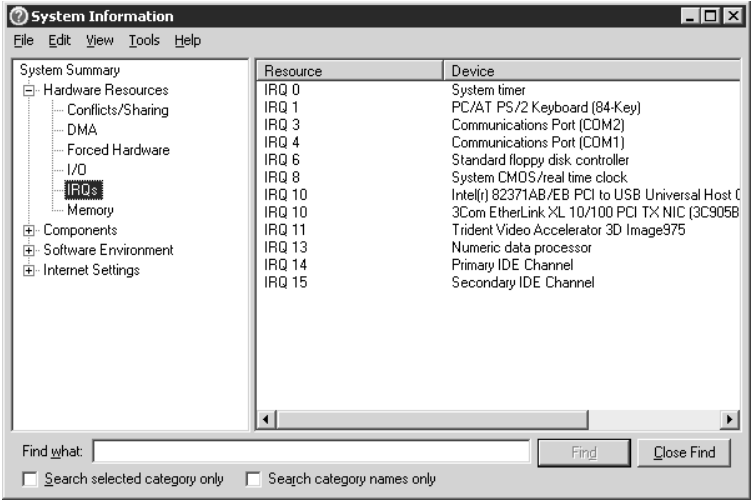

## Hardware Resources

The Hardware Resources folder (see Figure 19.27) lists all the resources that might be used by the hardware in your services and shows what hardware actually *is* using those resources, as described in Table 19.5.

Why is this information important? Basically, everything in Table 19.5 represents either a channel for devices to pass information to the processor for processing or a storage place for such data while it's waiting for processor time. Each channel must have its own hotline to the processor so that when the processor responds to a call for processing (an *interrupt*), it knows whose data it's crunching and can pass back the results accordingly. Some devices can share some kinds of channels; IRQs, for example, can be shared by some modern hardware. But memory storage areas cannot be shared, and not all channels can be shared. If you suspect that two or more devices are using the same resources and can't share, then you can use this tool to find out.

**FIGURE 19.27**  
The Hardware Resources folder with the contents of one folder showing

**TABLE 19.5: RESOURCES USED BY SERVER HARDWARE**

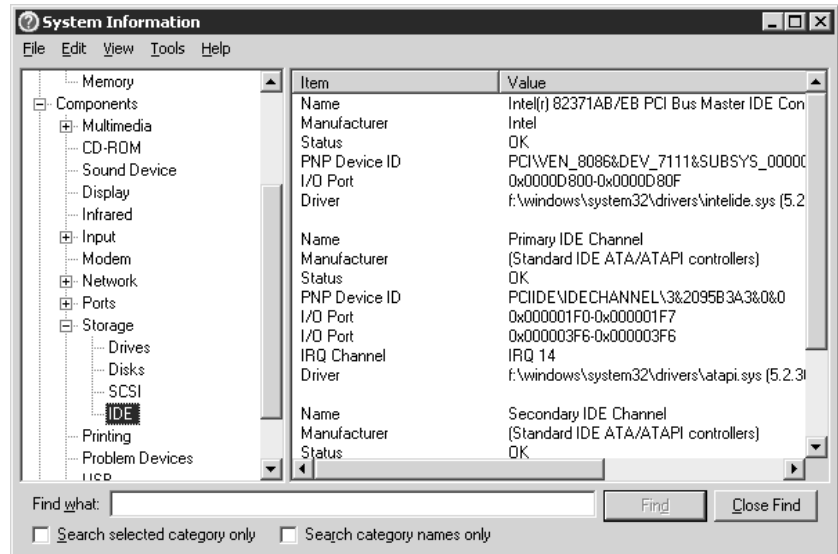

RESOURCE TYPE	DESCRIPTION
Conflicts/Sharing	Lists the components either sharing an IRQ or in conflict over one. Components sharing an IRQ should be working fine (or if they're not, the IRQ in common shouldn't be the problem). If multiple devices are in conflict over an IRQ, however, then one or all won't work.
DMA	Direct Memory Access (DMA) channels are rarely required; most often these days, they're used by audio devices. Basically, the DMA chips on the motherboard can move data from a device to RAM without the CPU having to be involved in the process. Any device that can use DMA needs its own DMA channel as its dedicated path for data moving.
Forced Hardware	Lists older devices not supporting Plug and Play that require specific IRQs.
I/O	Shows what devices are using what parts of virtual memory for storage. The information here is similar to what's in the Memory folder but is taken from the perspective of the memory, not the devices using it.
IRQs	Interrupt request lines, or IRQs, represent each device's hotline to the processor. IRQs are like DMA channels in that they're specific to a given device, but are unlike them in that they don't take care of the process of shoving data to the processor—the processor must still be involved. Some devices can share IRQs.
Memory	Shows the I/O buffer areas that each device is using to store data waiting for processing. Essentially, these buffer areas are mailboxes that the processor can use both to pick up data waiting for it and to drop off instructions for the device to which that I/O area belongs. Each device must have its own I/O area so that the CPU will drop off the appropriate instructions to each device. It's going to cause no end of confusion if the processor asks the network card to play a sound.

## Components

The **Hardware Resources** folder looks at the types of resources available and shows you what devices are using them. The **Components** folder's approach (Figure 19.28) is the opposite—you look at the devices installed and see what resources they're using. But not only resources. The properties pages for the installed devices provide just about all information relevant to a piece of hardware, including resources used, driver versions, and the type of device it is.

**FIGURE 19.28**

The contents of the IDE section of the **Components** folder

**NOTE** The **Components** folder is a list of all possible devices, not actual devices. For example, even if your server doesn't have a modem installed, it will still have a **Modem** folder.

The exact data within a given object in the **Components** folder depends heavily on what the device it represents does. For example, the data for the display reports information such as the color density, refresh rate and resolution, video adapter's name, and other display-related information. The network's folder has three subfolders: one for the adapter, one for protocols used, and one for Winsock version information. Storage media show their size, media type, compression data, and so forth. There's even a section for problem devices, listing any devices that the OS can tell aren't working as expected. For instance, at one time I had a SCSI removable drive attached to this server. After I removed the drive, the OS still expected to find it, so it's now listed in the **Problem Devices** folder.

## Software Environment

The information in the **Software Environment** folder (Figure 19.29) describes all of the software running on the system, who's using it, and what files and services are loaded. It includes the components listed in Table 19.6.

FIGURE 19.29

The Software Environment folder with one folder open

TABLE 19.6: SYSTEM PARTS DESCRIBED IN THE SOFTWARE ENVIRONMENT FOLDER

SYSTEM PART	DESCRIPTION
System Drivers	Lists all the system drivers. Each driver lists a brief description, its type (kernel driver or file system driver), its state (whether stopped or running), its start mode, its status (all drivers are OK) and whether it can be stopped or paused.
Signed Drivers	Lists all the signed drivers installed on the server and information about them, including whether they really are signed (the options are Yes and Not Available), the device class (e.g., NET for network drivers), the driver version (available only for signed drives), the manufacturer, the INF name, and (theoretically) the driver name. “Theoretically” because this information is available for neither signed nor unsigned drivers.
Environment Variables	Lists all the environment variables for the server, including the processor identification, location of all temporary files, path information for system files, and OS version.
Print Jobs	Lists all currently running print jobs.
Network Connections	Lists all current network connections and the drive letters they’re mapped to (if applicable).
Running Tasks	Lists all the executable files run by the services running on the server. File path, version, file size, and file date are all listed here. If you want to know what version of a given EXE you’ve got, this is where to look.

Continued on next page

**TABLE 19.6:** SYSTEM PARTS DESCRIBED IN THE SOFTWARE ENVIRONMENT FOLDER (*continued*)

SYSTEM PART	DESCRIPTION
Loaded Modules	Like the Running Tasks folder, except that it lists all dynamic link libraries in memory. Version, size, file date, manufacturer, and path information are all displayed. If you want to know what version of a given DLL you've got, this is where to look.
Services	Lists all the (nonboot or system) services available on the server by name. The state of each service, its start mode (manual, automatic, or disabled), and its type are all shown.
Program Groups	Lists all the groups available from the Start menu. The view shows the users for whom the groups are customized (this information is stored as part of each user's profile, so you may have several different listings of the same program group, each associated with a different user). Terminal server profile associations will be displayed here.
Startup Programs	Lists all the programs configured to run at system startup.
OLE Registration	Shows all the object linking and embedding associations used to open data files in the right kind of application.
Windows Error Reporting	Lists some errors appearing in the Event Log, their type (e.g., DHCP errors or hanging applications) and some details for the error.

## Internet Settings

As you can see in Figure 19.30 and Table 19.7, all the settings for IE are listed in the Internet Explorer folder within the Internet Settings folder, although (as with the other settings in the System Summary folder) you can't change any of them.

**FIGURE 19.30**

Contents of the Internet Explorer folder

TABLE 19.7: SYSTEM CONFIGURATION SETTINGS IN THE INTERNET EXPLORER FOLDER

SYSTEM PART	DESCRIPTION
Summary	Lists basic version and path information about IE. The most useful information indicates the degree of encryption IE is set up to use, which printers are set up to work with IE, whether the Content Advisor (ratings software) is on, and whether the Internet Explorer Administration Kit is installed.
File Versions	Lists all the files installed that support IE, including their version number, date, size, path, and the company supplying them. If a file is expected but not present, it's still listed, but its version is recorded as "file missing."
Connectivity	Lists the connection settings for the browser. Most of what's here applies to proxy server settings, but also listed is whether the dialer is set up to kick in when you start IE.
Cache	Lists the objects in the IE cache (stored when you view online content so that when you need the images again they can be loaded from the cache). It also lists the size of the cache.
Content	Lists the content controls in place on your IE setup. Again, it's indicating whether the Content Advisor is enabled. Any certificates in place (your own or someone else's) are also listed here.
Security	Lists the security settings you have in place for different site classes: trusted, local intranet, Internet, and restricted.

**Saving System Configuration Information**

All this information is great, but sometimes it won't help you get the answers you need to resolve problems with the server. That doesn't mean that it can't get someone *else* the answers they need to fix problems. The System Information tool lets you save and load configuration information. Using this capability, you can save your server's configuration to a text file or system information file. You can then e-mail that file to a tech support person who has Server 2003 installed (or not, but if not they'll have to read the text file) and can then load the file and view your computer's information as if they were connected to the server.

***TIP** To save only part of the system information, select the part you want to save before starting the save procedure. For example, to save only information related to the network card's configuration, make sure that folder is selected in the left pane.*

**SAVING AND OPENING SYSTEM INFORMATION FILES**

To save information as a file, open the File menu in the System Information tool and choose Save. In the dialog box that appears, type a name for the file (it will have an .nfo extension, just as these files did in Windows 2000) and click Save. The server will chug away for a minute or two as it inventories your system (so that the saved file reflects the most current information), and then store the file in your My Documents folder unless you specify otherwise. The file isn't too big—mine is 198KB—so

you can fit it onto a floppy if necessary. To open a saved file, choose Open from the File menu, browse for the file, and—get this—open it. (I detail this mostly because opening saved files in Windows 2000 was something of a pain. It's much simpler in Server 2003.)

### SAVING SYSTEM INFORMATION AS TEXT

Saving system information as a text file works much the same way as saving it as an NFO file. In the System Information tool, choose Export from the File menu. Again, the default location is the My Documents folder. When you click the Save button, the server will inventory itself to make sure that the most current settings are saved, then put them into a TXT file that you can read with an editor such as Notepad. It's a long file; this is a partial dump of the information I collected from one server:

Directory	C:\WINNT
User Name	REDROOM\ChristaA
Time Zone	Eastern Standard Time
Daylight Savings Time	Eastern Daylight Time
Total Physical Memory	130612 kbytes
Available Physical Memory	14572 kbytes
Total Virtual Memory	2097024 kbytes
Available Virtual Memory	1988656 kbytes
Page File Space	311252 kbytes
Page File	C:\pagefile.sys

Needless to say, I'd rather analyze the data from an organized system information file than from a 225KB ASCII file, but the fact that you can save the information as text means that you *can* give someone your system configuration for analysis without them being able to read NFO files.

### SAVING INFORMATION FROM THE COMMAND LINE

You don't have to open the graphical tool if all you want to do is create a system information log. Msinfo32.exe supports the command-line switches shown in Table 19.8 to generate a local or remote system information file.

**TABLE 19.8: WINMSD COMMAND-LINE OPTIONS**

SWITCH	DESCRIPTION
/?	Displays Help
/msinfo_file	Opens the specified saved file
/nfo filename	Outputs an NFO file with the specified filename and quits
/report filename	Outputs a text-format file to the specified filename and quits
/computer computername	Connects to the specified computer
/categories catlist	Displays or outputs the specified categories
/category catlist	Sets the focus to a specific category at startup

So, for example, typing `msinfo32.exe /nfo g:\tools\report.nfo` will generate a complete copy of the local computer's system information and store it as an NFO file in `G:\tools`. (Notice that I must include the file suffix even though I've specified that I want to create an NFO file—`winmsd` isn't smart enough to generate the suffix information on its own.) When I open this file on any computer with the MMC installed, it will show up as the local system information. If I wanted to create a text report (again, I don't recommend doing this unless you simply have no other options—it's too long), then I'd type the command like this: `msinfo32.exe /report g:\tools\report.txt`.

**NOTE** *Generating the report takes a few minutes, even on a fast computer.*

## Troubleshooting the Boot Process

The operating system includes several tools that can help you recover from problems related to the operating system, but these tools are no good if you can't get to the Advanced Options menu (discussed later) available at boot time for troubleshooting or get the Setup menu to recognize that your server does, in fact, have a hard disk. In this section, I'll describe the steps the server follows to boot, including the outward manifestations of those steps so you can figure out which step went wrong.

### Prequel: The Hardware Must Work

Before you can even attack the problem of "What's wrong with the operating system?" you must make sure that it's not a problem of "What's wrong with the server?" You will not be able to boot the server at all if either of the following are true:

- ◆ The boot drive, the boot drive's disk controller, or the cable connecting the two is malfunctioning or incorrectly set up.
- ◆ The processor or the motherboard is dead.

Other hardware can give you problems, but these are the two that will really stop you in your tracks. To isolate the problem, watch and see where the problem appears:

- ◆ A computer that does not boot *at all*, does not make noise, does not do anything at all, probably has a dead (or turned off) power supply or a dead power cord.
- ◆ A computer that will start its fan but doesn't do anything beyond that probably has a problem with its motherboard.
- ◆ A computer that will count up memory but isn't displaying anything on the monitor (you can hear it, but you can't see it) and beeps at you probably has a problem with the video card.
- ◆ A computer that starts to load the operating system (in this example) and then blue-screens before displaying the logon screen may be having memory problems. Bad device drivers are also a possibility.
- ◆ A computer that will boot and find the CD and floppy but doesn't find the hard disk controller probably has a problem with the hard disk controller.
- ◆ A computer that will boot and identify the hard disk controller but doesn't find a bootable hard disk probably has a hard disk problem. If you're still not positive and you have a spare system around, swap in an easy part of the computer, such as the hard disk controller, if you're not sure whether the problem lies in the disk or the controller.

***TIP** Keep an eye on the fans in your servers. Those fans are vital to keeping delicate components cool. A cooked computer is a dead computer, sooner or later. A company called PC Power and Cooling ([www.pcpowercooling.com](http://www.pcpowercooling.com)) makes a temperature sensor, the 110 Alert, that fits inside a PC and squawks when the internal temperature rises above 110 degrees.*

Finally—is the server plugged in? Is its UPS turned on? I know, I know—but check.

## Using the Advanced Options Menu

If it's not the hardware, then what if it's the operating system?

No matter how careful you are, mistakes sometimes happen or something just goes wrong. In such a case, you'll need to fix your installation, hopefully without reinstalling the operating system. Sometimes you have to reinstall to make things right again, but it's definitely something to be avoided, since restoring a server back to its original greatness is generally a bit more comprehensive than just running Setup and blasting by all the defaults. When installing isn't the only option, I prefer to spend my time doing something a little more useful.

If you've made some change to your operating system that makes it unusable, all is not lost—so long as the system will boot at all and can recognize the hard disk that the operating system is installed on. The Advanced Options menu gives you several methods for fixing or debugging a broken operating system. You get to this menu by pressing F8 when the boot menu appears, or (if Server 2003 is the only available operating system) by pressing it when the OS is loading—early on, please. Do so, and you'll see a text menu like the following:

```
Windows Advanced Options Menu
Please Select an option:
```

```
Safe Mode
Safe Mode with Networking
Safe Mode with Command Prompt
```

```
Enable Boot Logging
Enable VGA Mode
Last Known Good Configuration (your most recent settings that worked)
Directory Services Restore Mode (Windows domain controllers Only)
Debugging Mode
```

```
Start Windows Normally
Reboot
Return to OS Choices Menu
```

Incidentally, the Advanced Options menu is one more reason why, any time you're running a dual-boot computer supporting two versions of NT (e.g., NT and Server 2003), you *must* install the older one first. If you install the older OS second, then you may not see the prompt to press F8 to open the Windows Advanced Options menu, the “Starting Windows” progress bar at the bottom of the screen, or the proper startup graphic. The problem is that NT 4 overwrites the shared Windows boot files (Ntldr and Ntdetect.com). To fix this, boot from the installation CD-ROM. At the Windows Setup screen, press R to repair the Windows installation. Then, press C to use Recovery Console. Copy the Ntldr and Ntdetect.com files from the I386 folder on the CD-ROM to the root folder of the boot drive.

I discussed Directory Services Restore Mode earlier in “Backing Up and Restoring the Active Directory.” Let’s take a look at the other modes.

## Using Safe Mode Options

The various forms of Safe Mode—with networking, without networking, with command prompt—load a minimal version of the operating system with only the drivers and files needed to support that minimal version (such as NTOSKRNL). These tools can be handy when something is preventing your system from booting and you suspect an errant driver. Whichever mode you choose, during boot, the OS will display a list of all the drivers and services as they’re loading. When you log out, the machine will restart as usual.

### SAFE MODE

Safe Mode starts the OS with only the drivers and services required to boot the computer. No network drivers are loaded, and network-dependent services are changed to start option 3 (meaning that they’re set for manual starting) but can’t be started even from the Services section of the MMC or with `net start`. Use this version of Safe Mode to fix problems related to network services that are keeping the computer from working at all.

### SAFE MODE WITH NETWORKING

Safe Mode with Networking is what it sounds like—a pared-down version of the OS that includes network support. Use this version when you need network support and you’re sure that the network drivers are not causing any problems. When you boot the computer into Directory Services Restore Mode, it’s booting into Safe Mode with Networking.

### SAFE MODE WITH COMMAND PROMPT

If you’re expecting Safe Mode with Command Prompt to be a strictly command-line version of Server 2003, you’re mistaken. When you boot to this option, you’ll see a list of the files that the OS is loading, and then the graphical interface will appear, running in 640×480. However, rather than loading the Desktop, Server 2003 will use the command prompt for its shell.

Safe Mode with Command Prompt is a network-disabled version of Server 2003 that replaces the `Explorer.exe` shell normally used with `cmd.exe`. You can do anything on the local computer that you can do in the usual shell—you can even run GUI applications, if you don’t mind them running with a maximum resolution of 640×480 and 16 colors, with no working network services. But everything you do you must start from the command prompt or from the Task Manager (still available if you press `Ctrl+Alt+Delete`). Use Safe Mode with Command Prompt to run a stand-alone version of Server 2003 when something is wrong with Explorer that keeps the OS from starting. You can run Explorer from this mode and gain access to the graphical Desktop, if you like, but you’re not dependent on it as you are in the other versions of Safe Mode. If you don’t open Explorer, you can shut down the server with the `shutdown` command.

**TIP** To get a complete list of all the commands supported from the command prompt, type `help | more`. (You can just type `help`, but there’s more commands than will fit on a single screen.) To get help with the syntax of a specific command, type `commandname /?`.

Please note that Safe Mode with Command Prompt is *not* the same thing as the Recovery Console, which I'll get to shortly. I've seen some confusion about this and want to make sure that the difference is clear. Safe Mode with Command Prompt is a minimal version of the OS that uses `cmd.exe` as the default shell (operating environment) but can run any graphical tool so long as you know the command to invoke it. The Recovery Console is for resolving problems that can keep the computer from booting at all. It supports only a subset of commands and cannot run graphical utilities under any circumstances.

## The Last Known Good Configuration

One purpose of the Last Known Good Configuration option is to save you from your better ideas. For example, one time I thought I'd try installing the CD-burning software designed for a Windows 98 computer on a Windows 2000 Professional computer. While installing, I saw an error warning me that the software was not designed for Windows 2000, but I persevered. (Rules? Ha! We spit at rules.) Everything went smoothly, and I finished installing the tool. Feeling a little smug, I rebooted when prompted.

And Windows 2000 refused to start and instead displayed a blue screen. I stopped feeling smug.

Instead, I rebooted again, pressed F8 to display the Advanced Options menu, and chose to boot to the Last Known Good Configuration—the configuration that had been in place the last time I'd been logged into the computer. The computer unloaded the new driver, I booted successfully, and life was good. So long as the change you made produced no system-critical errors (at the time, that is—as you can see, it's okay if the change you made prevents the OS from starting up properly), and you successfully booted and logged in to the server once before you ran into the problem, all is not lost. You can load the Last Known Good Configuration and choose from three different system start-up options:

- ◆ Using the current configuration
- ◆ Using the Last Known Good Configuration—loaded the last time the server successfully booted and you started a session from the console
- ◆ Restarting the computer

## UNDERSTANDING HOW LAST KNOWN GOOD WORKS

The Last Known Good Configuration option works because of the way NT-based operating systems maintain configuration information. Every time you boot the computer and log in, the configuration information for the local machine is stored in `HKLM\System\CurrentControlSet`. The OS also stores a backup copy of this information and assigns it a number for organization purposes. This backup is used should the default set of configuration information—the current set—become corrupted and unusable.

Server 2003 stores several copies of the configuration information, numbering them consecutively (see Figure 19.31). Another numbered set is maintained as a Last Known Good Configuration, to be used if the default configuration set becomes unusable.

You can't tell from the numbers which configuration set your server is currently using. To find this information, look in the `\Select` key in `HKLM\System` (see Figure 19.32). There are four values here: Current, Default, Failed, and LastKnownGood. If you restart the machine and boot normally (that is, without using the Advanced Options menu), then the Default control set will be used. The value

of Failed is the configuration set that had been the default when you chose to start the machine from the Last Known Good Configuration menu. Because you told the OS to not start with that configuration set, it's now marked as Failed even if nothing is actually wrong with it.

**FIGURE 19.31**  
Contents of  
HKLM\System

**FIGURE 19.32**  
The \Select key  
displays all current  
control sets.

**REPAIRING A SERVER WITH THE LAST KNOWN GOOD CONFIGURATION**

That's just background so that you know what's happening; you don't have to tweak the Registry to make the Last Known Good option work.

If you do something that keeps the computer from starting normally, do *not* log on and try to fix it right away. Instead, restart the computer and follow these steps:

- 1. When the system has finished recognizing its hardware (and displays the boot menu if more than one OS is available), press F8 to open the Advanced Options menu.
- 2. Choose Last Known Good from the boot menu and press Enter. The boot menu will now reappear with the words *Last Known Good Configuration* at the bottom of the screen. This is to

remind you that, by loading that option, you're choosing to reverse all nonsecurity-related changes made to the Registry during the last session. As I mentioned in my earlier example, this includes unloading drivers installed during the previous session.

Server 2003 will start with the settings with which you started your last session. After you log in, you'll see an information message telling you that Server 2003 couldn't start with the current configuration and is starting with a previously saved configuration.

The Last Known Good option can't always help you. It applies only so long as you have never logged in with the new configuration, but *have* logged in at least once, and can boot the computer now. That means that it won't work if any of the following apply:

- ◆ You have never logged in successfully (that is, if you're just installing the OS).
- ◆ You edited the server's configuration, rebooted, and logged in successfully, and now want to restore your system to the way it was before the change.
- ◆ The change that you want to reverse is not related to control set information. You can't remove changes to user profiles or system policies with the Last Known Good menu, for example. Passwords are also unaffected by the Last Known Good option, so you can't use this option to recover from a forgotten Administrator's password.
- ◆ The system boots, someone logs in (even with automatic logon), and the system hangs or the problem you wanted to avoid still exists.
- ◆ The system won't boot at all and is unable to get to the boot menu.

## Enable VGA Mode

Those familiar with NT Server will remember that in previous versions of the operating system, the boot menu had two entries for each instance of NT installed on the computer: one with whatever graphics settings you'd chosen and one designed to run in vanilla VGA mode. There was a good reason for this. In NT 3.1, there was no VGA mode, and if you set up the wrong driver and logged in (making the Last Known Good option useless), then you had to go through a complicated sequence of keystrokes to navigate blindly to the Display applet in the Control Panel and fix things. This gave you a terrific sense of accomplishment when it actually worked, but it made video problems more than a little painful to resolve.

The VGA option is no longer in the main menu, however. To get to it, you must press F8 at boot time and choose Enable VGA Mode from the Advanced Options menu. Use this option if you've installed a bad video driver and need to correct the problem. Unlike the Last Known Good menu, this option will work at any time, not just before you've successfully logged in.

## Enable Boot Logging

Enabling boot logging from the Advanced Options menu starts Windows as usual, except that it creates a file called `NTBTlog.txt` and stores it in the top of your system root directory. The output will look like this snippet:

```
Microsoft (R) Windows (R) Version 5.2 (Build 3663)
11 11 2002 15:53:05.500
Loaded driver \WINDOWS\system32\ntoskrnl.exe
Loaded driver \WINDOWS\system32\hal.dll
```

```

Loaded driver \WINDOWS\system32\KDCOM.DLL
Loaded driver \WINDOWS\system32\BOOTVID.d11
Loaded driver pci.sys
Loaded driver isapnp.sys
Loaded driver intelide.sys
Loaded driver \WINDOWS\system32\DRIVERS\PCIIDEX.SYS
Loaded driver MountMgr.sys
Loaded driver ftdisk.sys
Loaded driver \WINDOWS\system32\DRIVERS\WMILIB.SYS
Loaded driver dmload.sys
Loaded driver dmio.sys
Loaded driver PartMgr.sys
Loaded driver VolSnap.sys
Loaded driver atapi.sys
Loaded driver disk.sys
Loaded driver \WINDOWS\system32\DRIVERS\CLASSPNP.SYS
Loaded driver Dfs.sys
Loaded driver KSecDD.sys
Loaded driver Ntfs.sys
Loaded driver NDIS.sys
Loaded driver Mup.sys
Loaded driver crcdisk.sys
Did not load driver Audio Codecs
Did not load driver Legacy Audio Drivers
Did not load driver Media Control Devices
Did not load driver Legacy Video Capture Devices
Did not load driver Video Codecs

```

If you're running into problems, then you can check this log to see what drivers did—and did not—load. It's normal for some drivers to not load; they're available, but if you haven't got anything running that requires them, the OS won't start them, so as to save memory. But if your network, for example, isn't working, you can scan the list of drivers to make sure that NDIS.SYS is present.

***TIP** At a time when the server is working normally, enable boot logging and save the output under another name, noting the date and any new changes to the server. (You can do this pretty easily—all filesystems in Server 2003 support long filenames.) If something does go wrong with the machine, you can compare the healthy boot record with the sick one to find the discrepancy.*

## Debugging Mode

This final option in the Advanced Options menu, Debugging Mode, sends debugging information to a computer connected to a Windows 2000 computer you're booting via the serial port. The basic gist of this is that it's a way to monitor the progress of a server's boot from another server.

## Preparing for Recovery

If the situation is too dire for any of the Advanced Options menu options to help you, all is not lost. Before it's time to reinstall, it's time to drag out one the recovery tools: the emergency repair disk or the Recovery Console, both of which are available through the Repair option in Setup.

## Installing the Recovery Console

How do you get to the recovery tools? You can install the Recovery Console from the Windows 2000 installation CD. Open the Run tool in the Start menu and type `d:\i386\winnt32 /cmdcons` where *d:* is the drive letter of your installation CD. The first time you do this, the setup program will display the message box shown in Figure 19.33.

**FIGURE 19.33**

Initial screen for installing the Recovery Console

Setup will copy some files from the installation CD (or, if you have a live connection to the Internet, from the Microsoft Web site), then prompt you to restart the computer. The Recovery Console will be in the Startup menu (the text menu you see when you start up the computer) when you reboot, listed as Microsoft Windows Recovery Console. To start it, just choose that option before the 30-second time-out to whatever your default startup option is.

**TIP** If you install the system partition as FAT and then think, “Hub. I have this Recovery Console that I could use to repair the system partition, so I’m going to install the Recovery Console and then convert that partition to NTFS,” you aren’t going to like the results. The Recovery Console uses different support files for NTFS and FAT partitions, so if you install it and then convert the system partition to NTFS, the computer will hang when you choose that option from the boot menu. Convert first, then install the Recovery Console.

Incidentally, you can install the Recovery Console onto NT computers as well. If you do so, then you can use NTFS to format the system partition without worrying that you won’t be able to reach this partition if you can’t boot normally.

Why isn’t it a default option to install the Recovery Console when you install the core OS? Good question—it’s so useful that you’d think it would be installed by default or that at least you’d have the option of doing so during Setup. The problem is that installing the Recovery Console deletes necessary files from the `$win_nt$.~bt` folder and thus prevents the existing Setup process from completing if the Setup process you’re using writes that folder to the disk. You *can* install the Recovery Console from within another operating system if you experience a problem that prevents Setup from continuing and that the Recovery Console could fix, such as a damaged master boot record (MBR).

You can also preinstall the Recovery Console by running the `winnt32 /cmdcons` command from the installation CD-ROM to place the files on the local hard disk. The only catch is that you must do this to a volume contained on a single physical disk, even if you later plan to mirror the system partition for system security. You can’t perform a clean installation of Server 2003 onto a currently mirrored partition, and installing the Recovery Console has the same restriction.

## Creating the Automated System Recovery Disk

Every time you successfully edit your system’s configuration, you should back the configuration up against the time when you unsuccessfully edit the settings. This backup disk is called the

*automated system recovery (ASR) disk.* (It used to be the “emergency repair disk”, but I’m guessing some focus group somewhere decided that that was too scary a name.)

**TIP** *Re-create the automated system recovery disk after you have successfully booted with the new configuration information. This way, you’ll know that the configuration you’re backing up works.*

### KNOW THY RECOVERY DISK

It’s important that you realize that the ASR disk you get with Server 2003 is different from the NT 4 emergency repair disk. The ASR disk does not include Registry data—probably because people could easily have a Security key file too big to fit on a disk.

You can replace parts of the system Registry from the Recovery Console, if you update the information in the RegBack folder on a regular basis. (The original files are in the \Config folder; the backups in \Repair\RegBack.) Just don’t expect to have that information anywhere if you don’t back it up when creating the ASR.

Curious about what you *do* with the ASR Disk? Turn to the next section.

To create the ASR disk, follow these steps:

1. Run the Backup utility found in Accessories/System Tools. On the initial screen of the utility, you’ll find buttons for three wizards: Backup Wizard, Restore Wizard, and Automated System Recovery Wizard. Click the latter button.
2. Choose a backup location for a complete system state backup of your computer. Do not choose the floppy disk—it won’t all fit. You’ll need a fair chunk of space for all the System State data.
3. After Backup is finished, insert a blank, formatted floppy disk in drive A: and press OK when prompted to let the wizard copy files to the disk.

Backup will copy the System State data, service information, and disk configuration information to the backup location and `asr.sif`, `asrnpn.sif`, and `setup.log` to the disk. The files are not bootable—this isn’t a boot disk. Those are system information files, like those used to install the OS. Basically, the SIF files.

### Creating a Boot Floppy

The ASR disk is not a bootable disk. If you want to make a floppy that you can use to load the OS when it won’t load off the hard disk, you’ll have to copy those files to a floppy. That floppy will not be machine-specific so long as all computers have the OS installed in the same directory, so you can keep it in your panic kit, and it’s filesystem-independent.

A boot floppy is useful in any of the following situations:

- ◆ Corrupted boot sector
- ◆ Corrupted master boot record (MBR)

- ◆ Boot virus infections that keep the machine from booting
- ◆ Missing or corrupt NTLDR or NTDetect.com
- ◆ Incorrect NTBootdd.sys driver

Oddly enough, although making an NT boot floppy has been common practice for years, there's still no utility in the OS that you can employ to make one. (You can create Setup disks from the `\bootdisk\makeboot` command on the installation CD, but that's not the same thing. Those are Setup disks, this is a boot floppy, like a DOS boot floppy with `autoexec.bat` and `config.sys` on it.) The Windows NT floppy disk must include the files NTLDR, NTDetect.com, boot.ini, and the correct device driver for your hard drive.

### CREATING A BOOT FLOPPY FROM THE CD

If you don't have another Server 2003 box around but do have the installation CD, then you can get the files you need. Copy the NTDetect.com and NTLDR files from the `i386` folder on the CD-ROM to the new disk. Rename the NTLDR file to `setupldr.bin`.

The next step is to create the `boot.ini` file that the OS uses to determine which operating system it should load and where that operating system is located. `boot.ini` files are just text files. For example, the following works for a single partition IDE drive with Server 2003 installed under `\winnt`; the exact value in the `[operating systems]` section depends upon the configuration of the Windows NT System you want to boot:

```
[boot loader]
timeout=30
Default= multi(0)disk(0)rdisk(0)partition(1)\winnt

[operating systems]
multi(0)disk(0)rdisk(0)partition(1)\winnt="Server 2003 "
```

WINNT, in this case, is the name of the system root directory.

**TIP** If your computer boots from a SCSI hard drive, replace the `multi(0)` with `scsi(0)`. If you are using `scsi(x)` in the `boot.ini`, copy the correct device driver for the SCSI controller in use on the computer, and then rename it on the floppy to `NTBootdd.sys`. If you are using `multi(x)` in `boot.ini`, you do not need to do this.

### CREATING A BOOT FLOPPY FROM ANOTHER COMPUTER

If you have a working copy of Server 2003 around, you can copy the files you need from it. Format a floppy disk using the `FORMAT` command on the working computer. Do a full format, not a quick format. Next, copy NTLDR and NTDetect.com from the computer to the floppy. Both NTLDR and NTDetect.com are in the root directory of the system folder.

Next, create a `boot.ini` file or copy one from a running computer (it's also in the root directory of the system folder) and modify it to match the computer you are trying to access.

**TIP** You'll need to edit the options on the View tab of Folder options (available from the folder's Tools menu) to stop hiding protected operating system files such as NTLDR, NTDetect.com, and boot.ini. Just choosing to show hidden files and folders won't show this file.

## Repairing—or Recovering—a Damaged Installation

The Last Known Good menu and the Safe Mode boot options aren't always enough to get a wounded installation back on its feet again. You still have some options before reinstalling, though. As I discussed in the previous section, Server 2003 offers two repair tools: the Recovery Console and automated system recovery. Both work on volumes formatted with either FAT or NTFS; one of the cool things about the Recovery Console is that you can format a system partition with NTFS for greater security but still have access to troubleshooting tools.

### Understanding Repair Options

The two repair options aren't identical. Automated system recovery is a simple procedure for those times when you don't know precisely what the problem is, but you want to fix it and get on with your life. There's little finesse involved: You start installing the OS; when asked whether you're doing a real installation or a repair, you choose to repair; and then you pop in the ASR disk and let Setup repair files that are different from the ones originally installed. (There's a little more to it than that, but that's the basic story. I'll go through the procedure a bit later in "Using the ASR Disk.") So long as you haven't replaced any drivers or DLLs in your system folders with new ones, you can safely choose to restore all system files to their originals, and you'll still get your installation back as you left it—just fixed.

The Recovery Console is a little more complicated. Rather than a means of restoring damaged files, it's a command-line utility from which you can perform a variety of tasks:

- ◆ Copy system files from a floppy disk or CD to a hard disk (although not from a hard disk to a floppy disk)
- ◆ Start and stop services
- ◆ Read and write data in the system directory on the local hard disk
- ◆ Format disks
- ◆ Repartition disks

Use the Recovery Console when you know precisely what's wrong and what you want to accomplish. If you don't know what's wrong, this is not an easy way of finding out.

In short, if your installation is dead and you're not sure why, then use the ASR disk to see whether restoring the original installation files will fix the problem. If you know what the problem is—like, for example, a bad or missing SYS file or a runaway service—then you can use the Recovery Console to copy the missing file to its new location without changing any other files.

If you didn't set up the Recovery Console before the OS became unbootable (or you want to run the ASR disk utility), then you'll need to run Setup from the installation CD. After Setup has copied all the files it needs to access the hardware it needs to run Setup, it will ask you whether you want to install the OS, repair it, or exit Setup. Choose R to open the Windows Repair Options menu, from which you can repair an installation either with the Recovery Console (press C) or with the automated system recovery disk (press F2).

### Using the Recovery Console

When you choose to run the Recovery Console, it will scan the disk and find any installations of Windows NT-based operating systems on the disk. Pick the one you want to repair. Type the

number of the option you want, and supply the password for the Administrator account—*not* the account of someone in the Administrators group, the Administrator account. So long as the SAM database is present and you can be properly authenticated, you're in. (If it's not, then you need to restore the backed-up Registry files you stored in %systemroot%\repair\regback before you can use the Recovery Console.)

**TIP** *On the off chance that you have a dual-boot NT/Server 2003 computer, you can repair Windows NT Server 4 installations on dual-boot computers with the Recovery Console even though NT does not come with the Recovery Console. Start the Repair Console as you normally would. When it returns the list of found NT installations, pick the NT 4 one.*

Although it looks like an ordinary command prompt, the Recovery Console is not the command prompt that you can open from the **Accessories** folder. First, it supports only a few commands and only locally—this is not a network tool, and you can't run just any command-line program or utility on it. Second, those commands are specialized for this interface and only perform a limited set of functions. By default, the wildcard options in the **copy** command don't work in the console; by default, you can only copy files from removable media to the system partition (but not the other way around—you can't use the console to back up files to other media); and although you can move to other logical drives on the hard disk, by default you can't read files on any partition other than the system partition—or even perform a **dir** function on them. If you try, you'll get an Access Denied error. (As you'll see, you can change some of the security settings to make the Recovery Console more useful, but these are the defaults.) The Recovery Console is not a command-line version of Server 2003, cool as that would be.

**NOTE** *Sadly, the Recovery Console does not include a command-line version of REGEDIT, like Windows 9x does.*

You can't back up files. You can't read the contents of any directory not in the system root. You can't use wildcards. You can't edit security information. What *can* you do with the Recovery Console?

Quite a lot, actually, if recovery is what interests you. As you can see in Table 19.9, the Recovery Console is a set of commands you can use to manipulate the files and structure of the system partition. As you can see, a lot of functions with duplicate commands use the same syntax; unless I specify otherwise, there's no difference between the two commands.

**TABLE 19.9: SUPPORTED RECOVERY CONSOLE COMMANDS**

COMMAND NAME	FUNCTION
attrib	Changes the attributes of a selected file or folder.
batch	Runs the commands specified in a text file so that you can complete many tasks in a single step.
cd or chdir	Displays the name of the current directory, or changes directories. Typing <b>cd..</b> closes the current directory and moves you up one in the tree.
chkdsk	Runs CheckDisk.
c!s	Wipes the screen of any previous output.

*Continued on next page*

**TABLE 19.9:** SUPPORTED RECOVERY CONSOLE COMMANDS (*continued*)

COMMAND NAME	FUNCTION
copy or extract	Copies files from removable media to the system folders on the hard disk. Does not accept wildcards.
del or delete	Deletes one or more files (does not accept wildcards).
dir	Lists the contents of the current or selected directory.
disable	Disables the named service or driver.
diskpart	Replaces the FDISK tool with which you're probably familiar. Creates or deletes disk partitions. Only use this command on basic disks—it can damage dynamic disks.
enable	Enables the named service or driver.
expand	Expands a compressed installation file (one with a .cab extension) onto the local fixed disk. Only works if you're running the Recovery Console from the installation CD.
fixboot	Writes a new partition boot sector on the system partition.
fixmbr	Writes a new master boot record (MBR) for the partition boot sector.
format	Formats the selected disk.
listsvc	Lists all the services running on the server installation.
logon	If you have multiple Server 2003 installations on the local hard disk, you can use this command to pick the installation you want to repair.
map	Displays the drive letter mappings currently in place. Handy for getting the information you need to use DISKPART. Only lists drives found in the partition table, not volumes listed only in the dynamic disks volume database.
md or mkdir	Creates a directory.
more, type	Displays the contents of the chosen text file.
rd or rmdir	Deletes a directory.
rename or ren	Renames a single file.
set	When enabled, allows you to display or modify four security settings governing file and folder access.
systemroot	Makes the current directory the system root of the drive you're logged in to.
Type	Displays a text file's contents to the screen of the Recovery Console.

**WARNING** *If you thought the Registry Editor was potentially dangerous, the Recovery Console is just as bad or worse. You can really screw up your system here, to the point that the only thing to do is reinstall and reload your backups. There's no Undo feature, not all the commands ask for confirmation, and there's no Read-Only setting such as the one in REGEDT32. If you're not used to working from the command line, review what you want to do and the tools you need to do it before you open the console, and practice on a test system before attempting any real recovery.*

Some of the commands in Table 19.9 will look familiar to old DOS hands, but many of them work a little differently from the way they did under DOS, using a slightly different syntax or only working under specific circumstances. Let's take a look at how you can use these commands to get things back up and running.

#### BEFORE YOU BEGIN: FIX THE SECURITY SETTINGS

Did you notice that I said *by default* you can't copy files to external media and *by default* you can't access any partition other than the system partition? The weasel wording wasn't accidental.

Normally, from the Recovery Console you can only use the following folders:

- ◆ The root folder
- ◆ The %SystemRoot% folder and the subfolders of the Windows installation you are currently logged in to
- ◆ The Cmdcons folder
- ◆ Removable media drives such as CD-ROM drives

You also can't use wildcards with commands that would normally support them or copy data to disks.

Bah. Let's use the SET command to make the Recovery Console a bit more flexible. This command allows you to display or modify four environment options:

Option	Default Setting	Description
AllowWildCards	FALSE	Controls whether you can use wildcards with some commands (such as <code>del *.tmp</code> )
AllowAllPaths	FALSE	Controls whether you can change directories (with the <code>cd</code> command) to include all folders on all local drives
AllowRemovableMedia	FALSE	Controls whether you can copy files from the hard disk to a floppy disk or other recognized removable media
NoCopyPrompt	FALSE	Controls whether you can copy files without being prompted to continue when you are overwriting an existing file

Oho—so you run `set AllowAllPaths = TRUE` (don't forget the spaces around the equal sign) and you can navigate anywhere on the local disk, right? Almost right. Before you ever start the Recovery Console, you need to edit some security settings before the SET command will work. Depending on what kind of computer this is—a server or a domain controller—go to the Security Configuration and Analysis snap-in in the MMC, the Domain Controller Security Policy in Administrative Tools, the Domain Security Policy in Administrative Tools, or the Local Security Policy in Administrative Tools. Whichever tool you choose, look under Computer Configuration\Windows Settings\Security Settings\Security Options and locate the two security policies pertaining to Recovery Console: Recovery Console: Allow Automatic Administrative Logon and Recovery Console: Allow floppy copy and access to all drives and all folders.

The first policy allows you to start Recovery Console without prompting for the administrative password stored in the local computer's account database. (That's kind of handy, but it does represent a security risk and I don't think it's a good idea.) The second policy enables the SET command while you are using Recovery Console. If you enable this policy, you can change any of the four environment variables to TRUE during a Recovery Console session.

After you enable the security policy, it must be applied (possibly across the domain) before becoming the effective policy on the local computer. This is necessary before the SET command is truly enabled and available for use during a Recovery Console session. To make it snappy, you can run `secedit /refreshpolicy machine_policy` to force a refresh of the local computer's policy after performing the policy change described previously.

After the local policy is refreshed and the enabled Recovery Console security policy is in effect, you should be able to start Recovery Console and use the SET command to enable any of the four environment options.

One last thing: You need to run SET every time you run the Recovery Console—it won't remember that you changed any settings from their defaults.

**TIP** Put the SET commands you want to apply to your Recovery Console sessions in a batch file so you can run the batch file with the BATCH command when you start the Recovery Console.

## ENABLING AND DISABLING SERVICES

Why would you need to enable or disable services from the command line? Therein lies a tale.

Lo these many years ago, I bought a new PC. Installed Windows NT Server; ran the installation program for the 3Com network card in the server. Life was good.

Until I rebooted the computer.

You see, a diagnostic program was part of the setup for the NIC—an unavoidable part that you could not choose to not install. (Trust me: I tried, on several computers with the same set of hardware.) Whenever I started up NT, this diagnostic program would scan the system and display a message that a newer version of my NIC's driver was available—did I want to use the new driver? Click OK or Cancel, and the message box would close for a second and then reopen, with the same message. Add to this that the searching and displaying was using up 100 percent of CPU time for a 350MHz Pentium II doing *nothing else but running the diagnostic*. Running the Task Manager (when I could get a spare cycle here or there to open it) didn't help because the program wouldn't shut down even when I killed the process.

**NOTE** Worried about this happening to you? Although I've run into several people who've had the same problem with one version of the driver for the 3Com 3C905X Ethernet 10Base-T card, this issue seems to be fixed in the driver published in April 1999. Other than this glitch, I've been very happy with these NICs.

Okay, I figured—the problem is a runaway service, so if I can shut down the service I will resolve the problem. But shutting down the service is hard when you're clicking OK in a repeatedly reappearing dialog box and then frantically grabbing CPU cycles to open the Control Panel and then Services before the dialog box opens and the processor usage starts running at 100 percent again.

In this case, I was finally able to get to the Services applet, find the service (named 3Com Diagnostics or some such, so identifying the problem child wasn't hard), and then stop and disable it.

Problem solved. But it took a lot of time and mouse-clicking to get to that point. A tool that would enable me to boot to the command prompt and disable that service without having to work around the cycle-eating message box would have been nice. And that's where the services-related tools in the Recovery Console come in.

The first step to fixing a problem like this is running the `listsvc` utility. There are no arguments to this—just type **listsvc** from the command prompt, and the Recovery Console will display a list of all the services and drivers currently installed, a short description of what they are, and their start type (boot, automatic, manual, system, or disabled). Seeing all the services will probably take a few pages of screen, but the services are listed alphabetically, so you can find the one you want fairly easily. Write down its name.

**TIP** *The names of services and drivers are not case sensitive.*

Once you've found the suspected problem child, it's time for the **disable** command. The syntax is simple: **disable servicename**. The Recovery Console will then notify you that it found the Registry entry for this service (or tell you that it can't find an entry for this service, in which case you need to check your spelling and try again). It will also display the current start type and new start type for the service. Write down the current start type for the service in case you want to start it again.

To make the change take effect, type **exit** to leave the Recovery Console and restart the computer. See whether disabling that service fixed the problem. If it did, then you're home free. (Not sure how you'd know? Depends on what the problem was. In the case of the runaway 3Com diagnostics, the fix was pretty immediate. As soon as I turned off the service, the problem disappeared.) If it didn't, then you can return to the console, enable that service, and try something else.

You don't have to disable a service to keep it from running when the OS starts, however. Instead, you could change its start type from automatic to manual. To do so, or to reenable a service you disabled, you'll need to use the **enable** command. Like **disable**, **enable**'s syntax is simple: **enable servicename**. If run on a disabled service, using this syntax will enable the service and restore it to whatever its start type was when it was disabled.

To change a service's start type without disabling it, add the new start type to the end of the **enable** command, like this:

```
enable servicename start_type
```

where *start\_type* is one of the options in Table 19.10.

**TABLE 19.10: START TYPES**

START TYPE	MEANING
Service_boot_start	Boot
Service_system_start	System
Service_demand_start	Manual
Service_auto_start	Automatic

So, for example, instead of disabling the 3Com diagnostic service, I could have changed its start type from automatic to manual. That way, I could have started it at any time, but it wouldn't start automatically.

### REPLACING DAMAGED FILES

Perhaps the problem isn't a runaway driver or service, but a corrupted part of the operating system, as in error messages that say **Bad or Missing NTOSKRNL.EXE**. In such a case, you may need to replace all or part of your operating system (although, if we're talking about more than a few files here or you aren't sure what's broken, it might be time for an automated system recovery). The tools most likely to apply to this scenario are the ones to create and delete directories, rename files, change attributes, and copy or extract files from other media.

Creating directories is simple. The command syntax is as follows:

```
md [drive:]path
mkdir [drive:]path
```

where *drive:* is the drive letter of the drive on which you want to create the folder, if it's not the current one, and *path* is the name of the directory you want to create. Just make sure that, if you don't spell out the location of the new directory, you're currently in the place where the new directory should be created.

The syntax for the **rmdir** and **rd** commands (for deleting directories) is the same as that for **md**. The only part of directory deletion that you have to watch is that you can't delete directories unless they're empty, with no subdirectories. If you try, you'll get an error message telling you that the directory is not empty, and there's no switch to make **rd** act like **deltree** (an old DOS command that would delete subdirectories).

Before you delete a directory, run the **dir** command to check out its contents and make sure that you really do want to remove it. Conveniently, **dir** displays all files, hidden or not, and shows their attributes.

Rather than deleting entire directories, however, you're more likely to need to replace individual files. That's where **copy** and **extract** come in. The **copy** command is what it sounds like: a method of copying a file from one location to another, with the caveat I've mentioned before that you can only copy *to* the system directory, not copy files from the system directory to removable media such as a Jaz drive. The syntax for copying files is simple:

```
copy source [destination]
```

where *source* is the name of the original file and *destination* is the directory where you're pasting the original (along with a new name, if you need it). If you don't specify a directory, the file will be copied to the directory from which you're running the command. The **extract** utility works the same way as **copy** and uses the same syntax, with one exception: You can only use **extract** if you started the Recovery Console from the Repair option in Setup. Neither copying utility supports wildcards (so you can't copy the entire contents of a directory very easily), but **copy** automatically decompresses compressed installation files for you. Both utilities will alert you if a file with the name of the one you're pasting already exists in that location.

If you're not sure that you want to replace an existing file, try renaming it and then copying the new file to the relevant location. The syntax for **rename** is as follows:

```
rename [drive:][path] filename1 filename2
```

`rename` works only on single files, and the renamed file must be in the same place as the original. That is, you can't use this command to move files. To do that, you'd need to use `copy`.

### FIXING BOOT SECTORS AND BOOT RECORDS

Your computer uses a couple of pieces of information to navigate your hard disk. Those two pieces are the boot sector and the master boot record (MBR). Most of the time, these pieces are pretty safe, but some things (such as some viruses) can target and infect them, or they can be lost. In such a case, you'll need a way to restore them.

First, a little background. The partition boot sector contains the information that the file system uses to access the volume. The MBR (discussed next) examines the information in the boot sector to load the boot loader.

The boot sector contains the following information:

- ◆ A jump instruction
- ◆ The name and version of the operating system files (such as Server 2003)
- ◆ A data structure called the BIOS Parameter Block, which describes the physical characteristics of the partition
- ◆ A data structure called the BIOS Extended Parameter Block, which describes the location of the master file table for NTFS volumes
- ◆ The bootstrap code

Most of the information in the boot sector describes the physical characteristics of the disk (for example, the number of sectors per track and clusters per sector), in addition to the location of the file allocation table (for FAT volumes) or the master file table (for NTFS volumes). The layout and exact information included in the boot sector depends on the disk format used.

Given that a disk may have more than one partition, how does the hard disk know where to find the different partitions? The first sector on every hard disk (whether the hard disk has an operating system on it or not) contains that disk's MBR. The MBR contains the partition table for that disk and a small amount of code used to read the partition table and find the system partition for that hard disk. Once it finds that partition, the MBR loads a copy of that partition's boot sector into memory. If the disk is not bootable (has no system partition), the code never gets used and the boot sector is not loaded.

In short, a hard disk needs a functioning MBR to boot. The MBR is in the same place on every hard disk, so it's potentially an easy virus target.

Okay—all that said, to write a new boot sector to a drive, type **fixboot**. This will write a new boot sector to the current boot drive. To create a new MBR, type **fixmbr**.

### DELETING, CREATING, AND FORMATTING PARTITIONS

The Recovery Console includes tools not only for fixing the OS, but for completely wiping things out and starting over. With these tools you can repartition and reformat your hard disk. *Partitioning* is setting up logical divisions of the disk; *formatting* is placing a file system on those drives so you can store data on them.

**WARNING** *You probably already know this, but just in case you've forgotten, repartitioning and formatting are destructive. Any data on the hard disk you've reformatted or repartitioned is history. Keep your backups.*

Before you start formatting or repartitioning, you might want to take a look at what you've already got in place. The Recovery Console's **map** command can help you do that. Type **map** at the command prompt, and you'll see output like the following:

```
?          OMB      Device\HardDisk0\Partition0
C:   FAT16  1028MB   Device\HardDisk0\Partition1
?          3310MB   Device\HardDisk0\Partition0
E:   NTFS   1028MB   Device\HardDisk0\Partition2
H:   NTFS   1028MB   Device\HardDisk0\Partition3
G:          1028MB   Device\HardDisk0\Partition4
?          227MB    Device\HardDisk0\Partition0
A:          Device\Floppy0
D:          Device\CDROM0
```

**TIP** If you're running **MAP** on a dynamic disk, only volumes created before you updated the disk (that is, volumes that were originally primary partitions or logical drives) will show up. **MAP** reads the partition table, and dynamic volumes created on dynamic disks are not in the partition table.

You can see from this that logical drive G: on the hard disk hasn't been formatted because it's not showing any file system. To format it, you would use the following syntax:

```
format g: [/q] [/fs:filesystem]
```

Here, **/q** tells **format** to do a quick format (not checking for bad sectors), and the **/fs** switch is for specifying the file system to use. You don't have to specify a file system (your options are NTFS, FAT32, and FAT), but if you don't, Win2K will format it to NTFS. When you run this command, Win2K will tell you that all data on that drive will be lost and ask you to confirm that the format should proceed. Do so, and a few seconds later you will have a newly formatted drive.

**TIP** You can convert a **FAT** partition to **NTFS**, but you cannot convert an **NTFS** partition to **FAT**.

You can format the G: drive safely, or at least without affecting any other logical drives. What you *can't* do, even before formatting, is repartition to make the G: drive bigger, perhaps giving it some of that space that isn't used on the disk. To do that, you need to boot the Disk Administrator and make G: part of a volume and then extend that volume—anyway, it's all in Chapter 10. If you do want to repartition the disk to reorganize its structure, run **DISKPART**.

**WARNING** **DISKPART** can damage your partition table if you've upgraded the disk to a dynamic disk. Do not modify the structure of dynamic disks unless you are using the Disk Management tool.

When you're done with the Recovery Console, type **exit** and press Enter. The computer will reboot.

## Using Automated System Recovery

Those who've read previous versions of this book may recall that the Windows 2000 recovery process using the ERD was fairly involved, requiring you to choose manual or fast repair to restore the system from the Registry backup. Automated System Recovery is more automatic than using the ERD was

with NT or Windows 2000. To make it work, you'll need the original installation CD and the ASR disk you created using the process described earlier in the "Creating the Automated System Recovery Disk" section. Start Setup on the damaged computer, then press F2 at the beginning of text-mode Setup when prompted at the bottom of the screen. (You'll see this prompt right after the prompt to press F6 to install third-party disk drivers.)

Setup will start formatting the disk as it would during a typical Setup operation. Next, Setup will copy the files to the Windows installation folders and load the configuration files. The computer will reboot and boot to Server 2003, going through the first stage of graphical Setup.

So far, the process is very similar to a typical Setup and you may find yourself wondering if you picked the right option. Fear not—after completing the first stage of graphical Setup, the recovery process will automatically begin Backup and start a Restore operation from the backup you created when making the ASR disk. This is a nonauthoritative restore of System State data, so if you're restoring a domain controller you'll need to use NTDSUTIL as described previously to make it authoritative for the domain. Also, since this backup only copied System State data, you'll need to restore any of that data separately.

The computer will reboot again, but this time normally. That's it—the computer is restored with all the settings that were in place at the time of your backup, even to the display resolution.

## Planning for Disaster Recovery

Sometimes using the Last Known Good Configuration or the Recovery Console doesn't fix your problems. Hard disk failures or natural disasters require a bit more in the way of hard-core disaster recovery.

What does *disaster recovery* mean? Essentially, it's exactly what it sounds like: a way of recovering from disaster—at best, turning a potential disaster into a minor inconvenience. Disaster can mean anything: theft, flood, an earthquake, a virus, or anything else that keeps you from being able to access your data. After all, it's not really the server that's important. Although a server may be expensive, it is replaceable. Your data, on the other hand, is either difficult or impossible to recover. Could you reproduce your client mailing list from memory? What about the corporate accounts?

### Creating a Disaster Recovery Plan

The most important part of a disaster recovery plan is identifying what "disaster" means to you and your company. Obviously, permanently losing all of your company's data would be a disaster, but what else would? How about your installation becoming inaccessible for a week or longer? When planning for disaster, think about all the conditions that could render your data or your workplace unreachable and plan accordingly.

### Implementing Disaster Recovery

Okay, it's 2:00 P.M. on Thursday, and you get a report that an important server has died. What do you do?

#### WRITE THINGS DOWN

Immediately write down everything that everyone tells you: what happened, when it happened, who gave you the information, and anything else that happened at the same time that might possibly be

related. Do not trust it to memory. First, you're apt to be a bit stressed at this point. Second, if it happened once, it could happen again—and if you write down the results of your interviews, you may not have to start from scratch.

### **CHECK THE EVENT LOGS**

If you can get to them, look at the security and event logs on the server to see if you can tell what happened right before the server crashed. If you're using directory replication to maintain a physically identical file server (also known as a *hot start* server because it's ready to go whenever you need it), the log information may be on the replicated server, even if you can't get to the original.

### **ASCERTAIN THE CAUSE OF THE FAILURE AND FIX IT**

"Easy for you to say," I hear someone muttering. It can be done, however. Once you know what events happened, it becomes easier to find out what they happened to.

#### ***Find Out If It's a Software Problem***

Is it a software problem? If it is, have you changed the configuration? If you've changed something, rebooted, and been unable to boot, it's time to use the Last Known Good Configuration discussed earlier. If you can boot but the operating system won't function properly, use the automated system recovery disk to restore the hardware configuration.

If you have another server with a Server 2003 installation identical to the server that failed, switch servers and see if the backup server works before you reinstall the operating system. If the hot start server doesn't work, you could be facing a network problem.

#### ***Find Out If It's a Hardware Problem***

Is it a hardware problem? If you have a hot start server around the office, put it in place of the failed server and see if you can bring the network back up. If so, the problem lies with the dead server, and you can fix or replace it while you have the other one in place. If not, check the network's cabling.

If one drive from a fault tolerant stripe set or mirror set has died, the system should still be fine (if the drive that died is not the one with the system partition on it), but you should still fix the set anyway. Striping and mirroring gives you access to your data while the missing data is being regenerated, but if something else happens to the set before you regenerate the missing data, you're sunk, because the set can only deal with one error at a time.

If necessary, reload the backups.

### **Make a Recovery "Coloring Book"**

No matter how much you know about reformatting SCSI drives or rebuilding boot sectors byte by byte, I guarantee you that the fastest way to recover from a disaster will often turn out to be a three-step process: replacing the bad hard disk and attendant hardware, installing a fresh copy of NT Server on the new hard disk, and restoring the data on the disk.

That sounds simple, but it's amazing how complex it can be in the heat of battle. Let's see, I'm reinstalling Server 2003, but what was the name of the domain? What IP address does the domain controller get? What's the WINS server address? Which services went on this server? What was the administrator's password set to?

At my shop, we decided to sit down and write a step-by-step, click-by-click instruction manual. It tells future network administrators which buttons to click and what text to type in the unlikely event that they ever need to take a new machine and rebuild our domain controller on it.

Just for an example, we have a primary domain controller on one of our domains that (as the logon traffic is relatively light) is also our DHCP, WINS, and DNS server. So, suppose the machine goes up in smoke, leaving us nothing but backup tapes—how do we rebuild that machine? We sat down and wrote out exactly what to do:

- ◆ Install Server 2003 on a new machine.
- ◆ Restore the SAM and SECURITY databases.
- ◆ Install DHCP on the machine.
- ◆ Restore the old DHCP database to the machine.
- ◆ Install WINS on the machine.
- ◆ Restore the WINS database.
- ◆ Install the DNS server on the machine.
- ◆ Restore our DNS zones and records.
- ◆ Restore the user data.

Assume that the person who'll be doing this knows nothing more than how to click a mouse and shove CDs into drives—someone with oatmeal for brains. Sound insulting? It's not; I like to think of myself as of at least basic intelligence, but under pressure I sometimes just don't think as well as I need to—oatmeal's as good as it gets, and if I'm really pressed my brains have the power of unidentified goo. If you're good under pressure, that's great—but making the disaster recovery guide an easy read is also a big help to your coworkers.

**TIP** *An easier and less error-prone solution is to create unattended installations for key servers, either using answer files or Remote Installation Services. See Chapter 5 for more information about unattended installations.*

Don't underestimate how long this will take: Putting the whole document together took two research assistants a couple of weeks, and it ended up being a 100+ page Word document! (Part of the reason why it was so large is that it made lavish use of screen shots wherever possible, and yours should, too. Just click the window you want to include in your document, press Alt+Prtsc, choose Edit/Paste Special in Word, choose Bitmap, and uncheck Float over Text.)

**WARNING** *Once you finish the document, be careful where you keep it. The document will contain the keys to your network: usernames of domain administrator accounts, the passwords of those accounts, and the like.*

## Making Sure the Plan Works

The first casualty of war isn't always the truth—it's often the battle plan itself.

The most crucial part of any disaster recovery plan is making sure that it works down to the last detail. Don't just check the hardware; check everything. When a server crashes, backups do no good at all if they are locked in a cabinet to which only the business manager has the keys and the business manager is on vacation in Tahiti.

In the interest of having your plan actually work, make sure you know the answers to the following questions.

### **WHO HAS THE KEYS?**

Who has the keys to the backups and/or the file server case? The example mentioned previously of the business manager having the only set of keys is an unacceptable situation, for reasons that should be painfully obvious. At any given time, someone *must* have access to the backups.

You could set up a rotating schedule of duty, where one person who has the keys is always on call, and the keys are passed on to the next person when a shift is up. However, that solution is not foolproof. If there's an emergency, the person on call could forget to hand the keys off to the next person, or the person on call could be rendered inaccessible through a dead beeper battery or downed telephone line. Better to trust two people with the keys to the backups and server so that if the person on call can't be reached, you have a backup key person.

### **CALLING IN THE MARINES: DISASTER RECOVERY SERVICES**

Disaster recovery isn't always fully successful. Perhaps your backups don't work or have themselves been destroyed. One more option remains before you have to tell everyone that everything they were working on for the past month is irretrievably gone: data recovery centers. Data recovery centers are staffed by people who are expert at getting data off media (most often hard disks, but not always) that can't be accessed by normal means.

Not all data recovery centers are the same. Some data recovery centers (in fact, the first data recovery centers) are staffed with people who are really, really good at getting dead hard disks back up and running. Using their skill, they can resuscitate the dead drive, copy its contents to other media, and then return the data—on the new media—to you.

Other data recovery services can retrieve data not recoverable with ordinary methods. These services operate at a binary level, reading the data from the dead media (sometimes even opening the hard disk, if the problem is serious enough) and then copying the data to your preferred media. Turnaround time is typically no more than a day or two, plus the shipping time.

The cost of data recovery depends on the following:

- ◆ The method of recovery used (the places that just fix hard disks tend to be cheaper but can't always recover the data)
- ◆ The turnaround time requested
- ◆ The amount of data recovered

Consider storing irreplaceable data on a different physical drive from data you can easily replace. A data recovery service can't selectively restore data. That is, if the data files and the system files are stored on a single physical disk, you can't save yourself a little money by asking the center only to recover the data files, even if the data is on two different logical partitions.

Until recently, you had to send the hard disk to the data recovery center to have its data retrieved, and this meant not having the data for at least a couple of days. Remote data recovery services can fix some software-related problems without requiring you to ship the drive anywhere or even take it out of the computer case. Using a direct dial-up connection, the data recovery center may be able to fix the problem across the telephone line.

**IS SPECIAL SOFTWARE REQUIRED FOR THE BACKUPS?**

Must any special software be loaded for the backups to work? I once nearly gave myself heart failure when, after repartitioning a hard disk and reinstalling the operating system, I attempted to restore the backups that I'd made before wiping out all the data on the file server's hard disk. The backups wouldn't work. After much frustration, I figured out that Service Pack 2 had been installed on the server. I reinstalled the service pack from my copy on another computer, and the backups worked. I just wish I had figured that out several hours earlier.

**DO THE BACKUPS WORK, AND CAN YOU RESTORE THEM?**

Do the backups work, and do you know how to restore them? Verifying backups takes a little longer than just backing them up, but if you verify, you know that what's on the tape matches what's on the drive. So, as far as restoring goes, practice restoring files *before* you have a problem. Learning to do it right is a lot easier if you don't have to learn under pressure, and if you restore files periodically, you know that the files backed up okay.

**HAVE USERS BACKED UP THEIR OWN WORK?**

In the interest of preventing your operation from coming to a complete halt while you're fixing the downed network, it might not be a bad idea to have people store a copy of whatever they're working on, and the application needed to run it, on their workstation. People who only work on one or two things at a time could still work while you're getting the server back online.

Disasters shouldn't happen, but they sometimes do. With the proper preventive planning beforehand, they can become entertaining war stories, rather than sources of battle fatigue.

## Chapter 20

# Installing and Managing Remote Access Service in Windows Server 2003

IT SEEMS LIKE IT was only a few years ago that the concept of remote computing or dial-up connectivity was relatively unknown. As far as most of the world was concerned, there was no such thing as the Internet, the idea of telecommuting hadn't been born yet, and e-mail didn't exist. Remote connectivity and dial-up modems were vague, mysterious technologies as far as the average person was concerned. Once considered the tools of businesses and technically oriented individuals to simply get "data" from one location to another, these concepts have now become part of even Grandma's everyday life.

Technology has changed the world in some remarkable ways, but the most amazing way is how "connected" people are these days (or, at least, they can be if they *want* to). Home computers are becoming more and more common, and the average home consumer can buy a dial-up modem just as easily as a toaster or CD player. Employees are being equipped with everything from laptops to palmtops and being sent out on the road, with the expectation that they should be just as connected on the road as they are when they're in the office. For better or for worse, this onslaught of technology has brought with it a demand for easy connectivity—anytime, anywhere.

These demands have put a heavy burden on the backs of system administrators. Not only does the typical administrator have to handle day-to-day support issues *within* the office, but with so much work happening outside the office an already difficult job seems impossible at times. Unfortunately, there isn't a magical solution for everyone yet (I doubt there ever will be), but Microsoft's Remote Access Service (RAS) has been designed and improved over the years to help administrators deal with some of these demands.

Originally developed in the early days of Windows NT, RAS was initially bundled as part of the base operating system. I've always felt the reason for this (at least partially) was to give NT a competitive advantage against other network operating systems out on the market—namely Novell. When remote computing was first starting to take off, Novell was the primary player in the Network Operating System market and they had developed add-on products like NetWare Connect to support dial-up connections to NetWare networks. Products like NetWare Connect worked well and

gave users the connectivity they needed, but these products had to be purchased separately and the license costs often increased in direct proportion to the number of simultaneous dial-in connections that needed to be supported.

While I can't be absolutely certain this is the reason Microsoft chose to bundle RAS with the operating system for free, it certainly seems like a reasonable assumption. As many recent court cases have highlighted, "bundling" is a popular Microsoft tactic to gain market share. Personally, I know of at least a few organizations that started deploying NT in its early days simply because of the number of things that were included for free with the operating system—things they would have had to pay extra for with any other network operating system. Whatever the reasons were, NT began to take off, and RAS capabilities grew with each new version of the operating system.

Microsoft has improved RAS with each new version of Windows NT to the point where it has grown into a full-featured remote access platform capable of handling even the most demanding environments. By the time Windows NT 4 was released, RAS was a solid, reliable part of the NT operating system. The Internet was a few years along in its transition from the government and education environment into the commercial world, and it was becoming more common for people to try to leverage their investments in Internet connectivity to meet their remote access needs. With the release of NT 4, Microsoft included support for Point-to-Point Tunneling Protocol as a means of encapsulating RAS packets and sending them over the Internet instead of a modem. The phrase "virtual private networking" started becoming a buzzword in the vocabulary of network administrators, and Microsoft improved on the virtual private networking capabilities of NT 4 by later releasing a routing update called Routing and Remote Access Service (RRAS).

With the advent of Windows Server 2003, Microsoft has put together the most comprehensive set of remote access capabilities to date, consolidating all the previous technologies and capacities in an easy-to-use interface. But with so many options available, at times it can be hard to know which solution is your best choice. In the pages that follow, I'll discuss what some of your options are, some common scenarios you will probably run into, and the solutions for those problems.

## Common Applications for Remote Access Service

For the purposes of this text, we'll assume that Remote Access Service is divided into two distinct functions: accepting inbound calls and placing outbound calls. Microsoft now commonly refers to the latter as Dial-Up Networking (DUN for short), and receiving inbound calls has pretty much always been referred to as Remote Access Service (or RAS). Even though RAS and DUN share some of the same setup and installation routines, when you see a reference to DUN, you can assume it is for an outbound call.

With that clarification taken care of, let's take a look at some of the tasks you can accomplish with the Remote Access Service in Windows Server 2003.

### Connecting Clients to the Internet

One of the more commonly used capabilities of Dial-Up Networking is to allow your computer to dial in to an ISP—usually via Point-to-Point Protocol (PPP)—and communicate with distant servers and hosts across the Internet. Although this might commonly be used for simple browsing and file transfers on a server, it is becoming common for e-mail and proxy servers to function entirely over dial-up connections to the Internet.

Windows 2000 Server included several functional improvements over previous versions of Windows NT for dial-up networking on the client side. Features such as demand dialing, reestablishing failed links, and the ability to repetitively dial unresponsive numbers made Win2K dial-up networking a pretty robust platform for establishing Internet connections and for keeping them online. Windows Server 2003 adds even more new features to the RAS environment. The introduction of Point to Point Protocol over Ethernet (PPPoE) drivers allows you to utilize your broadband connection for demand-dial connections. There are a few other improvements as well, including the ability to make your NAT interfaces work with Basic Firewall, the addition of support for L2TP/IPSec connections which originate from VPN clients located behind a NAT (network address translation) network, support for preshared keys using L2TP/IPSec authentication, and broadcast name resolution by a NetBT proxy located on the VPN server for networks which are operating without WINS or DNS. But first, I'll talk about the basics of RAS and why we need it.

### **Accepting Incoming Calls from Remote Clients**

Traveling workers, telecommuters, and late-night workaholics all share one thing in common: they all eventually need access to corporate resources from remote locations. Remote Access Service can serve as a platform to get these users connected to your internal networks and servers.

Whether you need to allow access to your NT network, Novell servers, Unix hosts, or any other internal devices, RAS can act as a universal gateway for all your inbound communication needs. By accepting inbound connections from several different devices (analog, ISDN, X.25, VPN) and routing the traffic to your internal network, RAS can provide seamless networking for your users. Workstations dialed into a network over RAS will work exactly the same as they would if they were connected directly to the network (albeit a bit slower—more on that later).

### **Connecting to a Private Network**

In addition to connecting a Windows Server 2003 to the Internet, it's often necessary to connect one network to another—perhaps to transfer data to suppliers or clients. In any case, Windows Server 2003 can be connected to another private network just as easily as to the Internet and take advantage of the same link-reliability features.

### **Acting as an Internet Gateway**

In response to popular demand, Microsoft added the capability for a Windows 2000 or Server 2003 to share an Internet connection among clients connected to an internal network. By the addition of NAT capabilities, Windows can act as a sort of proxy for getting internal clients connected to the Internet.

**NOTE** *It is worthwhile to note that this “proxy” service for getting internal clients connected to the Internet over a shared connection is completely different from the Microsoft Proxy BackOffice application, or their current version of Proxy, Internet Security and Acceleration (ISA) Server.*

Although this service is primarily of use to small and home offices, it has been a dramatic (and welcome) addition to the suite of services contained in RAS.

### **Accepting VPN Connections from Remote Clients**

Along with the advent of the Internet in the corporate world, the concept of virtual private networking (VPN) has emerged and become one of the hottest areas in networking. Virtual private networking,

loosely defined, is a means of running a secure private network over an insecure public network. Or, in plain English, you can have clients get connected (securely) to your office network by simply having an Internet connection and a valid (public) IP address and then establishing a VPN session to your RAS server. The VPN session is secure and encrypted, so your private data is protected as it passes over the public network (i.e., the Internet).

Microsoft leveraged their investments in RAS with the development of virtual private networking and this feature is continued in Server 2003. By incorporating PPTP and L2TP protocols within the operating system, you can effectively set up “virtual” modems that work over IP networks, instead of analog or digital circuits. The methodology and terms used to implement these virtual modems are the same that are used for regular modems, so learning how to implement virtual private networking is made easier.

Microsoft offers two choices for communication using VPNs. You can use the older PPTP and MPPE combination of encryption and authentication protocols, or you can use L2TP and IPSec. In Windows Server 2003, Microsoft has expanded the capabilities of using L2TP and IPSec from behind a network address translation interface, which was impossible previously. We’ll talk more about VPNs in the section titled “VPN Overview.”

## Dialing Up a Remote Network and Routing Traffic

With the addition of the Routing and Remote Access Service Update to Windows NT 4, Microsoft made it easier for a Windows NT Server to act as a router, connecting to remote networks as needed and routing traffic. This type of connection between locations is commonly referred to as wide area networking, or WAN connectivity.

With no more hardware than a dial-up modem at each site, internal clients and workstations can access resources on remote networks through this capability. By simply programming your internal workstations and devices to use your Windows Server 2003 as a “gateway,” RAS can accept client traffic destined for a remote network, establish a connection to that network, and then pass the traffic across the connection as necessary. Since most office-to-office connectivity has traditionally been handled via costly dedicated circuits, having this ability is a tremendous benefit.

This capability has helped organizations act in a completely “virtual” capacity—appearing to have a centralized network of resources that are actually individual servers spread across several sites, joined by demand-dial connections.

## Bandwidth Planning and Considerations

Before we begin discussing what types of hardware and software you need to start using RAS, it’s important to make sure you have an understanding of when RAS would and wouldn’t be a good solution. The two most important factors in determining this are speed and reliability.

No discussion of remote access would be complete without defining the two different types of communication that are often referred to when you hear the phrase “remote access.” These are sometimes referred to as *remote-node* and *remote-control* technologies. They may sound similar, and as far as end users are concerned they’re basically the same, but these two methods of remote access are in fact very different. Unfortunately, many administrators are often left with implementing vague management directives such as “make sure that our employees can work while they’re on the road,” which are amazing oversimplifications of remote access’s complexities. It’s important to understand the capabilities and limitations of each type of access so you can make the best decision for your needs.

## Remote Node

RAS is a remote-node method of communication and a very flexible and versatile means of getting users or networks connected to one another. Overall, I prefer remote-node solutions over remote control for most applications, but having an understanding of how remote node works will help you recognize the best time to use it.

One of the simplest ways to visualize remote-node communication is to view the phone line connecting a client to a network as a *very* long network cable. Like any normal network cable in your office, this one is plugged into two locations. It starts at the user's workstation or laptop, goes through the phone company, and then ends at a modem in your office. Visualize that entire connection as a network cable. That modem, in turn, is connected to a RAS server (or another similar device), and the RAS server is—presumably—connected to your network. The RAS server accepts the incoming data from that dial-in user and then simply “passes” their data onto a local network segment. The same is true for outgoing data. The RAS server will see any outgoing data destined for that user on the network and transmit it over the phone line. As far as end-user functionality goes, your network should work exactly the same way in the office as it does dialing in, albeit much slower.

Since typical office network connections these days are running at speeds of upwards of 10,000,000 to 100,000,000 bits per second, throughput can be amazingly fast. So fast, that it is easy to overlook the amount of data that is actually traveling across your network. Considering the fact that the best analog modems available today are only reaching speeds of 56,000 bits per second, throughput can be a problem with remote-node solutions. Basic math indicates that there's only about 1/20th of the bandwidth available over a 56K modem in comparison to a 10-megabit Ethernet connection. That simple fact has a direct impact on the speed and performance of applications being used on the network. For example, a 2.5MB Word document might open up in just a few seconds on a 10-megabit Ethernet connection in an office, but on a 56K modem connection, that document could take upwards of a few minutes to open up.

### CALCULATING MODEM TRANSMISSION TIMES

Use the following formula to calculate modem transmission times:

$$\frac{\text{File size in "bytes"} \times 8}{\text{Speed of connection in "bits" (i.e., 56k = 56,000)}} = \text{Transmission time in seconds}$$

### CASE IN POINT: CHOOSING THE RIGHT REMOTE ACCESS SOLUTION

If you implement a RAS solution without having some of these facts in your arsenal, you could end up with a solution that is effectively useless. Consider, for example, the case of one of my clients—let's call them the XYZ Corporation. The XYZ Corporation was in the process of moving into a new building but had to leave their accounting software and data on the file server in their old building due to several licensing and political issues. The accounting software was an old FoxPro file-based program that had served them well for many years, but it was eventually being replaced when they moved.

Their initial desire was to just have users dial in to the network in the old building and work on the accounting application as they did before. However, since the accounting application was file-based as opposed to being client-server (more on that later), the amount of data going back and forth between their workstations and servers was simply too great to make a remote-node solution work for their application. Simple analysis of their traffic indicated that their primary users of the accounting software were easily transferring 20 to 40 megabytes worth of data across their network in *as little as an hour*. If you've ever downloaded a large application from the Internet over a modem, you know how long it takes to move that much data—you probably start your download overnight and check it again the next morning.

Remembering our calculations from earlier, only about 1/20th of the bandwidth was available to XYZ Corporation over a dial-up remote-node connection. Quite simply, they were not going to be able to move that much data over a modem and maintain usable response times—a remote-node solution was *not* going to work for this client with this specific application.

The key factor that worked against XYZ Corporation was the fact that their critical application was file-based instead of being client-server. I can't emphasize enough how important it is to understand the mechanisms that computers typically use to move data around, so let's walk through some example applications of each of these types, see how they work, and see why some don't work well with remote-node solutions while others do.

#### **FILE-BASED APPS VERSUS CLIENT-SERVER APPS**

Consider, if you will, a simple Microsoft Access database of names and phone numbers that you have stored on your computer. For discussion purposes, we'll assume that you have not "indexed" this database (a process which makes searching databases faster) and are trying to look up the phone number for an individual with the last name of Justice. To find this name and number, you'd launch your Microsoft Access application, open your phone number database, and then do a search on the last name. Once you submit your search, your CPU would talk to your hard drive controller, tell it to open the database on your hard drive, and retrieve the first record in the database. When the first record comes back, it turns out that it's for somebody named Anderson. The CPU realizes that Anderson doesn't equal Justice, so it dumps the first record from its memory and then requests the second one. The second record is for Beveridge. Beveridge doesn't equal Justice either, so once again the CPU dumps that record from memory and reads the third one. And so on, and so on, until it finally gets to the record for Justice. Once it successfully finds Justice, it displays the record on the screen.

The important factor to take note of is the repetitive process the CPU had to go through to get the data it needed. It had to keep communicating with the hard drive controller to get the next record, and then receive the response (the actual data) and check it. Given how speedy today's computers are, this all happens in the blink of an eye. But as you can see, there's a lot of communication that has to go on to make that simple operation work.

That communication, however, is all taking place between the internal components of your systems—from the CPU, across the data bus, through the hard drive controller, to the hard drive, and back again. Since these devices are directly connected to each other, they're very fast. However, suppose you move that phone number database off your hard drive and onto a file server so everyone in your office can access it. If you do the same search as before, each time Microsoft Access has to get a new record to check, the CPU will send a request to the network controller instead of the hard drive controller. The network controller will transmit the request to the server for the record and wait for

the response from the file server. Once again, the CPU has to request this information over and over again from the network until it finally finds the record for Justice. Since a hard drive on a network file server probably isn't going to respond as fast as the hard drive in your computer, response time suffers.

To put some rough numbers to it, when the database was stored on the computer's internal hard drive, you might have had a maximum of 20 megabits' worth of bandwidth between the components inside your computer (hard drive, controller, bus, and CPU). Let's assume the last-name search took 1 second to complete. Once you move the database on your file server, your maximum bandwidth might have stepped down to only 10 megabits, assuming you're on a 10-megabit network. In theory, a search that took 1 second before could now take 2 seconds. That's still not too bad, and these are rough numbers (don't hold me to them), but they do illustrate the point I'm about to make.

The 1-second query operation became a 2-second query operation when the phone number database was moved off the local hard drive and onto the network file server. Part of the reason for that is the fact that the bandwidth between our CPU and the actual data was cut in half, from 20 megabits to 10. Since the CPU had to keep requesting each record in the file, the bandwidth available between the CPU and the data source plays a key role. Now, what if someone was dialing in to the network and trying to perform the same query? If you recall the 1/20th figure discussed earlier in regards to 56K modems, you can probably see where this is heading. Cutting the bandwidth down from 10 megabits to 56 kilobytes could potentially increase our search time twentyfold. It's entirely possible that our simple query could take upwards of 40 seconds over the 56K dial-up connection.

Now, I'll be the first to admit that I'm oversimplifying things here considerably to make a point. In reality, our example query probably wouldn't take 40 seconds over a dial-up connection, but the response time would be noticeably sluggish. Even if it only took 10 to 15 seconds to retrieve the data, slowdowns like that eventually produce productivity problems. The key to all this is the fact that bandwidth is a huge factor in remote computing if you have any applications that are file-based. So what's the solution? Try to stick with applications that are client-server based.

In keeping with our name-lookup scenario, let's assume that the data is stored in a SQL Server database instead of a standard Microsoft Access file. Using Microsoft Access (the *client* in client-server) as a "front-end" on your workstation, you can submit the same query for the last name Justice as before. However, instead of requesting each record individually this time and checking them one by one, Access will transmit a request to the SQL Server software (the *server* in client-server) for a specific record. Access will transmit a specific request such as "get me the record(s) with a last name of Justice." Small requests like those transmit very quickly, even over a slow connection (like a 56K modem). At that point, the responsibility of retrieving the correct data has shifted from the copy of Microsoft Access running on your CPU and is now in the hands of the SQL Server. Since the SQL Server presumably has high-speed access to the drives that store the data (most likely its own drives), it can find the answer in a few microseconds and then return an appropriate response back to Access.

The key thing to look for in determining whether an application is client-server or not is to see if there are two separate parts to the application. One part will run on your client workstations, and a second part will run on the server that stores your data (or at least on a server nearby with a high-speed connection on it). If there are two parts to your application, it is probably a client-server application and you shouldn't run into too many difficulties with remote-node users using it. However, if there aren't two parts to your application—if the only part is the client software that just uses directories and files on your file servers—you might run into performance problems using remote-node solutions.

Opening Word documents and Excel spreadsheets is, in effect, a file-based application, so it's worthwhile to look at your average document size to see how quickly it might transmit over a slow connection. Refer to the transmission times formula earlier in this section and figure out how long some sample documents would take to transmit over a modem. If most of your documents are simple and text-based, you probably won't run into too many performance issues. However, if your users typically work with large, multimegabyte documents on your server, you might need to consider other options.

## Remote Control

If remote-node communications can be viewed as using a phone line as a long network cable, then remote-control communications should be viewed as using a phone line as a long keyboard, mouse, and video cable. Remote-control solutions, by definition, allow you to remotely take control of a workstation on your network over a dial-up connection. Software on a workstation would typically have some sort of remote-control software running on it (such as pcAnywhere or VNC) and a modem attached to it. This is sometimes referred to as the host PC, since it is typically waiting to host an incoming caller. Then, presumably from another location, another workstation with compatible remote-control software would call into the host PC.

Once the two PCs have negotiated a connection, the host would begin sending its screen data to the calling computer, in effect, letting the person at that calling station see everything that is on the remote screen. The calling workstation would then pass any keystrokes or mouse movements to the host PC, which would perform those actions just as if the user were sitting at the host PC doing them herself. In effect, the remote-control software is tapping into the keyboard, mouse, and video input/output of the host PC and making it available to a remote PC over a phone line.

Traditionally, remote-control solutions have been a bit more expensive to develop and scale due to the increased hardware requirements on each side. Whereas one RAS server with an adequate amount of modems would theoretically be able to handle 256 simultaneous inbound modem connections, having that many simultaneous connections using certain remote-control products could require 256 computers—one to receive each of the connections. That can be rather cost prohibitive in most cases, not to mention difficult to manage. However, it is worth mentioning because in some cases it might be the only remote access solution that would work in your environment.

Microsoft began including some remote-control functionality in Win2K with the bundling of Terminal Services with the base operating system (hmmm, there's that "bundling" concept again). If you are using Windows XP, you can use the Remote Desktop Connection software to remotely control your computer. If you are in a position where a remote-node solution won't meet your needs, you might want to take a look at it and see if Terminal Services or Remote Desktop will work for you. Terminal Services can be a worthy option since it doesn't require a separate computer to handle each inbound connection; instead, it requires one huge computer, and everybody runs a Windows session on that device (note: there are some other third-party products that function in a similar manner).

**NOTE** For more detailed information on Terminal Services, see Chapter 16.

Since you've gotten this far, I'm assuming that you feel RAS is the right solution for you and you're ready to start working with it and implementing it on your network. If that's the case, keep reading. Let's talk a bit about what type of hardware and circuits you're going to need to have in place to make this all work.

## RAS Hardware Requirements

One of the first things to determine in remote networking is where you plan on connecting to and how fast you want to connect. Often, one or both of those criteria will help you determine what your available communications options are. In most instances, that will leave you with one of the following options:

Connection Type	Typical Maximum Speed	Typical Maximum Distance
Analog modem	Asymmetrical: 53Kbps down, 33.6Kbps up	Unlimited, usually domestic
ISDN	BRI—128Kbps, PRI—1.544Mbps	Unlimited, usually domestic
X.25	2400bps—64Kbps	Global
Serial cable	Serial port max—230Kbps in most cases	“Physically near (less than 50 feet),” according to Microsoft
Infrared	Varies	Very close, line-of-sight
Parallel cable	Up to 500Kbps	Very close
Frame relay	1.544Mbps	Global
Cable modem	Asymmetrical: 3–10Mbps down, 256Kbps–2Mbps up	Connect to a local provider
(A)DSL	Asymmetrical: up to 2Mbps down, 256Kbps–1Mbps up	~5 Kilometers (local provider)

Of course, it should go without saying that any devices you are considering purchasing for use with RAS should be checked against Microsoft’s Hardware Compatibility List (HCL) to make sure they are compatible with Windows Server 2003. By checking for HCL compatibility, you can be sure your choice of hardware has been specifically tested for compatibility with Server 2003 and has met the standards Microsoft has deemed necessary to be considered “compatible.”

Also, if you’re purchasing modems from a manufacturer that has several different models to choose from, pick your product carefully. While some modems might cost more than others due to features like voice or fax capability, if you’re looking at two different models from the same manufacturer with the same capabilities, I’d suggest buying the more expensive of the two. The reason for this is quite simple: lower-cost modems are often designed by manufacturers primarily for light-duty home use applications. These are usually the modems you will see on the shelves in retail computer outlets. They are marketed to consumers and designed with tolerances and specifications targeted at the average consumer’s needs. This doesn’t take into consideration the more demanding needs of using modems for routing links, mail servers, etc.

With that out of the way, let’s take a closer look at your hardware and circuit options, and then we’ll jump into configuring RAS on your Windows Server 2003.

## Analog Modems

Analog modems are the most commonly used connection device on RAS servers these days, so a good portion of our examples and configurations throughout this chapter will be using them.

A primer on how modems operate is in order for those of you who are unfamiliar with the technology. Modems are devices that accept binary signals (ones and zeros) from whatever device they are connected to, convert those binary signals into audible tones, and then transmit those tones over a phone line at a prescribed speed. (This process is described as “modulation” and is the derivative of the “mo” part of the word “modem.”)

On the other side of the telephone line, another modem receives these audible tones and converts them back into the binary ones and zeros they represent. Once they have been converted back (“demodulated”), they are passed through to the device the modem is connected to as binary data. As you probably guessed, this “demodulation” process represents the “dem” in the word “modem.”

Therefore, to complete a remote access or dial-up networking connection via a modem, you will need the following:

- ◆ Modem on the transmitting computer
- ◆ Modem on the receiving computer (this may be out of your control, for example, if you are dialing in to an ISP)
- ◆ Telephone connection between the two modems

In today’s world, analog modems can transmit *and* receive data over traditional phone lines at speeds anywhere from 300 to 33,600 bits per second (sometimes referred to as the baud of the modem). As I mentioned earlier, the modems on either end of the connection convert the stream of bits to analog signals and transmit them over the phone line at a prenegotiated speed. But what about those “56K” modems?

### WHEN 56K ISN’T QUITE 56K

A lot of hype and marketing has gone into the 56K modems that are currently available on the market. The modem manufacturers would love for you to believe that these modems are running at the full 56,000 bits per second, in both directions, but unfortunately that isn’t quite the case. If you’re planning on implementing a remote access solution for your organization, it’s important to understand exactly how these modems work, what speeds you can hope to get from them, and what you can and can’t expect from them.

First, you should realize that 56K modems *cannot* send and receive data at that speed in both directions. At the time of this writing, the maximum bidirectional speed anyone has been able to get out of typical analog connections is 33,600 bits per second. Much of that has to do with analog connections and the signal loss that is inherent as the analog data travels from one location to another. However, modem manufacturers are clever and have found a way to work around that limitation by removing half the analog signaling from the equation. By using a special server-side modem at one of the locations and a digital connection directly to the phone company’s central office, data can be sent all the way from the server-side modem to the phone company with zero signal loss. Once the signal is within the phone company’s systems, it usually travels through their system completely digital as well. The net result of this is that speeds of up to 56,000 bits per second are possible but only in one direction—the direction going from the server-side modem to the phone company. Communication in the other direction—from the location with the analog modem toward the phone company—is still limited by the inherent signal loss and peaks out at 33,600 bits per second.

Companies like Internet service providers have been the primary beneficiaries of 56K technology, and 56K modems are a great tool for getting a bit more speed when connecting to the Internet. However, it's important to realize that *you cannot purchase two identical 56K modems, plug them into regular analog lines, and expect to get a connection any higher than 33,600 bits per second between them.* Without having a server-side modem at one of your locations and a digital line from that modem to the phone company, you will be bound by the existing 33,600 limitations.

It's also worth mentioning that even when dialing in to a location with a server-side modem that supports 56K, under current FCC regulations in the United States, if you're using an analog line you will *never* get a 56,000 connection. The FCC has placed limits on the amount of voltage *any* device can transmit over a phone line, which currently restricts all modems to a maximum capability of 53,000 bits per second. However, most analyses and studies of 56K modems have revealed that reasonable speeds to expect for your connections are anywhere from 42,000 to 48,000 for data coming from the server-side modem (or "downlink speed") and, of course, 33,600 for data going to the server-side modem (or "uplink speed"). The amount of speed you get will depend on the quality of the equipment at your local phone company, the condition of the lines in your area, and your physical distance from the phone company's central office. One of my own computers was never able to get speeds higher than 42,000–44,000bps when dialing in to a local ISP until I recently moved. Nothing else changed with my computer except the location it was in, but when I dialed in from my new home, I was consistently connecting at 48,000 bits per second.

## ISDN

A few years ago, a 56K analog modem would be more than enough bandwidth for most remote data needs. However, as computers have grown in size and complexity, so have the files and data that computers typically need to move around. Downloading multimegabyte items from the Internet, such as Windows 2000 Service Packs, could literally take hours over a standard dial-up connection. Fortunately, Integrated Services Digital Network (ISDN) is an option to get more bandwidth without having to get a dedicated circuit in place.

ISDN typically comes in two different flavors, ISDN Basic Rate Interface (BRI) or ISDN Primary Rate Interface (PRI). The main difference between the two is speed (and therefore, price). BRI can support data speeds of up to 128Kbps over standard copper telephone lines, and PRI supports data speeds of up to 1.544Mbps over T1 cable. Since ISDN BRI can run over the same copper wires that most people have wired in their homes, it's more commonly implemented.

ISDN BRI consists of three separate data channels on one connection. Two of the channels are 64Kbps bearer channels, commonly referred to as B channels. These two channels, when combined, make up the 128Kbps that ISDN can use to move data from one location to another. The third channel (commonly referred to as the D channel) is a special 16Kbps out-of-band channel used for signaling between your equipment and the phone company. Although all three channels add up to 144Kbps, most ISDN implementations will either use one or both B channels, so I'll refer to ISDN as being able to support 64Kbps or 128Kbps.

To use ISDN for remote access, you will need the following:

- ◆ An ISDN modem at each location and, optionally, an NT1 network termination device (most ISDN modems come with these built-in today)
- ◆ A digital ISDN connection at each location

## Digital Subscriber Line (DSL)

DSL (Digital Subscriber Line) has become a more common and affordable high-speed connection method in recent years. Using broadband technology, DSL passes data over your phone line and can reach speeds of approximately 140 times the speed of the fastest analog modems. There are many different implementations of DSL, but the most common form is ADSL, or Asymmetric DSL, which is what I'll be referring to here.

One of the benefits of using DSL as a connection method is its “always on” functionality. Unlike analog modems, DSL doesn't require you to connect and disconnect by dialing up to a receiving modem. Instead, once the DSL modem is installed, the connection is persistent and remains on at all times. Another great benefit of using DSL is that, although it does use your phone line to transmit data, you can still transmit voice data at the same time, which means that you don't have to stop talking on the phone so that you can dial up to the Internet.

While analog modems transmit signals through a public telephone network—the same facility that's used to connect telephone conversations—DSL modems “piggyback” data signals over the voice signal. This means that the data gets sent to two different places—your voice calls are sent to the telephone network and your data signals go to the Internet.

DSL modems are generally equipped with Ethernet ports so that, by adding a router, you can connect many machines to a single DSL connection, thus sharing the connection among all of the computers in a small office.

## Cable Modems

Another “always on” technology that is becoming more and more popular is called a cable modem. Cable modems offer high-speed Internet access over a shared cable television line in a geographical area. Like DSL, the connection is persistent, no logging on or off or dealing with busy signals. Unlike DSL though, this technology uses a cable television line rather than a phone line.

While cable modems have greater downstream bandwidth capabilities than DSL, keep in mind that the bandwidth will be shared between all users in the near geographic neighborhood. As a result, the available bandwidth will vary, sometimes dramatically, as more people in that area access the Internet at the same time.

In general, the upstream traffic on a cable modem tends to be slower than that of DSL, sometimes because the individual cable modem equipment is slower and sometimes because there are just too many people in the area are trying to utilize the bandwidth at a time.

Like DSL modems, most cable modems offer an Ethernet connection so that you can tie in the rest of your network and have all your machines use that single access to the Internet. Keep in mind, that although we refer to modems when we talk about both DSL and cable modem technologies, we aren't really talking about modems in the traditional sense. You can't dial up to a RAS server using a telephone number with either of these connection types. What you get is a permanent connection to the Internet, allowing you lots more functionality than the traditional method of using dialup.

## Direct Options (Null Modem, Parallel, and Infrared)

Given the affordability and broad universal support for network cards these days, using a null modem or parallel cable to connect two computers has really become more of a niche than a mainstream use of RAS. However, there may be occasions when it is the only option—maybe you have a specialty

device that can't support a network card and can only communicate with the outside world via a serial or parallel port. If that's the case, a null modem cable, parallel cable, or infrared connection between your systems can be used for a connection.

Null modem cables are typically available at any computer store or through mail-order catalogs. However, according to Microsoft, standard off-the-shelf null modem cables might not be wired correctly for use with RAS. If possible, have your cabling vendor build a custom cable according to the pin configurations listed in Table 20.1. By connecting the null modem cable to the serial ports on each of your devices, you can connect your two computers together as needed. However, you will be limited to your serial port's speed and distance limitations of roughly 50 feet.

**TABLE 20.1: MICROSOFT-SPECIFIED NULL MODEM CABLING REQUIREMENTS FOR RAS**

9-PIN TO 9-PIN		9-PIN TO 25-PIN		25-PIN TO 25-PIN		MAC RS422/423 TO 25-PIN	
HOST SYSTEM	CALLING	25-PIN	9-PIN SYSTEM	HOST SYSTEM	CALLING	MAC	SERVER 2003
3	2	2	2	2	3	1	6, 8
2	3	3	3	3	2	2	20
7	8	4	8	4	5	3	3
8	7	5	7	5	4	4, 8	7
6, 1	4	6, 8	4	6, 8	20	5	2
5	5	7	5	7	7	6	—
4	6, 1	20	6, 1	20	6, 8	7	—

Source: Microsoft Corporation

Parallel connections can be made between two computers using the standard or enhanced (ECP) parallel ports of each device. By connecting devices together in this fashion, it is reasonable to expect throughput speeds of up to 500–600Kbps, but the distance between devices is again very limited. Microsoft lists a specific vendor, Parallel Technologies, in their help files included with Windows Server 2003 as a source for compatible parallel cables to use.

**NOTE** To contact Parallel Technologies about their DirectParallel line of products, call (800) 789-4784 or visit them on the Web at [www.1pt.com](http://www.1pt.com).

Infrared connections were new in Windows 2000 Server and will continue in Server 2003 to serve as a useful option for small offices. Since the connection distance is limited by the strength of the infrared signal *and* a direct line-of-sight requirement, it will be an easy method of connecting (no cables!) but limited in usefulness.

## X.25

X.25 is a protocol that coordinates communication between multiple machines, routing information through a packet-switched public data network. Instead of establishing direct connections from one device to another, all devices in an X.25 network simply connect to a “cloud” and pass their data to the cloud. It is up to the company that maintains and manages the cloud to ensure that the data reaches the correct destination point. X.25 is a relatively outdated technology, which is why throughput speeds top out at 56K to 64K.

So, why use X.25? Well, even though it is an extremely slow transport medium, it is also an exceptionally reliable one. There is an extensive amount of error checking and correction that occurs as a part of the X.25 protocol, which makes it a worthwhile consideration in areas with poor telecommunication services. X.25 is available globally and in some cases may be the only reasonable option for connectivity in certain countries.

## Frame Relay

Frame relay is quickly becoming a preferred option to X.25 connections, as it functions on roughly the same principle—each system passing data into a data cloud—but at much higher speeds. Frame relay can support connections ranging from 56Kbps all the way up to 1.544Mbps. Since frame relay only requires a single connection from each site into the cloud, it is an excellent choice for global connectivity; otherwise dedicated wide area network links across continents could end up being prohibitively expensive to implement.

## RAS Installation and Setup

Now that I’ve laid the groundwork for you to understand how remote access works, it’s time to start working through some of the sample applications discussed earlier.

### Installing Devices for Remote Access

Since a modem is one of the most widely used tools for remote access services, I’ll start by quickly walking you through installing your modem on a Windows Server 2003, making sure that the correct drivers are installed, ports are selected, etc.

To begin adding modems to your system, click the Start button. Choose the Control Panel option, and then click the Phone and Modem Options icon. If this is your first time using this option, you will be probably be prompted for information about your area code, what type of dialing the system should use (tone or pulse), etc. After you’ve entered some of that preliminary information, you will be taken to the Phone and Modem Options applet. Click the Modems tab. More than likely, you won’t have any modems listed. Click the Add button to launch the Add Hardware Wizard, as seen in Figure 20.1.

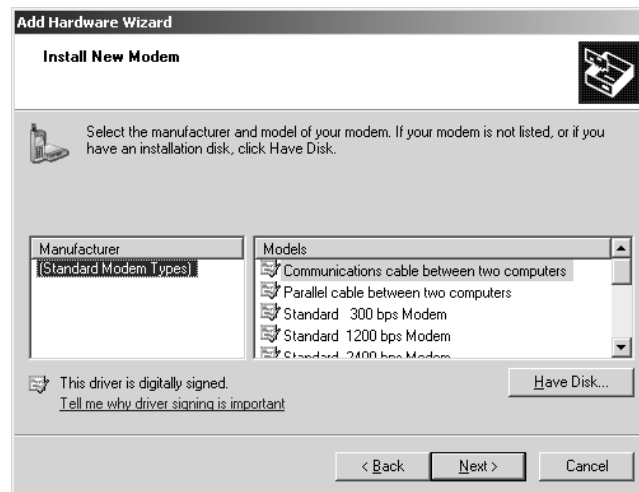

Depending on your preferences, you can either have Windows Server 2003 attempt to detect your modem automatically or you can select it manually from a list. If your modem is a bit older (as in, it was on the market before Server 2003 was introduced), you are probably safe letting Server 2003 attempt to find the correct driver for your modem. Leave the Don’t Detect My Modem; I Will Select It From a List box unchecked, and click Next to begin the detection process.

If your modem is newer than the release of Windows Server 2003, or if you prefer to configure these options yourself (*I prefer setting all these things myself*), check the Don’t Detect My Modem; I Will Select It From a List box, and click Next. You’ll be taken to the screen shown in Figure 20.2.

**FIGURE 20.1**  
Add Hardware Wizard

**FIGURE 20.2**  
Install New Modem selection screen

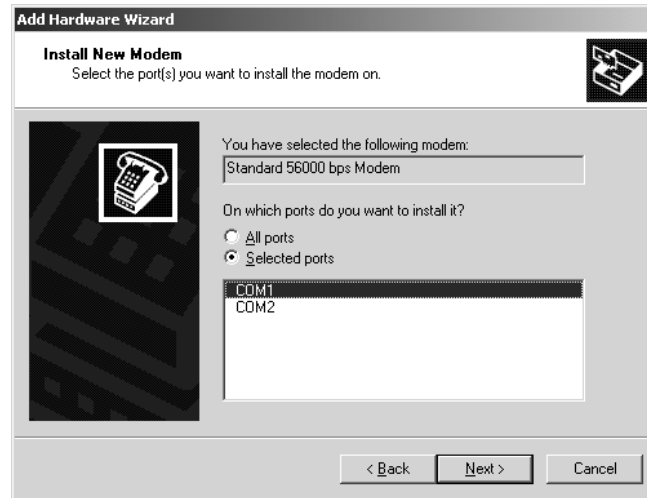

From here, you can choose from a myriad of different modem drivers. Find the driver that matches your modem, select it, and then click Next to install it. If, for some reason, an appropriate driver isn't listed for your modem, you can always use one of the standard modem drivers listed in the Standard Modem Types selection under Manufacturer. The standard modem drivers are reasonably good and are reliable in most circumstances. There are even standard modem drivers for 56K modems supporting the V.90, x2, and k56Flex standards. If your modem manufacturer included a driver disk along with the purchase of your modem, click the Have Disk button and insert your driver disk in the appropriate drive. You will need to tell Windows to look in that location by giving it the appropriate path to check for the driver (usually A:\; consult your modem manufacturer's documentation for further information).

If you are installing your driver by hand, you will need to tell Windows what communications port this modem is connected to, as shown in Figure 20.3.

**FIGURE 20.3**

Selecting communications ports

If you have identical modems on all your communications ports, you can select the All Ports radio button. Otherwise, you should select the port your modem is currently attached to. If you have multiple modems on many ports (but not *all* ports), hold down the Ctrl key while selecting each port. When you have selected the correct ports, click Next to complete the installation. You should receive a confirmation dialog box indicating that your modem has been successfully installed.

Now that you have a modem installed, it's time to take it for a test drive. One of the easiest things to do in Windows Server 2003 is to define a dial-up connection to the Internet, so we'll start there first.

## Connecting to the Internet

It's no secret that Windows Server 2003 was designed with the Internet in mind. Given that fact, Microsoft has made it easy to get your computer connected to the Internet. If you are running Windows Server 2003 as a proxy server so your internal clients can surf the Web, or if you're running it as an e-mail server, dial-up connections to the Internet are an option worth looking into. Due to some readily available fine-tuning parameters you can set for dial-up connections, you can create a rather reliable link to the Internet with just a modem. Let's get started.

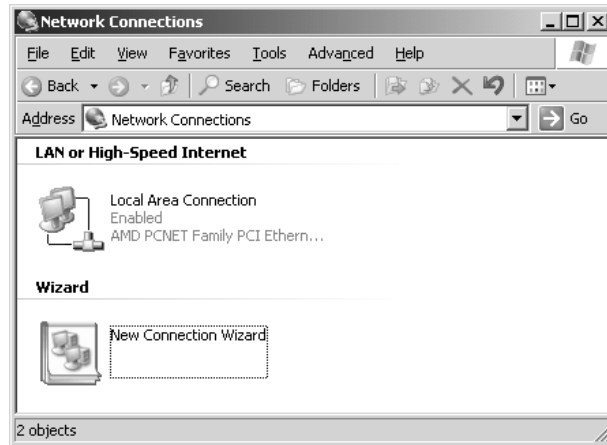

The first thing you'll need to do before connecting to the Internet is set up an account with an Internet service provider (ISP). We won't go through the specifics of how to do that here, but once you have an account you will need a minimum of three things handy to create your dial-up connection to the Internet:

- ◆ A local access phone number to dial (whether analog or ISDN)
- ◆ A username and password combination
- ◆ Optionally, an IP address to assign to your dial-up connection, and DNS addresses to use (most ISPs won't require you to program this information in, but in case yours does, be sure to have this handy in advance)

When you're ready to build your connection to the Internet, choose Start/Control Panel/Network Connections. You should get a window that looks like the screen in Figure 20.4.

**FIGURE 20.4**

Network  
Connections  
window

From here, double-click the New Connection Wizard icon to start the wizard. Click Next in the initial screen of the wizard and you will be presented with a list of connection types you can establish. Select the Connect to the Internet option and then click Next. This will walk you through the process of setting up an ISP account. You will be asked whether you want to set up your Internet connection over a modem, a broadband connection such as DSL or cable modem (with or without requiring a password), or a LAN. If you have in-house Internet connectivity that is already running, then a LAN would be the option you would want to choose. However, since we're discussing modems, let's walk through the modem configuration.

After you select the Connect Using a Dial-Up Modem option and click Next, you will be taken through a process to collect the information we discussed earlier, beginning with the name of your ISP. Once you enter the name of your ISP and the phone number to dial, and choose whether to make this connection available to all users on the system or save it in your profile for your exclusive use, you will need to enter the account information used to authenticate to your provider, as shown in Figure 20.5.

**FIGURE 20.5**

Entering account  
information

**New Connection Wizard**

**Internet Account Information**  
You will need an account name and password to sign in to your Internet account.

Type an ISP account name and password, then write down this information and store it in a safe place. (If you have forgotten an existing account name or password, contact your ISP.)

User name: MicheleB

Password: .....

Confirm password: .....

☒ Use this account name and password when anyone connects to the Internet from this computer

☒ Make this the default Internet connection

☒ Turn on Internet Connection Firewall for this connection

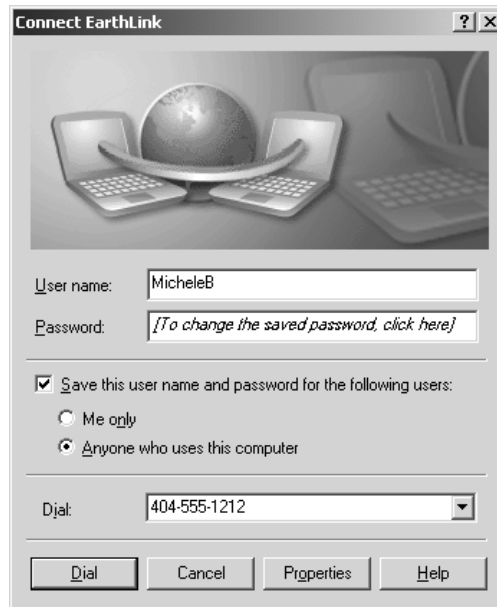

< Back   Next >   Cancel

Here you will enter the user credentials (username and password) your ISP has provided you for use with your account. This information will be stored along with all the other information for this dial-up networking entry so Windows Server 2003 doesn't have to prompt you for it every time you want to make a connection. If you don't feel comfortable having this information stored on your machine, leave the password field blank.

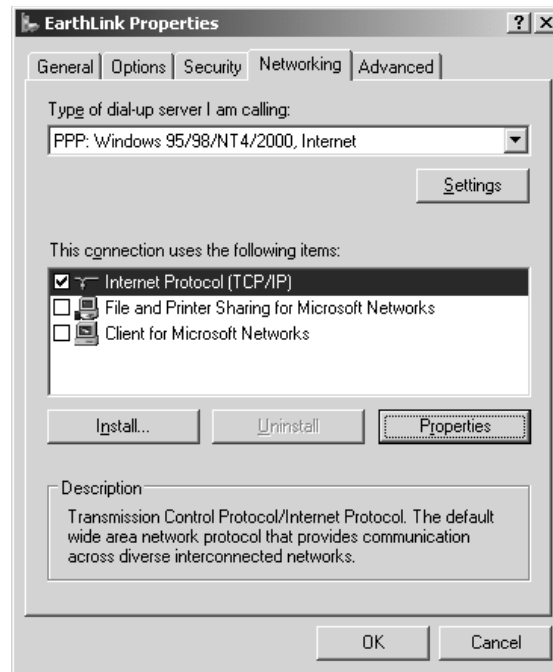

The final options on this screen enable you to choose whether to apply the authentication information to all users, decide if you want this to act as the default Internet connection, and decide whether to turn on the built-in firewall software for the local machine. When you click Next, you will be reminded of your choices in the final screen of the New Connection Wizard. Click Finish to end the wizard and you will be presented with a Connect <YOUR ISP NAME> dialog box that contains the account information for the ISP you just entered, as shown in Figure 20.6. Click Dial to test your connection.

**FIGURE 20.6**

Connect to your ISP.

You may have noticed that you weren't required to enter an IP address to use for this connection. That's because, unlike Windows 2000, the New Connection Wizard in Server 2003 now assumes that your IP address for this connection will be issued by your ISP. Of course, you have the option of setting that information manually if you prefer, as well as choosing the settings for your default gateway, DNS servers, and WINS server information. Let's look at the various options that are available for this dial-up connection. Click the Properties button to view the properties for the connection, then choose the Networking tab to view the screen in Figure 20.7. Highlight the TCP/IP protocol option and then click the Properties button to view the TCP/IP properties page.

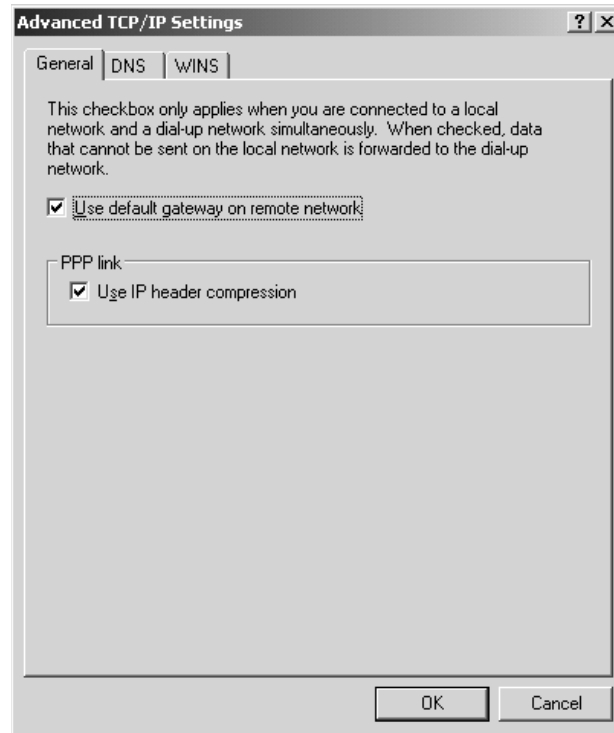

**FIGURE 20.7**Networking  
properties

Even though most ISPs automatically assign you an IP address, if your ISP requires you to manually assign yourself an address, click the Use the Following IP Address radio button in the top of the window and enter the appropriate address in the IP Address field. Some ISPs may still require you to enter DNS server information (DNS is how Windows Server 2003 translates names like [www.microsoft.com](http://www.microsoft.com) into IP addresses). If so, click the Use the Following DNS Server Addresses radio button in the bottom half of the window, and enter your primary and secondary DNS server IP addresses exactly as your ISP provided them to you.

Clicking the Advanced button in this screen will allow you to configure the additional network settings you see in Figure 20.8. Notice the check box called Use Default Gateway On Remote Network. If your machine is not connected to a LAN, you don't need to worry about this option. If your machine does have a LAN connection, in addition to your dial-up connection, then you'll need to understand something about default gateways.

A default gateway is a network address to which your IP requests are sent when the request is for an IP address that lies outside of the local network that your machine resides on.

The default in Windows Server 2003, as you can see here, is to use the default gateway of your ISP provider when connected using the dial-up connection. This enables you to communicate on the Internet via your ISP. However, since your machine can only have one default gateway at any one time, your ability to communicate on your local LAN is limited, at least outside your local network. So, if your computer resides in a larger network environment, your computer will be unable to make requests that would normally need to be sent to the default gateway on your LAN. You can get more information about default gateways in Chapter 6.

**FIGURE 20.8**Advanced TCP/IP  
Settings screen

Click OK, and then click OK again to return to the Networking properties sheet for your ISP connection. Now that you have configured your networking properties for the connection, let's look at some additional options for the dial-up connection.

### Optional Internet Connection Settings

Since you have verified that your Internet connection is working properly, there are some optional settings you might find useful for controlling the behavior of this dial-up connection. Such items include:

- ◆ Programming a list of alternate numbers for Windows Server 2003 to attempt when dialing
- ◆ Disconnecting idle connections (good for per-minute connections such as ISDN)
- ◆ Automatic redialing of busy or nonresponsive numbers
- ◆ Automatic reestablishing of connections that have dropped

All these features are useful enough by themselves. However, if you're running a Windows Server 2003 that *depends* on having an Internet connection available, you'll find these extra features useful. It takes much less administration when a server can take care of establishing and reestablishing its own Internet connections without any human intervention.

To get to these options, you can either click the Properties button from the Connect <YOUR ISP NAME> dialog box or right-click the connection and choose Properties in the Network Connections dialog box. Open the Network Connections window again and right-click your ISP dial-up entry. Select the Properties option, and you should get to the dialog box shown in Figure 20.9.

**FIGURE 20.9**

Advanced Properties  
for the dial-up  
connection

If your ISP has several local phone numbers available for you to use, you can program Windows Server 2003 to cycle through the entire list until it gets a connection. Click the Alternates button next to the phone number, and you should see a screen like the one in Figure 20.10.

From the Alternate Phone Numbers dialog, you can enter as many numbers as you would like Windows Server 2003 to use to attempt to establish this connection. Click the Add button to add a new number to the list, and then use the arrow buttons on the right side of the dialog box to adjust the order of which number should be dialed first.

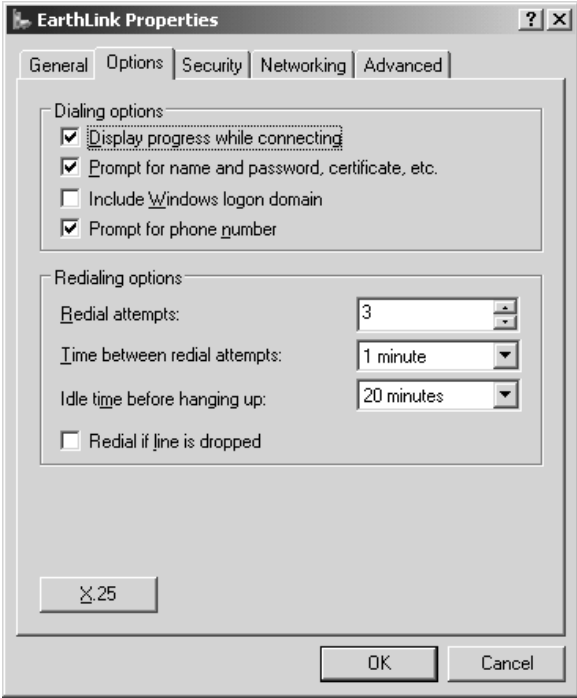

As an additional option, Windows Server 2003 can remember which number was successful last time you connected and try that one first if you check the Move Successful Number to Top of List option. This will make sure that if for some reason one of your ISP's local access numbers goes offline for a while, it won't stay in the top of the list and Windows Server 2003 won't keep trying to dial that number first.

When you're finished entering alternate numbers, click the OK button to return to the main properties dialog box for this dial-up connection. To reach the next set of editable items for this connection, click the Options tab. This should bring you to a screen similar to Figure 20.11.

**FIGURE 20.10**  
Entering alternate  
dial-up numbers

**FIGURE 20.11**  
Editing options for  
dial-up entries

This dialog box has several options available, the most useful of which regard dialing, idle time-outs, and reestablishing broken connections. Let's go through these one by one and show how they can be used.

**Prompt for Name and Password, Certificate, etc.** When you first created this dial-up networking entry using the New Connection Wizard, one of the steps you should have gone through was for entering a username and password to use for this connection. If you decided not to enter your password directly into the settings for this dial-up networking entry, you will want to check this option. Otherwise, Windows Server 2003 will simply try to use a blank password when establishing this connection. Checking this option will cause Windows to prompt you for a username and password to use instead of the existing username and password stored with this dial-up networking entry.

**Redial Attempts and Time Between Redial Attempts** If your local ISP has a problem with busy signals, you will appreciate these options. By choosing the number of times to attempt to redial and the time to wait between attempts, you can program Server 2003 to keep dialing your ISP until a number becomes available. Personally, I've found this setting to be extremely useful in times of inclement weather when everyone is stuck in their homes and clogging my ISP's lines.

**Idle Time Before Hanging Up** If the same phone company that serves my area serves yours, then you are accustomed to paying for your ISDN access by the minute. These per-minute charges can add up to a rather substantial phone bill if your ISDN connection stays up all day. If your server only really needs to have a connection during business hours (for example, for proxy server clients browsing the Internet), set an appropriate idle time-out value here in minutes. Once the specified number of minutes has passed without any activity, Windows Server 2003 will drop the connection.

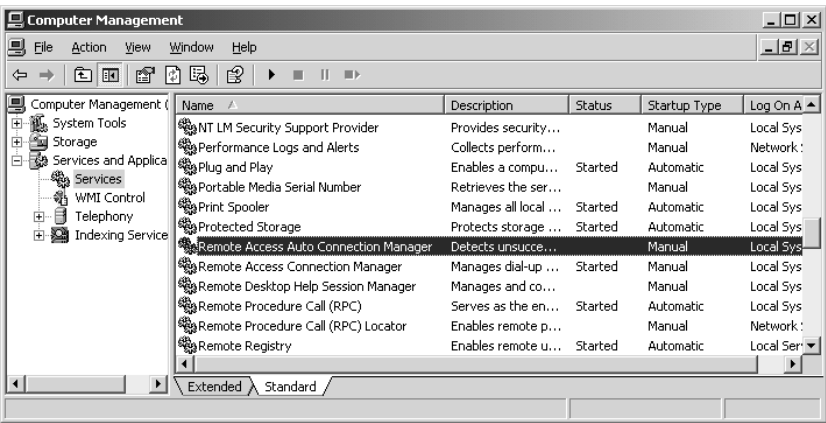

**Redial If Line Is Dropped** It's simply a fact of life—dial-up connections “drop” sometimes. It just happens, but it can cause considerable headaches if people are depending on this connection being up and you happen to be away when it goes down. Checking this option causes Windows Server 2003 to automatically redial and reestablish your connection if it drops. Assuming something hasn't failed on the ISP side of your connection, your link should come back up automatically within about a minute.

For this feature to work, you must have the Remote Access Auto Connection Manager service running. This service doesn't automatically start on Windows Server 2003 by default, so you will need to enable it manually. To do this, enter the Computer Management Console by selecting Start/Programs/Administrative Tools/Computer Management or by right-clicking My Computer and selecting the Manage option. This will bring you into the Microsoft Management Console (MMC) for managing computers on your network. In the left pane of the MMC, you should see an option for Services under the Services and Applications group (you might need to expand Services and Applications to see it). Click the Services icon in the left pane, and you should see a listing of all the services running on your Windows Server 2003 in the result pane. The MMC screen should look like Figure 20.12.

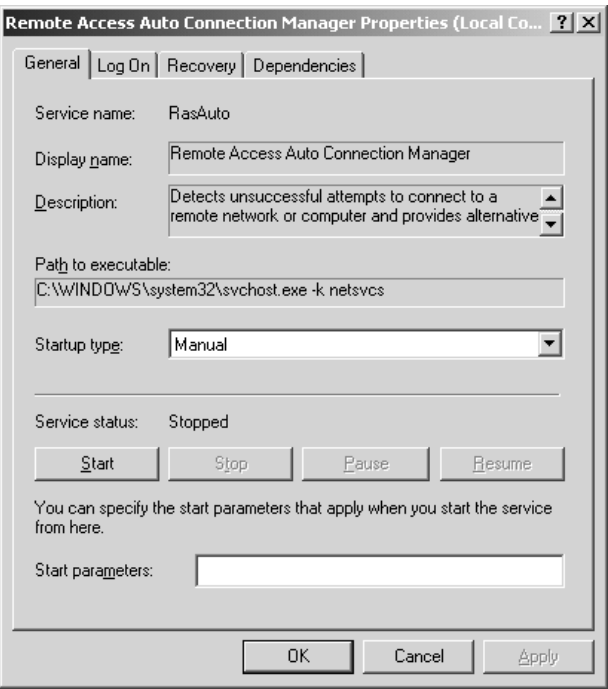

Find the Remote Access Auto Connection Manager service in the listing on the right, and double-click it to edit the properties. From here, you can start the service manually and configure it to start

up automatically every time your Windows Server 2003 boots up. The properties page for this service should look like Figure 20.13.

**FIGURE 20.12**  
Computer Management MMC for enabling Remote Access Auto Connection Manager

**FIGURE 20.13**  
Service properties for RAS Auto Connection Manager

To start this service manually, click the Start button in the dialog box. If everything goes okay, the status of this service should change to Started. Now, to make sure that this service starts every time

your Windows Server 2003 boots, select the Automatic option from the Startup Type pull-down box. Click OK to save your changes and then exit the Computer Management MMC.

To test the redial functionality, try establishing a connection with this ISP dial-up entry and then pull the phone plug out of your modem. Wait a few seconds so that you're sure the carrier has dropped (if you have an icon in your Taskbar indicating that you're connected, it should disappear), and then plug the phone line back in. Within a minute, Windows Server 2003 should attempt to reestablish this connection for you without any intervention whatsoever.

## Accepting Incoming Calls from Remote Users

In today's business world, there are several buzzwords that tend to make an administrator's job a bit more challenging. Phrases like telecommuting, mobile computing, and sales force automation are all centered around one common principle—getting corporate data into the hands of people who need it, exactly when they need it, wherever they are located. In terms of systems administration, this typically means accepting inbound connections from remote clients. If you have yet to face this administrative challenge, rest assured that in the near future you most likely will. The tendency toward remote computing simply shows no signs of slowing down anytime soon.

Whatever your dial-in needs are, Windows Server 2003 can act as a universal gateway to get remote clients into your network. Thanks to built-in support for PPP, an RFC-defined dial-up standard, Windows Server 2003 can receive calls from almost any type of device. Windows PCs, Macintosh systems, Unix hosts, and even personal digital assistants (PDAs) can all establish PPP connections to remote networks. Windows Server 2003 can accept traffic from any of these devices and route it to the devices on your internal network, whether they're NT servers, Novell servers, Unix hosts, etc.

To start accepting incoming calls from remote clients, you will need the following:

- ◆ Windows Server 2003 with remote access software configured to accept incoming calls
- ◆ Connection device of some sort (modem, ISDN, X.25, etc.) connected to Windows Server 2003 to accept calls from the remote clients
- ◆ Client computer capable of establishing a PPP session (Windows 9x/Me, NT 4, 2000, and XP; Macintosh; 3Com Palm; etc.)
- ◆ Connection device of some sort (modem, ISDN, X.25, etc.) connected to the remote client and capable of establishing a connection to the corresponding device on Windows Server 2003
- ◆ Circuit (phone line, ISDN line, etc.) between the two devices
- ◆ User account on your Windows Server 2003 (or within your Active Directory) with dial-in rights granted to it

For the sake of brevity, we'll assume that you've gone through the detailed steps earlier in this chapter to add your modems (ISDN devices or whatever you might be using) to your Windows Server 2003 and that they are functioning properly. With that out of the way, let's get started on accepting incoming calls from remote clients.

To be sure we're all working from the same baseline, I'll assume that you do not have the Routing and Remote Access Service installed on your computer. If you do have it installed, going through this

procedure will stop your existing services and reinstall them with the answers provided to the configuration wizard.

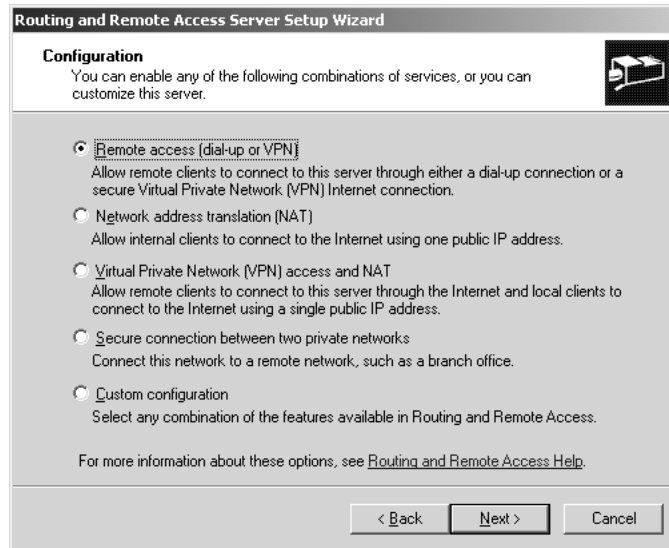

## Remote Access Server Installation and Setup

Start the installation for Routing and Remote Access Service by clicking Start/Administrative Tools/Routing and Remote Access. You will see an MMC window appear, and you should see your server listed somewhere in the left pane. Right-click your server, and select the Configure and Enable Routing and Remote Access option.

This will begin the RRAS installation process. This process is aided by a wizard that will help you configure the necessary services to allow remote clients to dial in. After a welcome dialog box (in which you will click Next), the first dialog box you will see should look similar to the screen shown in Figure 20.14.

**FIGURE 20.14**

RRAS Setup Wizard: role of server

The first step of the configuration wizard is to determine what role your Windows Server 2003 will play. If you are simply looking to accept connections from dial-in clients, click the Remote Access (Dial-Up or VPN) radio button, and then click Next to move on to the next step of the wizard. On the next screen (Figure 20.15) you can decide whether you want to offer a VPN service, dial-up, or both of these types of connections to your clients. Choose Dial-Up and click Next to continue to the next step of the wizard, shown in Figure 20.16.

The next step of the wizard—assuming you have TCP/IP installed on your server—will ask you how to handle assignment of IP addresses to remote dial-in clients. Since every device on the network must have its own IP address, your dial-in workstations need a way to get addresses as well. By default, RRAS will want to assign addresses to your dial-in users automatically from a DHCP server. If you have a DHCP server running, you will probably want to accept the default Automatically option. Whether DHCP and RAS are running on the same server or on separate systems, the RAS service will

attempt to obtain a DHCP-assigned address from the internal network and then pass it along to the remote client to use. The key with this option is to make sure you have a working DHCP server somewhere on your network and that it has enough IP addresses that can be used for dial-in connections.

**NOTE** For further reading on setting up a DHCP server, see Chapter 7.

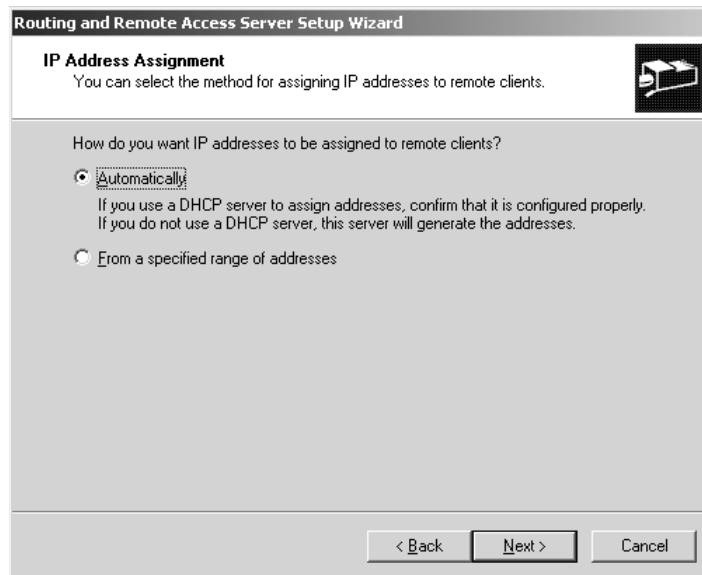

**FIGURE 20.15**

RRAS Setup Wizard: configuring connection types

**FIGURE 20.16**

RRAS Setup Wizard: IP address assignment

Under some special circumstances, you might want to control which IP addresses RAS hands out to dial-in clients. For example, if you have developed login scripts or other automation routines that depend on IP addresses, having a preset range might be useful. Or you might have security policies in place on your networks that only allow certain IP addresses to connect to certain devices. Either way, if you need to make sure RAS clients always fall within a certain range of IP addresses, select the From a Specified Range of Addresses option and then click Next to proceed to Address Range Assignment, shown in Figure 20.17.

**FIGURE 20.17**  
RRAS Setup  
Wizard: address  
range assignment

**Routing and Remote Access Server Setup Wizard**

**Address Range Assignment**  
You can specify the address ranges that this server will use to assign addresses to remote clients.

Enter the address ranges (static pools) that you want to use. This server will assign all of the addresses in the first range before continuing to the next.

Address ranges:

From	To	Number
10.16.0.101	10.16.0.150	50

New... Edit... Delete

< Back Next > Cancel

Through address range assignment, you can enter a series of IP address ranges for RRAS to use when clients dial in to your network. You can make these ranges as small or as large as you would like—just so long as you know that they are usable addresses within your network. To add a range (or ranges) to your system, click the New button and enter a start and end range of IP addresses to use. The New Address Range dialog box will automatically calculate how many addresses are in the range you provided. In the example shown in Figure 20.17, I have already entered a range of 10.16.0.101 to 10.16.0.150 for this RRAS server to use. When you have finished entering your addresses, click Next to proceed with the next step in the wizard, shown in Figure 20.18.

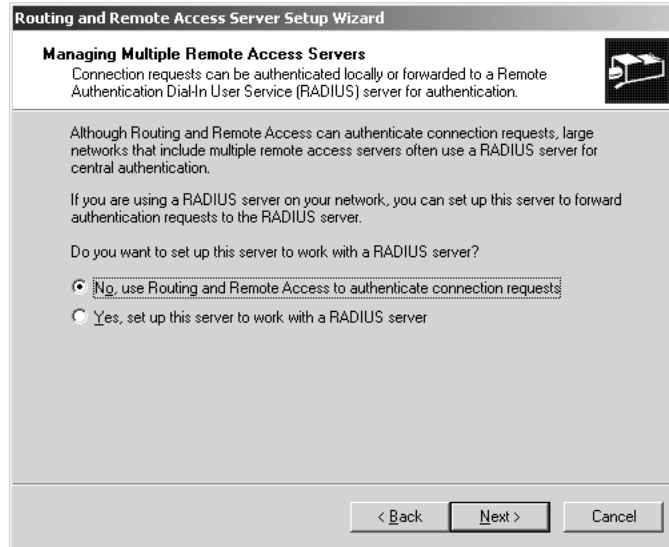

Although the next step of the wizard might look like it's simply asking if you have a RADIUS (Remote Authentication Dial-In User Service) server available on your network, it's actually asking far more than that. This step of the wizard is asking how you would like to handle dial-in authentications. Your choices are limited to two simple options.

If you are currently using RADIUS services on your network for authentication and logging of other dial-in access, you can set up your RRAS server to use the existing RADIUS server instead of using its own authentication and logging mechanisms. To specify your own RADIUS information, select the Yes, Set Up This Server to Work with a RADIUS Server option, and then click Next. Since RADIUS is outside the scope of this chapter, we'll assume that you will stick to using

Windows Server 2003's own authentication and logging mechanisms. Therefore, you can leave the default No, Use Routing and Remote Access to Authenticate Connection Requests option, and then click Next to continue.

**FIGURE 20.18**  
RRAS Setup  
Wizard: RADIUS  
services

Since the option for RADIUS selection is the final step of the wizard, your server should be configured after you click Finish on the final panel of the wizard.

### Granting Dial-In Permissions to User(s)

Once you've successfully installed the Routing and Remote Access Service, the next thing to do is grant dial-in permissions to a user account in your Active Directory tree. (We'll assume you already have an account created for this purpose.)

**NOTE** If you need to add a new account for this exercise, see Chapter 9.

To grant dial-in permissions to selected users, choose the Active Directory Users and Computers MMC by clicking Start/Administrative Tools/Active Directory Users and Computers. Navigate through the Active Directory tree to the user you want to grant dial-in permissions to, and right-click the corresponding record. By selecting the option to edit the properties for this user, you'll be taken to a dialog box to edit options for this user. Click the Dial-In tab, and you should be left with a screen similar to the one in Figure 20.19.

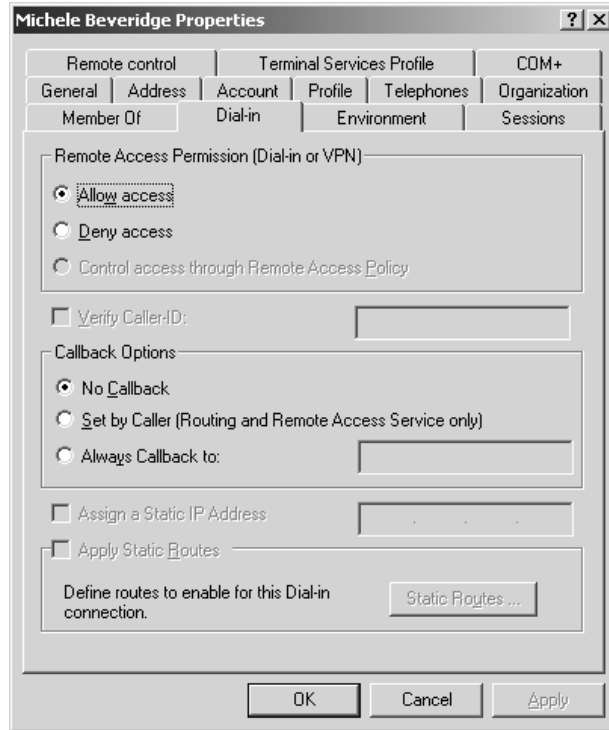

By default, the user account you've selected will probably have the Deny Access option selected at the top of the dialog box. Click Allow Access to grant dial-in permissions to this user. You also have the option to edit some user-specific settings through this dialog box.

For example, if you'd like to implement an additional measure of security by making sure a certain user's remote access session always comes from a specific phone number, you have a few options available. First, if your modem and phone line supports caller ID service, you can simply select the Verify

Caller-ID option box and enter the phone number this user must call in on. However, if you are using hardware that doesn't support caller ID or that service is unavailable in your area, you can achieve the same type of security by having your RAS server call the user back at a certain phone number. Selecting one of the Callback Options available in the middle of the screen activates this feature.

**FIGURE 20.19**

Granting dial-in permissions via user properties

If you have home users who dial in either via long-distance or local long-distance, callback options might also save you some money when it comes to your remote access costs. If the telephone service you have in your office has a better per-minute rate than the rates your users typically have in their homes, you can save money on your remote access connections by having your RAS server call users back at the cheaper rates.

In addition to callback options, you can also specify a fixed IP address for this specific user to receive. This feature first occurred in Windows 2000 and can be exceptionally useful when setting up internal access policies based on IP address (firewall rules, etc.).

Now, take a moment and relax. Your server is set up to receive calls. You should be able to test this by calling the number associated with your RAS server from a standard phone and getting a carrier tone. If you don't hear a carrier tone, double-check your work and make sure everything is connected properly. If, for some reason, you still don't get a carrier tone when you call in, try rebooting the server (oddly enough, this happened to me once, and rebooting it corrected the problem).

**WARNING** In Figure 20.19 you can see that some of the options are unavailable. These settings only become available if your domain is running in at least Windows 2000 Native Mode. Why? If your domain is still in Mixed Mode, then you still have NT 4 DCs, which means that you can only edit the user attributes that were available in NT 4. NT 4 does not have the ability to store user attributes that are new to Windows 2000 and Server 2003.

## Changing RAS Server Configurations after Installation

Wizards are both a blessing and a curse for the Windows operating system. Although they make complex tasks easier, they also tend to assume several answers for you with no chance to change those assumptions. The RRAS configuration wizard is guilty of this practice; it will make several assumptions for you as you configure your system. You may want to check these configurations to make sure they are exactly the way you want them to be.

If you need to change any of your configurations at a later time, you can easily do so by right-clicking your server in the Routing and Remote Access MMC and then selecting Properties. Through the RRAS properties dialog boxes, you can add or remove support for certain protocols for dial-up connections, increase authentication security, and fine-tune the PPP controls for establishing connections to client systems. I'll walk you through each of these areas, starting with the controls for security shown in Figure 20.20.

**FIGURE 20.20**

Editing security properties for RAS service

Through this screen, you can control several behaviors for the security and encryption used with your dial-up connections. Although there are pros and cons for using each (with the pros usually

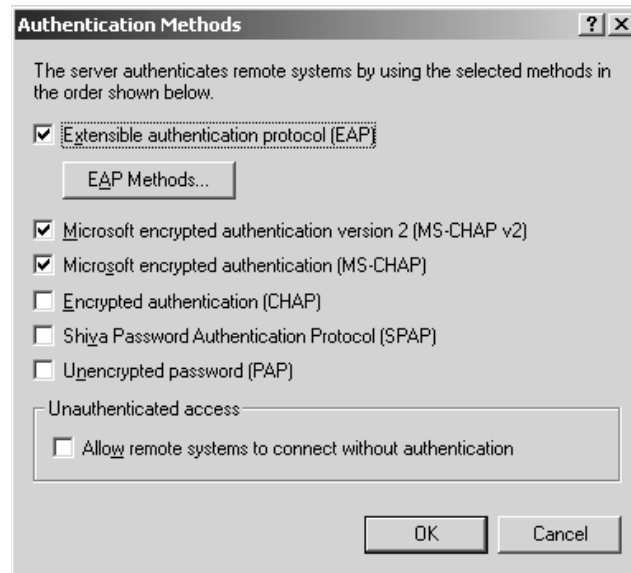

being increased security and the cons being limited client support), we'll discuss each option briefly so you can make your own judgments as to which one is best to use.

By default, the authentication provider that should be automatically configured is Windows Authentication. If you have an external RADIUS server, you can change Windows to use the RADIUS server instead by selecting the RADIUS option from the pull-down box and then clicking the Configure button to define the RADIUS servers to use. You can also configure Microsoft's implementation of RADIUS, called IAS, to manage authentication. But again, since RADIUS servers are outside of the scope of this chapter, we'll simply stick to Windows Authentication methods.

By clicking the Authentication Methods button below the Authentication Provider pull-down box, you will be taken to a screen similar to the one shown in Figure 20.21.

**FIGURE 20.21**

Editing authentication types for RAS service

As you can see, there are several authentication options to choose from:

**Extensible Authentication Protocol (EAP)** Because security and authentication is a constantly changing field, embedding authentication schemes into an operating system is impractical at times. To solve this problem, Microsoft has included support for EAP, which is simply a means of “plugging in” new authentication schemes as needed. Currently, Windows Server 2003 supports MD-5 Challenge, Smart Card or other Certificate (TLS), Protected EAP (PEAP), and Secured Password (EAP-MSCHAP v2), but this option will allow for future authentication protocols to be plugged into the operating system easily.

**Microsoft Encrypted Authentication version 2 (MS-CHAP v2)** Microsoft’s derivative of CHAP, or Challenge Handshake Authentication Protocol (see the next entry). Using MS-CHAP allows you to encrypt an entire dial-up session, not just the original authentication, which is especially important when it comes to setting up virtual private networking sessions. MS-CHAP v2 support is included in Windows 2000 and Server 2003 for all types of connections and

in Windows NT 4 and Windows 9x (with the Dial-Up Networking 1.3 upgrade) for VPN connections.

**Encrypted Authentication (CHAP)** Defined in RFC 1334 and later revised in RFC 1994, the Challenge Handshake Authentication Protocol is a means of encrypting authentication sessions between a client and server. Since this protocol is defined by an RFC, it enjoys a broad base of support among many operating systems and other devices.

**Shiva Password Authentication Protocol (SPAP)** SPAP, short for Shiva Password Authentication Protocol, is an encrypted password authentication method used by Shiva LAN Rover clients and servers. Windows Server 2003 can act as a server when Shiva LAN Rover clients are dialing in by providing the correct authentication sequence for them.

**Unencrypted Password (PAP)** Password Authentication Protocol (PAP) is one of the last two options listed, and it is also one of the least secure. It is no more secure than a simple conversation from your server saying, “What is your name and password?” to the client and the client responding with, “My name is Marty and my password is ‘let-me-in.’” There is no encryption of authentication credentials whatsoever.

**Unauthenticated Access** At first glance, this option wouldn’t seem to make much sense—leaving a wide-open access point to your network with no authentication required whatsoever. However, when paired with caller ID verification, this option can make a simple and secure method for getting clients connected to your network.

If a dial-in user provides a username only, that username will be checked against the Active Directory. If there is a caller ID verification set for that user, the caller ID information will be checked and the connection will be accepted or rejected based on whether the information matches. If the user does not send a username at all, the Guest account will be used by default. Therefore, if you intend to use this option, you might want to make sure the Guest account is still disabled on your system (it is disabled by default in Windows Server 2003).

Once you’ve set your authentication methods, click OK to return to the security properties page. The final option available allows you to direct the client to a custom IPSec policy using a preshared key.

**TIP** To learn more about IPSec, see Chapter 6.

Although Windows Server 2003 still supports IPX/SPX as a protocol, it is no longer available for use by the RRAS service. And, with the advent of Windows Server 2003, we can formally say so long to our old friend the NetBEUI protocol. It is no longer supported in Windows Server 2003, although it may still be possible to make it work if you add the correct DLLs. Within the properties for the RAS service, you have the ability to fine-tune each protocol accepted by the RAS server and passed on to the internal network. By clicking the appropriate tabs (shown in Figure 20.22) for IP and AppleTalk, you can edit the following options for each protocol:

**Enable IP Routing** One way to increase the security of your dial-in system is to only allow dial-in users to access the dial-in server itself. For example, if traveling workers only need to access a set of word-processing documents or spreadsheets, these could be kept on the remote access server.

By unchecking the Enable IP Routing option, clients will only be able to access the RAS server itself.

**FIGURE 20.22**  
Editing protocol  
security properties  
for RAS service

**Allow <Protocol>-Based Remote Access and Demand-Dial Connections (available for IP and AppleTalk)** To enable or disable support for individual protocols, check the boxes for each protocol to allow and uncheck the boxes for each protocol to reject. If you used the automatic wizard to install Remote Access Service, you might find that Windows Server 2003 enabled support for all the protocols on your system by default. However, good security practices dictate only opening up support for the protocols you need, so it's probably a good idea to remove any protocols you aren't using.

**Dynamic Host Configuration Protocol (DHCP) or Static Address Pool (available for IP Only)** As was previously discussed in the configuration of Remote Access Service, here you can select whether your RAS server will use a DHCP server to hand out IP addresses to dial-in clients or if it will manually assign addresses from a static pool. If you choose to assign addresses from a static pool, you will need to provide the correct TCP/IP network address range and subnet mask to use.

**NOTE** For more information on calculating address ranges and subnet masks, see Chapter 6.

If you need to fine-tune the parameters for your RAS server to use when establishing PPP sessions with clients, click the PPP tab to edit the properties of these items, as shown in Figure 20.23. The default settings will be acceptable in most instances, but, if needed, you can enable or disable the following options.

**FIGURE 20.23**  
Editing PPP  
properties for  
RAS service

**Multilink Connections** Multilink Point-to-Point Protocol (MPPP for short) was defined in RFC 1717 as a means of joining (often referred to as “bonding”) two or more PPP sessions together to increase bandwidth. Effectively, you could double or triple your bandwidth between a client and a server if you had two or three modems at each location, two or three phone numbers, etc. This option must be selected if you want to be able to choose the next option.

**Dynamic Bandwidth Control Using BAP or BACP** Defined in RFC 2125, Bandwidth Allocation Protocol (BAP), and Bandwidth Allocation Control Protocol (BACP) are similar in nature to Multilink Protocol in that they are both used to bond connections together for increased bandwidth. However, while Multilink Protocol is a “fixed” solution that will automatically join all the channels it can, BAP/BACP will only initiate additional connections as needed due to high bandwidth utilization. This is an excellent option if you have connections that are subject to per-minute charges and don’t need to have them online all the time.

**Link Control Protocol (LCP) Extensions** Enabling Link Control Protocol (LCP) extensions is a necessary part of supporting callback security on a RAS server. If you are planning on having your system be able to call users back at a specified number, you must have this option enabled.

**Software Compression** Never missing an opportunity to define a protocol for something and create another standard, Microsoft has developed the Microsoft Point-to-Point Compression (MPPC) protocol to compress data as it travels across a remote access link. MPPC is defined in RFC 2118.

In addition to configuring protocol and authentication types to use, you may also want to configure what ports on your system are used to accept incoming RRAS calls. For example, you may have some modems that are to be used strictly for dial-in and others strictly for dial-out. The RRAS configuration wizard will simply assume you want to use *all* your modems for dial-in purposes.

To alter the configuration of ports on your system, return to the Routing and Remote Access MMC and expand your server in the left pane of the window. Below your server, you should see an option for Ports. Highlight that option, and then select Properties from the Action pull-down menu (or by right-clicking the item). That should take you to a window similar to the one shown in Figure 20.24.

**FIGURE 20.24**

Configuring RRAS ports via the Routing and Remote Access Service MMC

As you can see on this screen, all the interfaces that can support RRAS clients are listed for you to choose from. Highlight the interface(s) that you'd like to accept incoming calls from and then click the Configure button. This will open the individual properties page for this device. Check the box labeled Remote Access Connections (Inbound Only) and—if you can—enter the phone number for the line connected to that device in the Phone Number of This Device field. The phone number will allow you to support BAP for devices to initiate additional connections to your server (although since this requires multiple modems and lines at each location, it might not be an option you need). Repeat this procedure for all the ports on your server.

**NOTE** *It is important to note that all types of ports are automatically configured for your RRAS server—including the VPN ports for PPTP and L2TP. If this server is accessible over the Internet, these ports will be “openings” that outsiders can use to try to authenticate to your network. I recommend that you change the Maximum Ports value for L2TP to zero and for PPTP to one (the minimum value allowed), unless you specifically intend to implement virtual private networking (discussed later in this chapter).*

## Client Configurations

Now that you have a RAS server that's running smoothly, it's time to enable some clients and get connected into the network. While I can't cover every possible platform under the sun when it comes to remote access, we'll look at a few of the more common options, namely Windows NT 4 Workstation, Windows 9x, and Windows XP Professional. Windows 2000 Professional Dial-Up Networking will follow a routine very similar to the Windows Server 2003 Dial-Up Networking steps, outlined in detail in the next section, so I won't cover it here.

All these client configurations assume that you have Dial-Up Networking already installed on your system and correctly configured. Assistance on installing Dial-Up Networking on other platforms is outside the scope of this book.

**TIP** *I frequently get calls from clients who have configured one of their users' home computers to dial in to the corporate network but are having trouble browsing the Network Neighborhood and seeing any resources. In most cases, this is due to the workgroup and domain settings on the home system not matching the settings for workstations in the office. Make sure you use the same settings in both locations.*

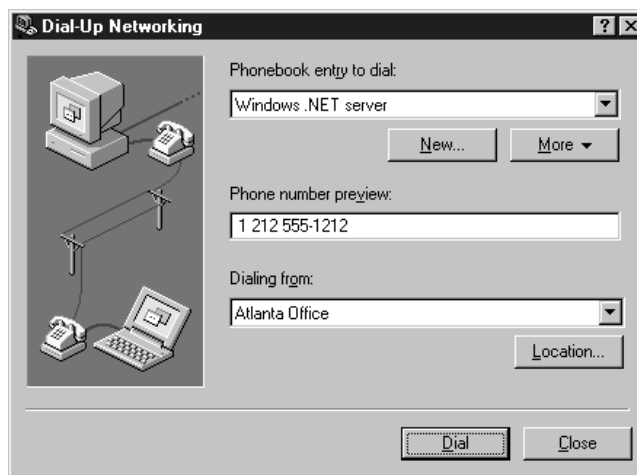

### WINDOWS NT 4 WORKSTATION

From the Windows NT 4 Desktop, double-click My Computer and then Dial-Up Networking to bring up the main Dial-Up Networking program. If this is the first time you are using Dial-Up Networking, you might get a message about your phonebook being empty—this is okay because it is simply Windows telling you it doesn't know how to dial anyone yet. If you get that message, click OK to continue, and that should leave you at the main Dial-Up Networking screen as shown in Figure 20.25.

To add a new entry for your Windows Server 2003, click the New button to start defining a new phonebook entry. The initial screen will let you enter information such as a friendly name to use for this phonebook entry, the number to dial, which modem to use, etc. Enter the appropriate information as needed and then click the Server tab to enter information about the server you are calling into. Your phonebook entry screen should look similar to Figure 20.26.

**FIGURE 20.25**

Dial-Up  
Networking in  
Windows NT 4  
Workstation

**FIGURE 20.26**

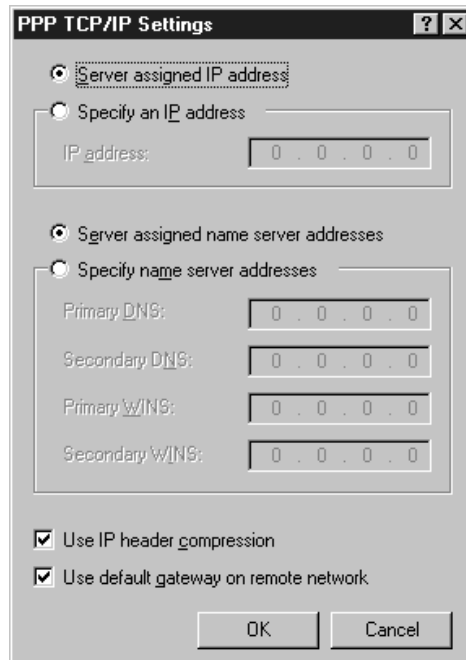

Selecting server  
options for a new  
phonebook entry,  
Windows NT 4  
Workstation

By default, Windows NT 4 Workstation will assume you are going to be dialing in to a PPP-compatible server, so it will use that selection as a default for the Dial-Up Server Type pull-down box. Also, NT Workstation will assume you want to use software compression and PPP LCP extensions (as seen by the check boxes in the bottom of the window). These are also acceptable defaults for most dial-up connections and can be left checked in most cases. These settings directly correspond to the PPP settings defined on the configured RAS server.

By far, the most important settings in this dialog are the network protocol settings. In general, these settings should correspond directly to the protocols configured when installing RAS, as seen back in Figure 20.15. The client workstation obviously cannot connect on certain protocols if they are not installed on your server, so make sure you are using the same protocols in each location. If you plan on using TCP/IP (and I expect most readers will), click the TCP/IP Settings button to define protocol-specific parameters if necessary. The TCP/IP Settings screen should look like the one in Figure 20.27.

**FIGURE 20.27**  
TCP/IP settings  
on Windows NT 4  
Workstation dial-up  
networking

For most installations, the default TCP/IP settings should work fine, but if your situation is a bit more specific, you can enter values for the IP address that the client should use and which DNS servers and WINS servers to use for name resolution. If you don't enter any settings for the DNS and WINS servers to use, the dial-up networking client will inherit the same values the RAS server uses itself. This is an important point, because if you are using DHCP to assign addresses, you might assume that any DHCP scope options you have added to your address space would be automatically passed along to your RAS clients. However, even if your RAS server is consulting your DHCP server for addresses to use, it will not pass DHCP scope options along to RAS clients. Settings for DNS servers and WINS servers to use will come directly from the same settings programmed into your RAS server. So, if you're using DHCP on your network, make sure you hard-code an IP address for your RAS server and program in the correct name server addresses.

Once you have set your server and protocol settings as necessary, click the Security tab to define the appropriate authentication options for your dial-in client. The security settings are shown in Figure 20.28. Just as the correct configuration for the server settings on the dial-up client depends on how your RAS server was configured, the security settings on the client will depend on how the security is configured on the RAS server as well.

**FIGURE 20.28**

Security settings on Windows NT 4 Workstation dial-up networking

By default, Windows NT 4 Workstation selects the option to Accept Any Authentication Including Clear Text. If the RAS server is configured to only allow MS-CHAP authentication, then the dial-up networking client will submit an MS-CHAP authentication and should be validated without any difficulty. If you run into problems logging in, make sure your authentication settings between your server and your client match on at least some level.

When you have completed making the necessary settings for this dial-up networking entry, click OK and then click Dial to dial in to your Windows Server 2003. You will be prompted for a valid username, password, and domain name to log in with. Use the username(s) you granted dial-in permission to on your servers, click OK, and if everything goes according to plan your Windows NT 4 Workstation should be connected!

### **WINDOWS 9x**

From the Windows 9x Desktop, double-click My Computer and then Dial-Up Networking to bring up the Dial-Up Networking program. If this is the first time you are using dial-up networking, you might be asked to enter information about your local area code, whether to use touch-tone or pulse dialing, and any prefixes you need to dial. Simply fill in the information and click OK to continue. This should bring you to the Make New Connection window shown in Figure 20.29.

**FIGURE 20.29**  
Windows 9x Make  
New Connection  
window

At the first step of the Make New Connection dialog box, you can enter a friendly name for this Dial-Up Networking connection and select which modem device you'd like to use. Enter this information and then click Next to continue to the next step, shown in Figure 20.30.

**FIGURE 20.30**  
Windows 9x Make  
New Connection  
window, step two

In the second (and final) step, enter the area code and phone number of your RAS server and then click Next to complete the creation of this Dial-Up Networking entry. By default, Windows 9x will assume several things about this Dial-Up Networking entry, including which protocols and security settings you'd like to use. For example, Windows 9x will select all the protocols installed on your system and try to use them over this Dial-Up Networking connection.

If you'd prefer to configure these options yourself instead of having Windows 9x assume what you want, go back to the main Dial-Up Networking window (the one with the Make New Connection icon) and you should see an icon for your Dial-Up Networking session. Right-click the icon, and select Properties to edit the configuration. You will see the properties pages for this Dial-Up Networking connection, as shown in Figure 20.31.

**FIGURE 20.31**

Editing Windows 9x  
Dial-Up Networking  
entry properties

From here, you can (and should) change the security and protocol settings to match those of your RAS server. Configure the settings accordingly, and then launch your session to verify that it works.

### WINDOWS XP PROFESSIONAL

Once you have installed your modem, from the Windows XP Desktop, click Start/Control Panel/Network Connections (in category view, click Network and Internet Connections). From here you will need to start the New Connection Wizard to add a new connection to the server you wish to dial. Click Next to get through the initial screen of the wizard and you will see the screen shown in Figure 20.32. To create a connection using dial-up, choose the Connect to the Network at My Work-place option and click Next. Choose the Dial-up Connection option and continue by clicking Next.

Specify a name for the connection and, in the following screen of the wizard, type in the phone number for the connection. Next you will need to decide whether this connection will be used for everyone who uses your computer or whether it should only apply to your account profile. In the final screen of the wizard, you will be shown a summary of the options you selected, and you are given the

option of creating a shortcut to the connection on your Desktop. Click Finish to complete the wizard and you will be shown the Connect <Connection Name> dialog box, as seen in Figure 20.33.

**FIGURE 20.32**  
Choosing a  
connection type

**FIGURE 20.33**  
Connecting to the  
dial-up server

From here, choose the Dial button to test your connection. Since you already know the basics about adjusting the settings for your dial-up connection, just know that by choosing the Properties button from this screen you can configure the security settings, protocols, and phone options.

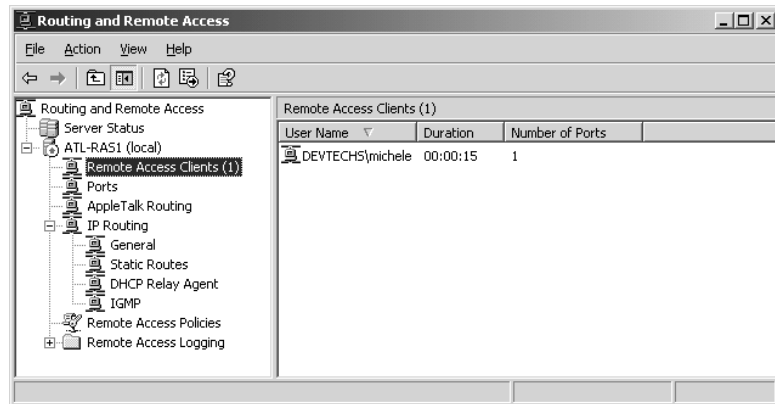

## Managing Connected Users

If you need to keep tabs on users connected to your network, the Routing and Remote Access MMC can give you an overview of all remote access connections currently connected to your server. Whether connections are coming into your systems from VPN connections, serial connections, analog modems, or ISDN lines, you can get an overview of all your remote connections from one convenient console.

To manage connected users, start by launching the Routing and Remote Access MMC by selecting Start/Administrative Tools/Routing and Remote Access. By expanding the details for your RAS server in the left pane, you should see a subitem for Remote Access Clients listed below your system, along with a number next to it in parentheses. This number indicates the number of dial-in users currently connected to your system. This screen should look similar to the one in Figure 20.34.

**FIGURE 20.34**

Managing remote access users through RRAS MMC

From this screen, you can get an overview of how long users have been connected to your network, who is currently connected, which ports are in use, etc. By double-clicking any of the listed connections on your system, you can get advanced details about that individual connection, such as what IP addresses were assigned to the system, how much data has been transferred, etc. You can disconnect an individual connection from the same properties page by clicking the Disconnect button, or you can disconnect a user by right-clicking that user's connection in the main list of connected users and choosing Disconnect. In addition to being able to disconnect a user from the main listing of connected users, you can also send a message to an individual user or to all connected users by right-clicking a connection and selecting either Send Message or Send to All, respectively.

## Connecting to a Private Network

Much like connecting to the Internet, at times you might need to connect your Windows Server 2003 to another private network. Maybe one of your servers needs to collect data from a client's systems

or transmit product orders to a supplier. The private network might be a Win2K network, an NT network, a Novell network, or a network that contains a combination of servers and other systems. In any case, dial-up networking can get your Windows Server 2003 connected with a minimal amount of effort.

Before getting started, there are a few things you will need to have to complete making a connection to another network. Namely, you will need to have the following information available in advance:

- ◆ Access phone number to dial
- ◆ Username and password combination
- ◆ Protocols that will be used on the remote network
- ◆ Authentication the remote network will require

To get started, we'll once again be working through the Network Connection Wizard by clicking Start/Control Panel/Network Connections and then choosing the New Connection Wizard icon. When the wizard starts, you should see the screen shown in Figure 20.35. Click Next to jump to the second screen of the wizard.

**FIGURE 20.35**  
New Connection Wizard: welcome screen

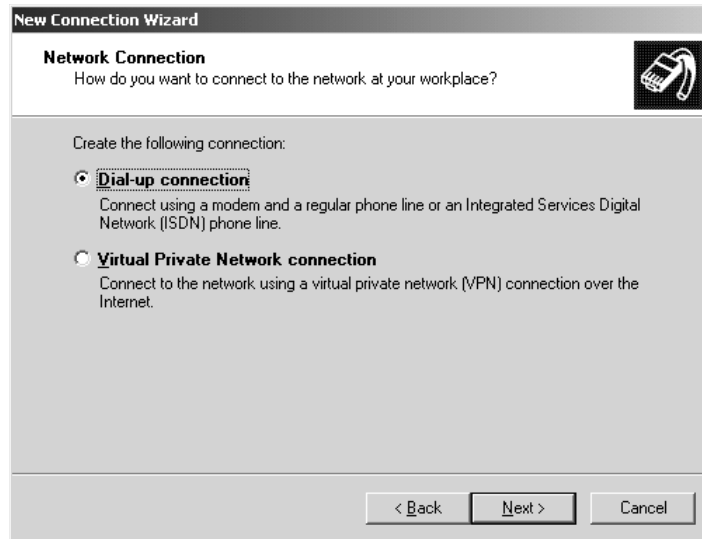

From this point, select the second option, Connect to the Network at My Workplace, and click Next to continue to the next step of the wizard, as seen in Figure 20.36. Here you'll have to choose whether you want to connect to the remote network using dial-up or a VPN. Choose Dial-Up Connection and continue to the next wizard screen. Enter the name that you want to give this connection and click Next.

Enter the phone number as prompted, and then click Next to get to the last step of the wizard, pictured in Figure 20.37.

**FIGURE 20.36**

New Connection Wizard: Network Connection

**FIGURE 20.37**

New Connection Wizard: Connection Availability

The last step of the Network Connection Wizard will ask if you would like to make this dial-up connection available to all users or to make it available only to the user who is creating this connection. For the purposes of simply connecting Windows Server 2003 to another network, select the My Use Only option here. The other option, Anyone's Use, would end up sharing this connection for other users on the network, a topic discussed in the next section ("Acting as an Internet Gateway"). Click Next when you are finished, click Finish when presented with the summary, and you will have successfully created a Dial-Up Networking entry.

Once the wizard is completed and your connection has been created, you will find that Server 2003 will have assumed several things about your dial-up networking entry that might not work for your specific situation. To double-check everything, edit the properties for this dial-up connection by right-clicking the icon for it in the Network Connections window. Clicking the Networking tab on the properties page should bring you to a page similar to the one shown in Figure 20.38.

**FIGURE 20.38**

Dial-Up Networking entry properties

Windows Server 2003 will assume you want to use several defaults when you try to connect to this remote network. For example, it will assume you want to use *all* the protocols loaded on your system for this connection, it will assume it can use unsecured passwords, etc. Some of these options might not make sense in specific situations. For example, if you are connecting to an IP-only network, it doesn't make much sense to try and negotiate an AppleTalk connection. Even though Server 2003 will realize that it can't establish the AppleTalk connection, why even try?

To fine-tune this connection, remove or add specific protocols as needed by checking the boxes next to the protocols listed under the Networking tab of the Dial-Up Networking entry properties pages. If you are connecting to a remote TCP/IP network and the device you are dialing in to does not provide you with an IP address or DNS server addresses automatically, you can program these in by highlighting the TCP/IP protocol and then clicking the Properties button. This will bring you to the specific TCP/IP settings to use for this connection (Figure 20.39).

**FIGURE 20.39**

Editing TCP/IP properties for Dial-Up Networking entries

On this screen you can enter the necessary information for your TCP/IP connection. If you are accessing a remote network that uses WINS servers but does not provide those addresses to you, enter them in the advanced TCP/IP settings area by clicking the Advanced button and then clicking the WINS tab.

Once you have your protocols configured correctly, click OK to get back to the main properties page for this dial-up connection. If you need to edit any other properties, such as the type of security or authentication to use, click the appropriate tabs and make those settings as necessary.

If you think this looks similar to the steps to connect to the Internet described earlier in this chapter, you are correct. Basically, all the mechanisms are the same in Dial-Up Networking, but different wizards will take a different approach to the settings that are applied by default. Therefore, some of the same advanced options discussed in the “Connecting to the Internet” section (reestablishing failed links, redialing non-responsive numbers, etc.) are available for regular dial-up connections to private networks.

## Acting as an Internet Gateway

One of the hottest little “niche” applications people always seemed to want to do with Windows NT 4 Server was to share an Internet connection with everyone else inside their organization. After all, NT servers were usually set up to share other resources (files, printers, etc.)—so it made sense that NT Server should have been able to share an Internet connection, right? Not exactly.

With enough tweaking and some strict rules to follow, you *could* actually have NT Server dial an Internet connection and route traffic for internal hosts out to the Internet. However, the setup is difficult and cumbersome, and it requires having valid (InterNIC-assigned) IP addresses available for everyone within the organization. Without using a third-party software solution, the act of simply sharing a \$20/month unlimited-access Internet account wasn't a viable option.

Now, Microsoft has included a variety of capabilities in Windows Server 2003—actually, this was around in Win2K too—that make this task relatively easy. With the correct information about what type of connectivity you need to the outside world, Windows Server 2003 can act as an Internet gateway for your internal clients, leveraging an existing Internet connection among all the workstations in your organization.

Although Microsoft has included some great tools for sharing connections on your network, it is important to note several subtle hints Microsoft has included in their documentation for this feature of Windows Server 2003. First and foremost, Microsoft often makes several references to small or home office networks, implying that this capability really isn't designed for use in medium-to-large environments. I would have to agree with them on this point; if you have a reasonable number of workstations on your network, you will probably be far better off going with a product such as Microsoft Proxy Server and a dedicated Internet connection.

The second point Microsoft makes repeatedly throughout their documentation is that “you should not use this feature in an existing network with other Windows Server 2003 domain controllers, DNS servers, gateways, DHCP servers, or systems configured for static IP.” Since this configuration requires a very specific IP configuration to work correctly, implementing this on a network that doesn't conform to that configuration could cause lots of difficulty. I would agree with Microsoft on this point as well.

Although acting as an Internet router isn't one of the options normally available through the New Connection Wizard used throughout this chapter, fortunately one of the other options will configure most everything necessary. By using the steps detailed in the last section, “Connecting to a Private Network,” and connecting to the Internet as the “private” network, you can make Windows Server 2003 act as an Internet gateway, routing traffic from your internal clients out to the Internet and back again.

## **Configuring Windows Server 2003 to Act as an Internet Gateway**

Start with the same steps listed in the section “Connecting to a Private Network” and go all the way up to the point where you enter the phone number, using a local access number for your ISP as the number of the private network to dial.

This time, when the New Connection Wizard (pictured back in Figure 20.37) asks if you would like to make this connection available to all users, select *Anyone's Use* instead of *My Use Only*. When you finish the wizard, you will be presented with the Connection dialog box. Here you need to enter a username and password in order to share the connection among all your users. Once you have entered the name and password, you will need to allow the connection to save the credentials by checking the *Save This User Name and Password for the Following Users* box. Of the two available sets of users, you will need to select the *Anyone Who Uses This Computer* radio button. Once you have finished, click the Properties button. Although there is no Apply button on the Connect <Connection Name> dialog box, the simple act of clicking the Properties

button seems to save the username and password combination. From the properties sheet, click the Advanced tab to complete the final step for the process of sharing this connection with your users (see Figure 20.40).

**FIGURE 20.40**  
Defining sharing options

Click the check box entitled Allow Other Network Users to Connect through This Computer's Internet Connection. This will enable the sharing properties for this connection. The other option you can see in the Internet Connection Sharing (ICS) section of this property sheet allows for a dial on-demand feature for the connection. That way, any time a user makes a request for this connection, the computer will know to automatically establish the connection. Since you are implementing a shared Internet connection, you probably want to select this option also. When you check the box for this feature and click OK, you should receive a warning dialog box similar to the one in Figure 20.41.

**FIGURE 20.41**  
Static IP address change warning

This dialog box lets you know that Windows Server 2003 will need to make several changes to its IP configuration for this functionality to work, including specifying a fixed IP address to use for the server's internal network connection. If anyone is connected to your server at this point, make sure they are disconnected before continuing, otherwise they may lose their connections to the system. Click Yes to continue, and Windows Server 2003 will make the appropriate IP changes to support sharing an Internet connection.

Once you have completed the wizard and made any changes to the settings, you should see an icon for your shared connection in the Network Connections dialog box. Launch the connection to verify that everything is working correctly. Since you have saved the username and password combination for this connection, when it is demand-dialed it will have what it needs. Once you have established that the connection works correctly in and of itself, it's time to define a few rules as to what you want to allow across your Internet connection.

### DEFINING SERVICE CONFIGURATIONS

By default, Windows Server 2003 will not automatically route any traffic from the Internet to the machines on your network. You must define specific rules as to what type of traffic (i.e., what TCP/IP packets) can go across your shared connection. To do this, begin by editing the properties for your shared Internet access connection by right-clicking the Shared Internet Connection icon in the Network Connections window and then selecting Properties. Click the Advanced tab, and you should see the same settings for enabling shared access for this connection and on-demand dialing that you saw in Figure 20.40. At the bottom of the window is a button labeled Settings. By clicking the button, you can define settings for which services can go across your shared Internet connection, as shown in Figure 20.42.

**FIGURE 20.42**

Configuring services settings for Internet Connection Sharing

**NOTE** The other two tabs you see in Figure 20.42 are only visible if you enable the Internet Connection Firewall (ICF) on the advanced properties sheet for the connection. Here's the short version of what ICF gives you. Basically, even if you don't enable ICF, your shared Internet connection won't allow any incoming traffic by default. Once you enable it, however, you can allow your connection to accept and/or respond to ICMP traffic, like ping (echo requests). You can also set up logging in the connection and record dropped packets and successful connections.

Sharing an Internet connection allows you to accept traffic from external hosts targeted at systems within your network. For example, maybe you have a small Web server running in your organization that you would like people to be able to access. Using a shared Internet connection not only lets your users share access to the Internet, but it can be programmed to allow Internet access to your internal shared resources as well. This is one of the reasons why it's important to define rules as to what is allowed in to your shared Internet connection.

If you need to have outside clients access services on a computer on your internal network, you will need to enable them from the Services tab in the Advanced Settings dialog box of your connection properties. Unless you want people from the outside world connecting to your internal systems, I recommend leaving this blank. But if you have a Web server or an FTP server that you need to have people connect to, this is the place to do it. Click the check box for the type of service that you want to allow external access to.

To define an internal host that Windows Server 2003 should direct that type of traffic to, click Edit. You should see the dialog box pictured in Figure 20.43.

**FIGURE 20.43**

Configuring a predefined service for ICS

As you can see in this example, you don't really need to know anything about ports to do this because Windows Server 2003 assumes the standard port settings for these services. However, if you prefer to use different port settings for any of your services, or if you want to add a service that is not in the predefined list, click OK to return to the Advanced Settings property sheet you saw in Figure 20.42. To define your own services, click the Add button and you will see the dialog box shown in Figure 20.44.

**FIGURE 20.44**  
Adding a shared  
access service

**Service Settings**

Description of service:  
Sales Client Server App

Name or IP address (for example 192.168.0.12) of the computer hosting this service on your network:  
ATL-APP51

External Port number for this service:  
60001

Internal Port number for this service:  
60001

☒ TCP ☐ UDP

OK Cancel

Keep in mind that services that are accessed on your network using ICS by external clients won't connect *directly* to the IP address assigned to your internal workstation that has the destination service (especially since in most cases the internal IP addresses won't be routable addresses on the Internet). Instead, external systems will connect to your Windows Server 2003 on a specific port, and based on what port they connect to, Server 2003 will redirect the request to one of your internal systems.

Start defining your service by giving it a name—for example, the name of your Web server or an application your clients will access, etc. and then list the name of the server that will host the service or application. If you are using DHCP to assign IP addresses to your internal computers, I recommend referencing the system by name in this dialog box, rather than the IP address. In the External Port Number for This Service field, enter the port you will expect incoming connections to come to. If you wanted to allow incoming HTTP traffic, for example, you would enter **80**. The Internal Port field is used to route your traffic to whatever port your service is being hosted on. Some services or applications use both TCP and UDP packets. You can't enable them both here, though. If you define this application to accept TCP packets as shown in Figure 20.44, you'd need to create another service definition with the same configurations to allow UDP packets to access the application across the port.

Once you have completed this definition, click OK and you should see the new service listed in the Services list. If you have a connection that is dialed on demand, though, it's important to note that this won't typically work for incoming connections. That is, your ISP won't know that it should dial *your* server whenever someone on the Internet tries to access a service or application on one of your systems. Therefore, if you are going to accept incoming service connections I'd recommend having your Internet connection online at all times.

Once you have defined the appropriate service settings, it's time to configure your clients to direct their Internet traffic to your Windows Server 2003 for routing.

### CONFIGURING CLIENTS

Once your server is ready, you will need to tell your clients to route their Internet traffic to your Windows Server 2003. When Windows Server 2003 receives these packets, it will realize that they are destined for the Internet and route them as necessary (initiating your demand-dialed connection if needed). You can either program each workstation manually or let DHCP do it for you by defining the correct scope and options to use.

**NOTE** For more information on configuring DHCP scopes, see Chapter 7.

The following information will work in your DHCP scope for getting your clients connected to the Internet (other slight variations would work as well; this is merely an example):

- ◆ Address range: 192.168.0.2 to 192.168.0.254
- ◆ Address mask: 255.255.255.0
- ◆ Default gateway: 192.168.0.1
- ◆ DNS servers to use: enter your ISP's DNS server addresses

To enter these settings manually on a Windows XP, 2000 Professional, NT 4, or 9x client, edit the TCP/IP properties of your computer to change the IP address to something in the range just listed. The mask should be 255.255.255.0 as listed, and the default gateway should be 192.168.0.1, the IP address your Windows Server 2003 will give itself once you enable the shared connection. In Windows XP Professional, this would look similar to the dialog box shown in Figure 20.45.

**FIGURE 20.45**

TCP/IP settings for shared access on Windows XP

The last setting to make is the DNS server setting. Since your workstation will need to look somewhere to translate host names into IP addresses, you will need to put the DNS server IP addresses for your ISP into your connection settings. If you don't know the IP addresses of your ISP's DNS servers, I recommend contacting them to ask them directly or see if they list the appropriate settings somewhere on their Web site.

Once you have the correct DNS and TCP/IP settings programmed in, you should be able to connect to the Internet using your newly configured ICS. You should see that your Windows Server 2003 automatically initiates the connection as needed whenever one of your client systems tries to access the Internet.

## Accepting VPN Connections from Remote Clients

Virtual private networking (VPN) is one of the hottest subjects in networking today. With the widespread presence of the Internet, it only makes sense that corporations and organizations would want to try to leverage existing investments in Internet connections for their corporate networks. But as exciting as VPN can be, it can also be a rather complex subject. Since it is basically a means of layering one logical network over another, the complexities of making a network connection are, in effect, doubled.

### VPN Overview

Loosely defined, a VPN allows you to run a secure, private network over an unsecured public network. You can use virtual private networking to get clients connected to your network over the Internet and do it securely, even though the Internet is inherently an unsecured network.

One of the better analogies I've found for explaining the concepts of a virtual private network is to refer to them as "pipes." To conceptualize VPNs, think of two pipes, one large and one small. Now, imagine that the small pipe actually runs *inside* of the large one. It starts and ends at the same places the large pipe does, and it can carry materials on its own, completely independent of whatever is happening in the large pipe. As a matter of fact, the only thing the small pipe depends on the large pipe for is the determination of the start and end points. Beyond that, the small pipe can operate independently of the large pipe in terms of direction of travel, materials it carries, etc.

To add another layer to this analogy, let's assume that the large pipe is made out of a transparent material, and the small pipe is made out of metal. If anyone were to take a look at the pipe-within-a-pipe, they would easily be able to see whatever was moving through the outside (large) pipe. However, whatever was traveling through the inside pipe would remain a mystery.

If this is starting to make sense, you should be thinking to yourself that the large pipe represents the unsecured network (i.e., the Internet) and the small pipe represents the virtual private network. VPN is a way of tunneling data packets through a connection that already exists but that can't be used on its own for privacy reasons. Obviously, the Internet is a perfect example of a network that often can't be used alone for privacy reasons.

So, what benefit does this have for the overworked network administrator? Well, for starters, it could reduce or eliminate your need to maintain a pool of modems at your site for remote dial-in users. Remote users don't need to call directly into your network to get connected; they can simply call in to a local ISP and get a valid Internet (unsecured) connection. Assuming you have a VPN/RAS server running on your network (and it's connected to the Internet), once the remote user has

connected to their ISP, the client just has to establish the VPN (secured) session with the RAS server. The cost of maintaining modems and phone lines is shifted to the ISP. As long as your RAS server is connected to the Internet, you can support multiple incoming calls all over that one connection. Also, in keeping with this example, since the VPN session is being established over the Internet, there is no need for any long-distance calls. If your remote user is hundreds of miles away, the cost to connect to your network is the same as if they were local, since the only call they would need to make would be to their ISP. This is a great way to support a geographically dispersed user base.

Microsoft has gone a long way toward making virtual private networking easy to implement since its inception in Windows NT 4. However, if there is one piece of advice I could give everyone trying to implement virtual private networking, it is this: get a good, solid RAS server working and accepting incoming connections *first*. Use standard connections (analog modems, ISDN, etc.) on your RAS server first to make sure everything is functioning correctly. Once you are sure RAS is working correctly for standard connections, only then is it advisable to try implementing VPN connections. Since virtual private networking adds another layer of functionality “on top of” RAS, it is crucial to have a stable foundation to begin with. RAS can be peculiar in its behavior at times, so it is important to have all your configurations working correctly (DHCP address assignment, browsing, etc.). If only I had a nickel for every time I heard someone say “this VPN thing is messed up,” only to find out that if they dial in to their network over a modem connection, they experience the exact same problems.

### **A Brief History of VPN: PPTP, L2F, and L2TP**

When virtual private networking was first being developed back in the mid-1990s, two of the largest companies in the computer/networking industry tried to run with implementations of VPNs in the hopes that they would enjoy widespread implementation and therefore become an “industry standard.” The two companies were Microsoft and Cisco, and each had its respective VPN technologies. Microsoft was approaching the VPN market from the operating systems point of view and had developed Point-to-Point Tunneling Protocol (PPTP) as a means to securely transmit data across unsecured networks. At the same time, Cisco was taking the lead in VPN from a strictly networking point of view with a protocol called Layer 2 Forwarding, or L2F.

Now, when either of these companies decides to develop an industry standard, they can usually get away with it if one doesn’t already exist. No single standard had obtained a large enough share of the VPN market to be considered an industry standard, so the playing field was literally wide open. However, the sheer muscle and momentum that either one of these companies can put behind an initiative wasn’t necessarily enough to displace the other. Each protocol had its strengths and weaknesses, and Microsoft’s and Cisco’s offerings enjoyed moderate successes.

Now, I’m speculating a bit here, but I think that since neither industry giant was going to successfully displace the other in the VPN market, they decided it would be better to cooperate than compete. In any case, Microsoft and Cisco made the decision to collaborate on virtual private networking by merging their protocols, PPTP and L2F, into one hybrid protocol. The final product of that collaboration is Layer 2 Tunneling Protocol, or L2TP for short.

Windows Server 2003 includes L2TP support for establishing virtual private networking connections, but it also includes support for PPTP for backward compatibility with other operating systems. L2TP is supported in Windows 2000 (Server and Professional) and Windows Server 2003. Windows 98, Me, and NT 4 can utilize the functionality of L2TP and IP Security (IPSec) by

installing an additional client. Okay, enough said. Let's assume you've got a good solid RAS server running and get on to the fun stuff.

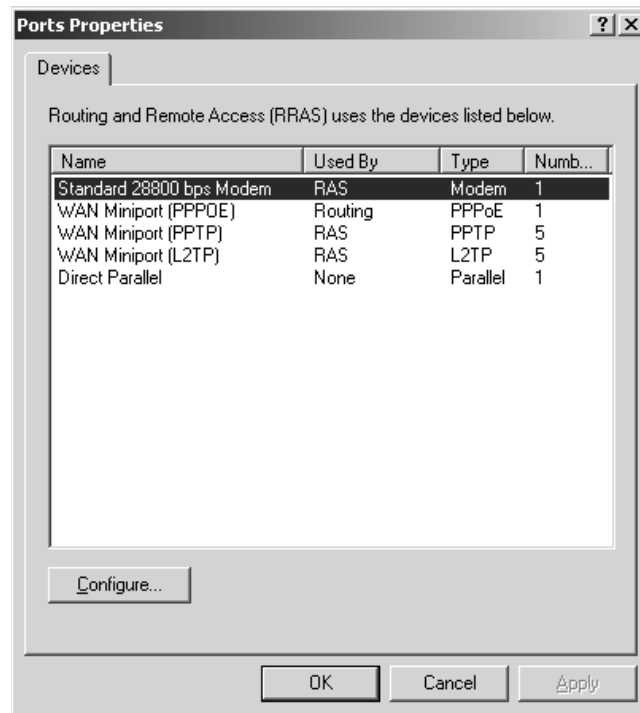

## Implementing VPN via PPTP and L2TP

If you went through the section "Accepting Incoming Calls from Remote Users," congratulations—you have 80 percent of what you need to support VPN connections in place already. When you install Remote Access Service, Windows Server 2003 should have added support for five PPTP connections and five L2TP connections by default. If you didn't go through the section to accept incoming calls from remote users, stop reading now and go back to complete the steps listed there. For the remainder of this section, we'll assume you have a functional RAS server in place.

We'll start by verifying that support for PPTP and L2TP is in place through the Routing and Remote Access MMC. Start the RRAS MMC by selecting Start/Administrative Tools/Routing and Remote Access. In the left portion of the MMC window, you should see the name of your RAS server listed; expand the information for that server by double-clicking it or clicking the plus sign next to the server. Right-click the listing for ports, and then select Properties to edit the ports (Figure 20.46).

**FIGURE 20.46**

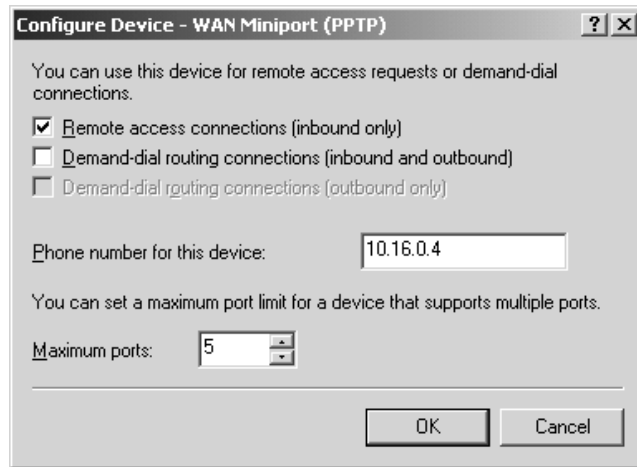

Ports Properties screen

In the Ports Properties screen, you will see all the ports that Server 2003 has recognized and can use for Remote Access Service. Each device has a usage listed, a device name, a type, and a number of ports associated with it. By default, RAS should have PPTP and L2TP devices installed on your system with five ports allocated to each.

Depending on which type of connections you will be allowing and how many you want to allow, you can edit your protocols and ports accordingly from here. For example, you may only need to support L2TP for your VPN, but if you still have clients using PPTP, then you'll need to keep those available. You can also extend the number of L2TP and PPTP ports to 128 each, if required. In any case, to edit the port properties for either type, double-click the item to edit or just highlight it and click the Configure button. This will take you into the port configuration screen shown in Figure 20.47 (the screen looks the same whether you are configuring PPTP, L2TP, or modem ports).

**FIGURE 20.47**  
Configuring RAS  
ports (PPTP shown)

To configure your server to accept VPN connections, make sure the Remote Access Connections (Inbound Only) option is checked in the Configure Device dialog box. Despite the fact that the dialog box has a Phone Number for This Device field, you need to enter the public Internet IP address of your server (assuming the Internet is the public, unsecured network you will be using). This is the IP address that clients will eventually connect to across the Internet for establishing VPN circuits.

**TIP** I strongly recommend that you use a fixed IP address and Internet connection for your server. Yes, you can use a dial-up connection from your RAS server to the Internet, and you can even make dynamic IP addresses work for this. But with dynamic IP addresses, your server's IP address will change every time it has to reestablish its link, quickly becoming a management nightmare.

Depending on how many simultaneous virtual private networking connections you plan on supporting, adjust the Maximum Ports value accordingly (up to 128) and then click OK.

**TIP** I recommend disabling any and all VPN connections that you don't plan on using. For example, if you are only going to support L2TP connections, disable PPTP by unchecking the Remote Access Connections (Inbound Only) option on the properties page for PPTP. This will prevent anyone from trying to establish a connection to your server via PPTP without your knowing about it.

### CLIENT CONFIGURATION

To get a client workstation connected to a Windows Server 2003 running VPN protocols, you will need to have one of the following:

- ◆ Windows 95 with the Dial-Up Networking 1.2 upgrade or better (PPTP only)
- ◆ Windows 98 (PPTP or L2TP)
- ◆ Windows Me (PPTP or L2TP)
- ◆ Windows NT 4 Workstation or Server (PPTP or L2TP)
- ◆ Windows 2000 Professional or Server (PPTP or L2TP)
- ◆ Windows XP Professional (PPTP or L2TP)

Let's go through getting some of these clients connected to a VPN using PPTP. Since older operating systems such as Windows 95 and Windows NT 4 don't install tunneling protocols by default, the first thing to do is add PPTP support to the client system. PPTP is a standard protocol, just like NetBEUI or NWLink, so the procedures for adding this new protocol are roughly the same. In addition, support for L2TP is relatively recent in most of these clients. Microsoft released a VPN client software download recently to upgrade the VPN clients on these older systems so that they could be compatible with the L2TP/IPSec standards.

### Windows NT 4 Workstation

Assuming you already have Dial-Up Networking set up on your NT 4 Workstation, the first step to adding VPN support is to add the Point-to-Point Tunneling Protocol in the Control Panel/Network applet. Start by clicking Start/Settings/Control Panel/Network, and then click the Protocols tab. Clicking the Add button from the protocols properties page will bring you to the protocol properties dialog box, as shown in Figure 20.48.

**FIGURE 20.48**

Protocols properties  
page in NT 4  
Workstation

Once you have selected the Point-to-Point Tunneling Protocol and clicked OK, NT 4 Workstation will ask you how many simultaneous virtual circuits you'd like to support in the dialog box in Figure 20.49.

**FIGURE 20.49**

Configuring the number of virtual circuits to support

The number of circuits you choose here will determine how many virtual ports Windows NT 4 will add to its configuration. Each virtual port will be called VPN $x$ , with  $x$  referring to the specific port number. In effect, they function similarly to modems running on COM ports (COM $x$ ), so think of these VPN devices as virtual modems. If you will only be connecting to one virtual private network at a time, choose 1 and click OK.

Once you have completed selecting the number of virtual circuits to support, NT 4 Workstation will invoke RAS setup to allow you to add your new virtual modem(s) to the RAS configuration.

Click the Add button in Remote Access Setup and you should see your VPN device in the Add RAS Device window (see Figure 20.50). If you see a modem or some other device there, try pulling down the list and then selecting your VPN device. Once you have your VPN device selected, click OK and it will be added to your RAS configuration.

**FIGURE 20.50**

Adding VPN devices to RAS in NT 4 Workstation

Once you are back to the Remote Access Setup screen, highlight your VPN device and click the Configure button. This device should be configured for Dial-Out Only, as shown in Figure 20.51.

Once everything is set correctly, click OK and RAS will start the installation routine. This will most likely require a reboot of your computer, so go ahead and restart it and get back into Windows. To use your VPN device, the last step you need to perform is creating a Dial-Up Networking entry.

**FIGURE 20.51**

Configuring VPN devices for dial-out only in NT 4 Workstation

Double-click My Computer and then Dial-Up Networking to begin creating a new Dial-Up Networking entry. Creating a VPN Dial-Up Networking entry is almost identical to creating a regular Dial-Up Networking entry for a phone line, except that you will use an IP address instead of a phone number to dial and the VPNx device instead of a modem. This is shown in Figure 20.52.

**FIGURE 20.52**

Creating a VPN Dial-Up Networking entry in Windows NT 4 Workstation

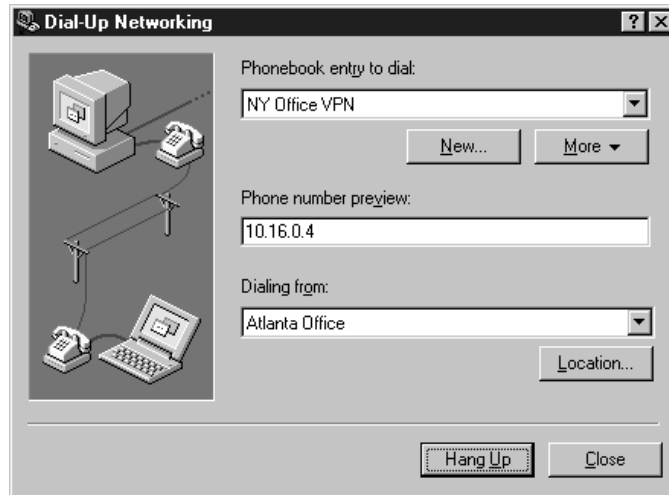

As you can see, this Dial-Up Networking entry will call a VPN server at IP address 10.16.0.4, the same IP address used in the configuration of the RAS/VPN server earlier in this chapter. As long as the VPN device is selected in the Dial Using pull-down box, everything should be set for this connection.

Unlike the newer clients, you may have to perform two steps to initiate a connection to your VPN server. The first step to making this connection is to make sure you have an actual, valid Internet IP address before doing so. If you need to use Dial-Up Networking to connect to an ISP for this, do that first. Once you have a valid IP address available, launch your VPN Dial-Up Networking Connection

to get connected to your remote system. Once you provide a set of valid user credentials, you'll be connected to your VPN. To disconnect from the VPN, simply double-click the Dial-Up Networking icon in My Computer, select the phonebook entry for the VPN, and click the Hang Up button, as shown in Figure 20.53. You can also right-click the Dial-Up Networking Monitor icon in the system tray and choose Hang Up.

**FIGURE 20.53**

Disconnecting a  
VPN session in  
NT 4 Workstation

### Windows 9x

Windows 9x takes a unique approach to implementing virtual private networking through the use of a Microsoft VPN adapter. Instead of adding support for PPTP or other protocols (like in other Microsoft operating systems), all you need to do is add the VPN adapter to your system to get connected.

**NOTE** To add VPN support for Windows 95, you must have the Dial-Up Networking upgrade v1.2 or later installed on your system. Windows 95 only has support for PPTP, remember. VPN support for PPTP is included in Windows 98 right out of the box, and with the addition of the L2TP VPN client, which you can download from the Microsoft Web site, Windows 98 will support L2TP as well as PPTP.

Start by editing the network properties of Windows 9x by selecting Start/Settings/Control Panel/Network. When the Network properties page comes up, click the Add button, and then select Adapter as the component type you'd like to install. Your screen should look like Figure 20.54.

In the list of adapters supplied, scroll down to Microsoft for the manufacturer, then select the Microsoft Virtual Private Networking Adapter listed on the right side of the screen. Click OK, and Windows 9x will add the VPN adapter to its system. Of course, this will require a reboot for the changes to take effect.

Once your system has rebooted, the next step to getting connected is creating a Dial-Up Networking entry to connect to your VPN server. From the Windows 9x Desktop, double-click My Computer,

then Dial-Up Networking, and then Make New Connection to launch the Make New Connection Wizard, shown in Figure 20.55.

**FIGURE 20.54**

Adding the  
Microsoft VPN  
Adapter to  
Windows 9x

**FIGURE 20.55**

Windows 9x Make  
New Connection  
Wizard

From the Select a Device pull-down box, choose the Microsoft VPN Adapter if it isn't already selected. Click Next to move to the next step of the wizard shown in Figure 20.56.

Enter the IP address or DNS name of your VPN server in the box as needed. In the example in Figure 20.56, we have used an IP address of 10.16.0.4. You may remember that this is the same IP address used in the configuration of the RAS/VPN server earlier in this chapter. After entering the hostname or address, clicking Next will complete the wizard and place a VPN Dial-Up Networking entry on your system.

**FIGURE 20.56**

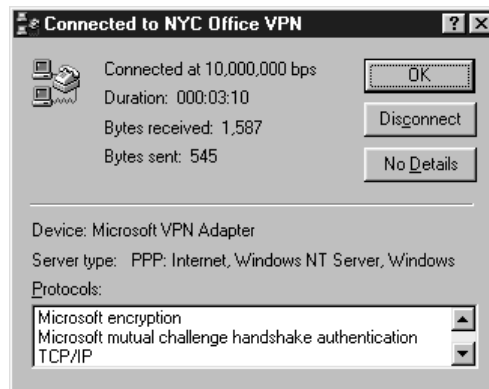

Entering the IP address of a VPN server in Windows 9x

To make the VPN connection, you must make sure you have an actual, valid Internet IP address before doing so. As with NT 4, you may need to connect to the VPN in two steps. If you need to use Dial-Up Networking to connect to an ISP for your IP address, do that first. Once you have a valid IP address available, you can then launch your VPN Dial-Up Networking connection to get connected to your remote system. After providing a valid set of user credentials, you'll be connected to the VPN server. To disconnect the connection, simply double-click Dial-Up Networking from My Computer, double-click the connection to the VPN server, and then click Disconnect, as shown in Figure 20.57. Or you can right-click the connection in the Dial-Up Networking window and click Disconnect.

**FIGURE 20.57**

Disconnecting the VPN connection in Windows 9x

### Windows 2000

Windows 2000 added a few nice features to the client side of establishing VPN connections, namely the ability to automatically associate one DUN entry with another. For example, if you need to dial an ISP before you can connect with your virtual private network, Windows 2000 can join these

two functions. The end result is that when you (or your users) need to connect to the virtual private network, doing so only requires launching one Dial-Up Networking session, rather than the two steps required with the older clients. Windows 2000 also includes support for L2TP without any additional add-on software components.

Like most of the remote access functionality in Win2K, to define a VPN connection, you will begin with Start/Settings/Network and Dial-Up Connections, and then the Make New Connection Wizard. Remember, you may have to add your phone information here if this is the first time you've initiated this. After clicking Next in the initial screen of the wizard, select the option Connect to a Private Network Through the Internet, as shown in Figure 20.58.

**FIGURE 20.58**

Creating a VPN connection on Windows 2000

Click Next to continue. If you have already created a dial-up connection on your system, Win2K will then ask if you need to establish a public network (Internet) connection first before establishing the VPN connection, as shown in Figure 20.59.

**TIP** If you have not yet created a dial-up connection, Win2K will not give you the option to decide whether or not to dial it during the wizard. However, if you create a dial-up connection after you create the VPN connection, you can make sure that Win2K knows to use the dial-up connection first by changing the setting in the VPN connection properties sheet. To set this, simply right-click the VPN Connection icon from the Network and Dial-Up Connections window and click Properties. Then check the Dial Another Connection First check box.

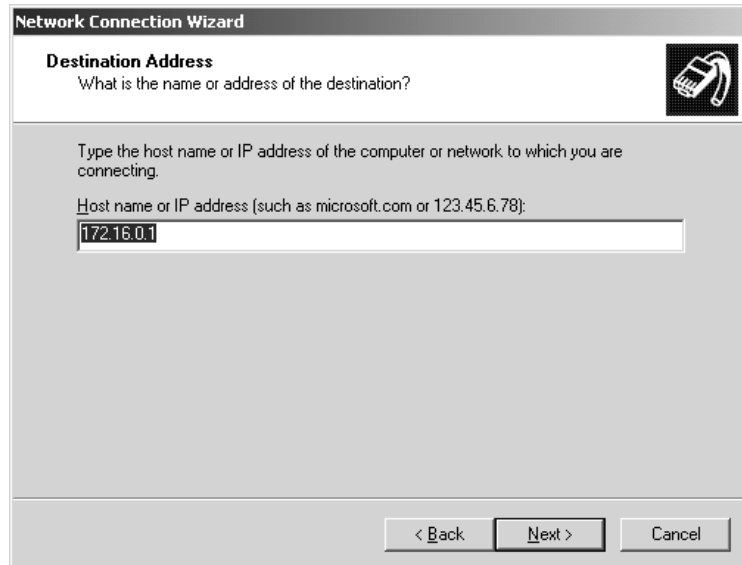

If the Win2K device you will be connecting already has a valid, public Internet IP address, answer Do Not Dial the Initial Connection to this question. Otherwise, if you need to obtain an IP address first from an ISP, select Automatically Dial This Initial Connection and choose the connection that will get you connected to the Internet. Doing so will cause your VPN Dial-Up Networking connection to initiate an ISP connection first. Click Next to continue on to entering the IP address or hostname of the target server, as shown in Figure 20.60.

**FIGURE 20.59**

Creating a public connection before a VPN connection

**FIGURE 20.60**

Entering the IP address of the VPN server

Much like many of the other client platforms we've already discussed, you will need to enter the IP address of your target system or a DNS-resolvable hostname. As you can see, this Dial-Up Networking entry will call a VPN server at IP address 172.16.0.1. Click Next to continue, and the final step of the wizard will ask you whether you want to make this VPN connection available to

all users or just yourself. For the purposes of this section, I'll assume that you just want to use the VPN connection for yourself, so click the *Only for Myself* radio button and click *Next* to finish creating the Dial-Up Networking entry. Select a name for the connection and click *Next* to finish the wizard. You also have the opportunity here to have Win2K create a shortcut on the Desktop for this connection, a handy feature if the connection will be used often.

Once you have completed the wizard, you will have an opportunity to test the connection. When it comes time to actually establish this connection, if you selected the option to have Win2K dial an initial connection, you will see a dialog box like the one in Figure 20.61 asking you if the public network connection should be initiated first.

**FIGURE 20.61**

Windows 2000 asking if an initial public network connection should be established first

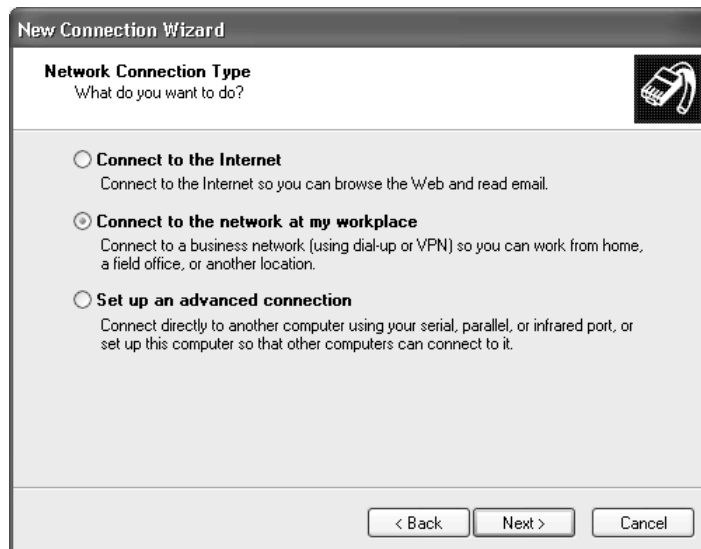

### Windows XP

To create a virtual private network connection in Windows XP, open Control Panel from the Start menu and double-click the Network Connections icon. Start the New Connection Wizard by double-clicking that icon and click *Next* in the initial screen of the wizard. Click the *Connect to the Network at My Workplace* radio button (Figure 20.62) and then click *Next*.

**FIGURE 20.62**

Setting up a VPN connection in Windows XP

In the next screen, choose the Virtual Private Network Connection option and click Next. Type in the name you want to use for this connection and click Next. If you have previously set up a dial-up connection on your XP client, you will now receive the option of whether to dial that first, before connecting to the VPN. If, for instance, you need to connect to an ISP to receive a valid IP address, which is required before you can utilize the VPN, choose the Automatically Dial This Initial Connection option as seen in Figure 20.63.

**FIGURE 20.63**

Windows XP asking if an initial dial-up connection should be established before connecting to the VPN

**NOTE** When I say that your VPN client needs a valid IP address, realize that if your client machine is on a network which uses NAT or private IP addresses routed through a centralized device like a router, a demand-dial server, or your cable modem at home—as long as that device supports VPN traffic—you will be able to connect to the VPN just as you would to the Internet from that machine, no matter what kind of IP address you have.

In the next screen of the wizard, type in the IP address or hostname of the VPN server (172.16.0.1 in the example) and click Next. The next screen asks you to decide who will use this VPN connection that you are creating (see Figure 20.64). If you want to share the connection among several users on the machine, choose the Anyone's Use option and the connection will be copied to the All Users profile on the machine. For now, choose the My Use Only radio button to reserve the use of this connection and user credentials to one user.

The final screen of the wizard allows you to view the options you have selected and enables you to create a shortcut to this VPN connection on your Desktop, which can be handy if you will be using it often. When you have completed the wizard, if you have opted to dial another connection first, you will be asked if you would like to dial that initial connection at this time. If you do not have another connection that you need to dial before connecting to the VPN, you will be taken to the Connect <Connection Name> dialog box, where you can click the Connect button to test your connection (Figure 20.65).

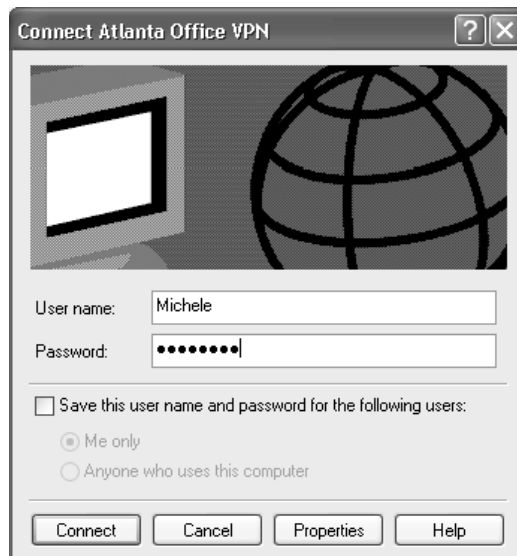

**FIGURE 20.64**

Decide who will be allowed to use the VPN connection on this machine.

**FIGURE 20.65**

Test your connection.

Once you are connected and your credentials are verified, you can use the VPN connection to access resources on the remote network, use drive mappings and even browse the remote network using Network Places. You can copy this VPN connection in the Network Connections folder and rename it if you need to create multiple VPN connections on this machine. Just change the connection and security settings for each connection to accommodate the various VPN servers you need to connect to.

To disconnect the VPN connection in Windows XP, right-click the connection and choose Disconnect. You can also, of course, double-click the connection and do the same thing or right-click the network icon in the notification area of the system tray and choose Disconnect. There are always at least three ways to do anything in a Windows environment, remember?

**NOTE** *Keep in mind that a firewall can keep you from being able to connect using your new VPN. If you are having trouble connecting, consider any firewalls that may exist, whether it is on a home pc or in the corporate environment in the course of your troubleshooting.*

## VPN Performance Considerations

Our section on virtual private networking wouldn't be complete without taking a bit of time to discuss performance issues to consider. Although virtual private networking is a neat technology, unfortunately there are some times when it just might not make sense to use it. Careful planning and consideration should help you determine if it is a solution that can add value to your organization.

In the right set of circumstances, virtual private networking can provide fast, reliable, and secure connections to remote networks across the Internet (or another unsecured network). However, in the wrong set of circumstances, a VPN can make an already slow dial-up connection seem even slower.

So what are the right circumstances? In my professional opinion, the right circumstances are when you have high-speed connectivity on your RAS server at the very least and preferably when you have high-speed connectivity on both your RAS server and your DUN client. On occasions when I have been able to implement VPN circuits at locations with a T1 or better available at both the server and client ends, performance has been wonderful and the connections reliable. However, due to the protocol overhead involved with PPTP and L2TP and the inherent latency of the Internet, if you are planning on implementing a VPN with dial-up modems on each side of your connection, I urge you to think twice.

I wish I could say that Microsoft's VPN implementations were going to give you the performance you might expect over modem connections, but they just won't. Simply due to the additional complexities of encrypting the data, bundling the payload data inside a TCP/IP packet, and the latency of communications across the Internet, you can expect a decrease in your performance ranging anywhere from 10 to 50 percent. Now, without getting into all the technical details, it is worthwhile to note that this isn't entirely Microsoft's fault; after all, they can't be blamed for the fact that the Internet can be inherently slow at times (or can they?). However, even with the worst-case scenario of a 50 percent reduction in performance, if there is a T1 on each side of the virtual private network, the effective speeds of the network are still roughly in the 760Kbps range. However, if you're using a 56K modem on each side of the virtual private network, which probably won't connect much faster than 48Kbps, you can easily see how a 50 percent performance penalty can make a connection go from "slow" to "unusable."

Simply put, if you are using a modem on your RAS server and a modem on your DUN client, you will get your best possible speeds by having one dial directly in to the other. And without a VPN, there is no protocol overhead getting in the way, nor is there the need for your data to travel across dozens of routers as it works its way to its destination. By creating a direct connection, data packets go directly from the DUN client to the target network.

However, everything in life is a trade-off, and it will be up to you to decide whether this will work adequately enough for your needs. After all, what is adequate to one person might be great to another

and unacceptable to yet another. In either case, expect a performance penalty when implementing virtual private networking and plan your bandwidth accordingly.

## Dialing Up a Remote Network and Routing Traffic

With the release of the Routing and Remote Access Service update to Windows NT 4 Server, Microsoft was able to improve on the routing capabilities that already existed in Windows NT. Although Windows NT 4 shipped with routing capabilities right out of the box, they were limited and cumbersome, to say the least. Microsoft then included all the capabilities of the Routing and Remote Access Service update in Windows 2000 Server, making that operating system a platform capable of solving several common routing scenarios right out of the box. Microsoft has added a few more features to Server 2003, including support for preshared keys in L2TP/IPSec authentication, the ability for NAT interfaces to work with Basic Firewall, support for L2TP/IPSec connections originating from VPN clients behind a network using NAT, and broadcast name resolution by a NetBT proxy on the VPN server for networks operating without WINS or DNS. All in all, Windows Server 2003 offers a fairly comprehensive package in its RRAS implementation.

Let's take an example of routing traffic from a central office to a remote office over an analog connection. Many organizations are often faced with a connectivity dilemma when opening remote offices, especially if there are only a small number of computers at the remote site. Installing dedicated links between locations can be cost-prohibitive depending on the number of people at the remote site, but having a group of individuals completely isolated from the organizational network usually isn't an acceptable alternative either. Windows Server 2003 is a perfect solution for this scenario, as it can establish demand-dialed links between locations whenever traffic needs to pass from one site to another. By using simple modems and ordinary phone lines, Windows Server 2003 can be a low-cost alternative to installing dedicated WAN links. To get started, let's walk through the details of a sample scenario.

### Sample Network

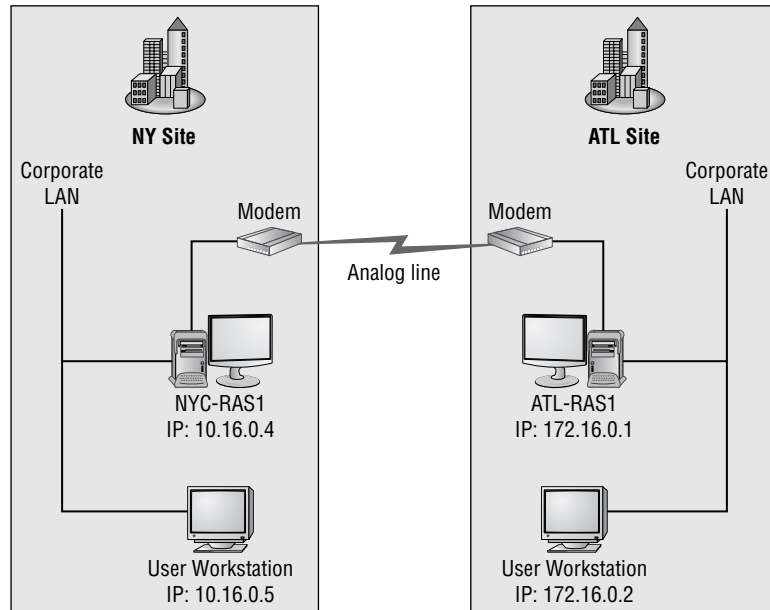

Our sample network consists of the following:

- ◆ Number of sites: two (New York and Atlanta)
- ◆ TCP/IP subnet for New York: 10.16.0.x with a subnet mask of 255.255.255.0
- ◆ TCP/IP subnet for Atlanta: 172.16.0.x with a subnet mask of 255.255.255.0
- ◆ Windows Server 2003 RRAS server in New York: NYC-RAS1 with an IP address of 10.16.0.4
- ◆ Windows Server 2003 RRAS server in Atlanta: ATL-RAS1 with an IP address of 172.16.0.1
- ◆ Phone number for analog line connected to New York Windows Server 2003 RRAS server: (212) 555-1212
- ◆ Phone number for analog line connected to Atlanta Windows Server 2003 RRAS server: (404) 555-1212
- ◆ User account created in the New York Active Directory and granted dial-in permissions: ATLANTA-ROUTER, password: atlanta
- ◆ User account created in the Atlanta Active Directory and granted dial-in permissions: NEWYORK-ROUTER, password: newyork

In effect, our network looks similar to the diagram shown in Figure 20.66.

**FIGURE 20.66**

Diagram of sample network

## Setting Up the First Server

To start building a demand-dialed analog connection between these two locations, you will need to have your Windows Server 2003 able to function as a router. If you've worked through any of the configurations previously discussed in this chapter, your system is probably configured to simply act as a Remote Access Server. Changing roles for the server is as simple as editing the properties for the Remote Access Service.

**NOTE** For the purposes of walking through the first server configuration, I will be configuring the necessary components on our New York router first, using the details just defined.

To change roles for your server, open the Routing and Remote Access MMC by selecting Start/Administrative Tools/Routing and Remote Access. Edit the properties for Remote Access Service on your server by right-clicking your server name and then selecting Properties. You should see a dialog box similar to the one pictured in Figure 20.67.

To add routing services to your system, put a check in the box labeled Router and then select one of the two radio buttons below that option. If you will only be using LAN-based interfaces (Ethernet adapters, etc.) as your routing devices on your system, you can leave the Local Area Network (LAN) Routing Only option selected. However, if you intend to use dial-up connections (as we will in this example), demand-dialed links, or VPN connections, select the LAN and Demand-Dial Routing option. Click OK to apply the changes, and Windows Server 2003 should stop and restart the Routing and Remote Access Service to implement the changes.

**FIGURE 20.67**

Editing RAS server properties to add routing capabilities

When you return to the Routing and Remote Access MMC, the next step will be to enable routing support for one of the ports on your system. In the Routing and Remote Access MMC, make sure you have expanded the RAS server by clicking the plus symbol next to it, then right-click the option for Ports and select Properties to get to the ports properties pages. Once you have the ports properties pages available, double-click the device you intend to use as your demand-dialed connection (if the device you want to use isn't listed, go back to the section on adding RAS devices earlier in this chapter). The configuration page for that device should look similar to the dialog box in Figure 20.68.

**FIGURE 20.68**

Editing properties for the demand-dial port

Configure this device by checking the Demand-Dial Routing Connections (Inbound and Outbound) option and clicking OK. If you would eventually like to use Bandwidth Allocation Protocol with this configuration—to increase bandwidth by adding more dial-up connections as needed—enter the phone number for your connection and click OK to accept the changes.

When you return to the Routing and Remote Access MMC, you might have noticed a new item called Network Interfaces in the results pane of the window when you look at your Windows Server 2003, as shown in Figure 20.69. This option was added when routing services were added to the server, and it is where you will begin to add your demand-dialled interface.

**FIGURE 20.69**

Adding a demand-dial interface to the RRAS MMC via Network Interfaces

To start creating a demand-dial interface, right-click the Network Interfaces selection, and then choose the option to add a new demand-dial interface. This will launch the Demand-Dial Interface Wizard, which will walk you through steps to create the interface. Once you click Next to get through the initial wizard screen, the first step of the wizard appears, as shown in Figure 20.70.

**FIGURE 20.70**

Defining a name for a demand-dial interface

In most cases of assigning a friendly name to a RAS or other type of connection, any name will do. However, in creating demand-dial routing connections, the name assigned to a demand-dial interface is important. The name assigned to a demand-dial connection *must* match the name of the user account entered into the Active Directory at the *same* site. The same must be true on both sides of the wide area network. To quote Microsoft directly: “The username in the authentication credentials sent by the calling router must exactly match the name of a demand-dial interface on the answering router.” If the username does not match a demand-dial interface name, the answering router will assume that the incoming call is a RAS *user*, not a remote router. Therefore, whatever name is entered here must also be used as a username on the same system’s Active Directory. Since we’re walking through setting up our New York remote office in our example that will dial out to the Atlanta office, I’ve decided to call this interface ATLANTA-ROUTER. When you have entered the appropriate name, click Next to continue to the next stage of the wizard, shown in Figure 20.71.

**FIGURE 20.71**

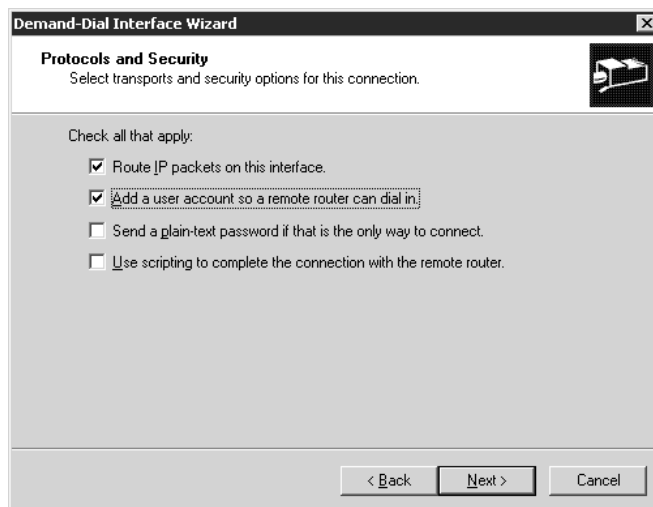

Selecting the connection type for the demand-dial interface

Here you will need to choose the option to Connect Using a Modem, ISDN Adapter or Other Physical Device or you can choose to use Point to Point Protocol over Ethernet (PPPoE), which allows you to utilize your broadband connection to pass packets from one LAN to another. Choose the first option and click Next. In the screen that follows, select the modem or adapter that you want to use. This step of the wizard should be relatively self-explanatory. The wizard needs to know what phone number Windows Server 2003 should dial when it is attempting to connect to Atlanta. Enter the number exactly as your system should dial it, including any prefixes, area codes, etc. If you have a list of alternate numbers that Windows Server 2003 can use to establish this demand-dial connection, click the Alternates button and enter the information there. When you click Next to move to the next step in the Demand-Dial Interface Wizard, you should see a dialog box similar to the one pictured in Figure 20.72.

**FIGURE 20.72**

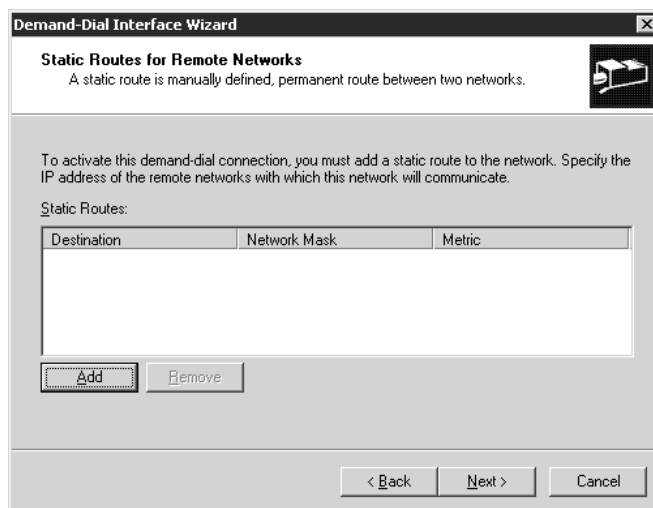

Selecting protocol and security options for a demand-dial interface

Depending on the network you are connecting to, here you can select which protocols Windows Server 2003 should route, although since Microsoft has dropped IPX/SPX from its list of RRAS protocols, this list is becoming pretty slim. In addition to selecting the appropriate protocols for the remote network, you can also choose to have Windows Server 2003 create a user account so that the remote network's router can dial in to your system. Lastly, you can choose custom connection options such as sending a plain-text password if that is the only way the remote router will let you connect, or any advanced scripting options you might need. Depending on the options you select from this screen, the remainder of the Demand-Dial Interface Wizard will vary, but for the purposes of our example we'll assume you've selected IP and decided to create a user account for a remote router as seen in this figure. Click Next to continue to the next step of the wizard, shown in Figure 20.73.

**FIGURE 20.73**

Adding static routes for the remote network

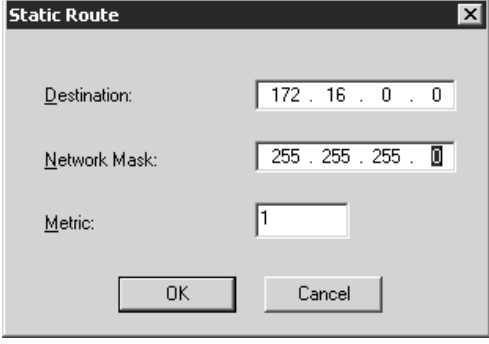

Here you will need to define a static route entry for the remote IP network. In effect, you will need to tell your Windows Server 2003 “whenever you need to contact these IP addresses, use this demand-dial interface to get there.” By entering a static routing entry for the remote network’s IP address range in the Atlanta office and then defining the demand-dial interface as the connection to use, Windows Server 2003 will know to route any packets for that network by dialing in to the remote router.

To add a static route, click Add and you should end up with a dialog box similar to the one in Figure 20.74.

**FIGURE 20.74**

Defining a static route to a remote network

The Static Route dialog box is shown with the following fields:

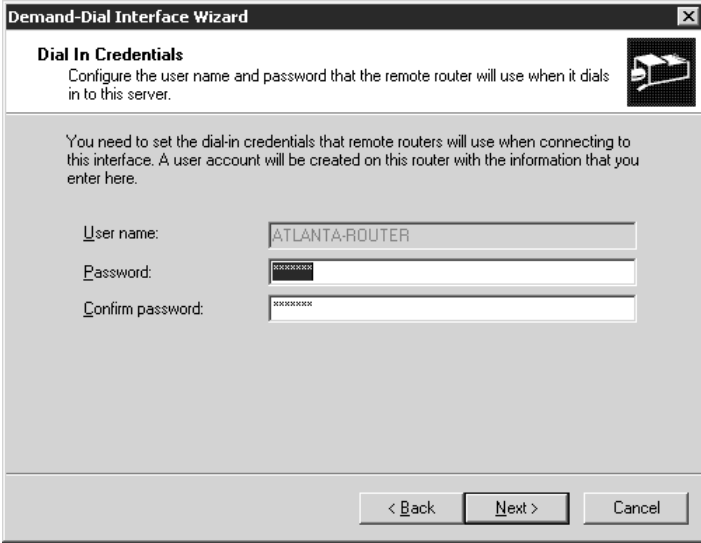

- Destination:** 172 . 16 . 0 . 0
- Network Mask:** 255 . 255 . 255 . 0
- Metric:** 1

Buttons: OK, Cancel

Here you can define the network address and mask for the remote network, which this interface will use to get the packets to their destination. Windows Server 2003 will use this information to determine if packets—when it receives them—match the IP address range of the remote network. If the packets match the range defined, Windows Server 2003 will route them. Lastly, you can leave the metric at 1. Once you have all this information entered, click OK and you should see your static route appear in the list of Static Routes. Click Next to move to the Dial-In Credentials pane of the wizard, as seen in Figure 20.75.

**FIGURE 20.75**

Configuring router dial-in credentials

The Demand-Dial Interface Wizard - Dial In Credentials pane is shown with the following fields:

- User name:** ATLANTA-ROUTER
- Password:** [REDACTED]
- Confirm password:** [REDACTED]

Buttons: < Back, Next >, Cancel

Remember that, although we are creating this interface to route our New York users to Atlanta by using the demand-dial connection, when users in Atlanta are routed to the New York office, the RAS server in Atlanta (ATL-RAS1) will need to access this interface we are creating in New York. When ATL-RAS1 attempts to connect to this interface, it will need to have credentials that are valid in New York. As previously stated, the friendly or descriptive name you use for a demand-dial interface needs to be the same as the credentials for that connection, otherwise the answering router (NYC-RAS1) will assume the incoming caller (ATL-RAS1) is simply a RAS connection, not a router. Since we are defining a demand-dial interface to also allow calls *into* the ATLANTA-ROUTER device we are creating here in New York, if ATL-RAS1 were to call the NYC-RAS1 system we're now configuring, it would need to identify itself as ATLANTA-ROUTER. Therefore, the username field is grayed out by default, preventing you from changing it. This is an important point, because if you decide to change the user accounts used by RRAS at a later date, but you don't change the interface names accordingly, you could end up with a broken routing system. Enter a password for this account to use, and make a note of it. Click Next to continue to the next screen in the wizard, as seen in Figure 20.76.

**FIGURE 20.76**

Configuring router dial-out credentials

Now we'll look at how we dial out to the Atlanta office from the interface we are creating here in New York. You will need to define the user credentials that NYC-RAS1 will use when calling the Atlanta office and dialing in to ATL-RAS1. The username entered here must match the name of the demand-dial interface configured on the remote system (ATL-RAS1) exactly or else the remote system in Atlanta will simply assume your Server 2003 is a standard RAS user. Remember the network configuration I showed you earlier for our scenario? We called the interface in Atlanta NEWYORK-ROUTER, so that is the user account that we will need to use when we connect to Atlanta from New York. Enter the appropriate domain, username, and password combination for your configuration and then click Next.

At this point, you have completed exactly half the work required to have your systems routing data over analog links. The other half of the job, of course, is to go through the exact same steps on the other system by configuring a demand-dial interface in the same manner we just described. In our case that other system would be the Atlanta system, called ATL-RAS1. On that system we will create a demand-dial interface called NEWYORK-ROUTER, which will be used both to route Atlanta network traffic destined for the New York office to NYC-RAS1 and to receive incoming calls from our NYC-RAS1 system.

Once you have both systems configured correctly, you should be able to test your connection to see if it works by doing a ping from one system to another.

**NOTE** For more information about Ping, see Chapter 6.

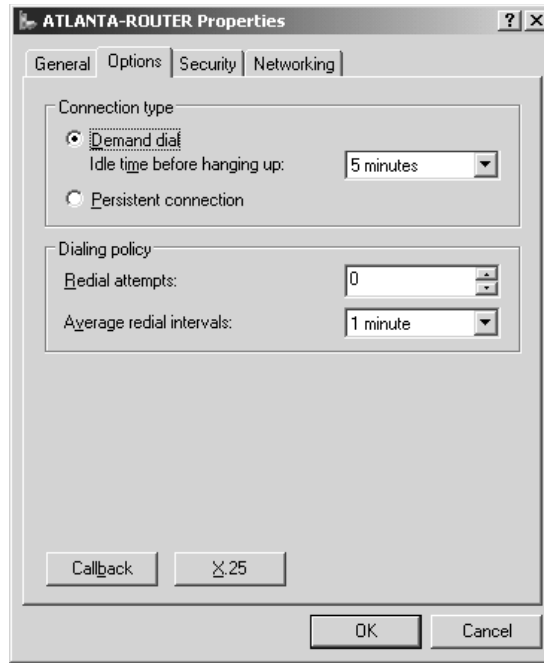

**WARNING** This may just be a bug that hasn't been ironed out, but despite the fact that the Demand-Dial Interface Wizard told me that it would create a user account for me, it didn't, at least not in the Active Directory. When I initially tested my new connection to the Atlanta office, I found that I couldn't authenticate. What happened? In Figure 20.75, you can see that I have no choice in the username that will need to authenticate in New York since it has to be the same as the interface name. Note that it doesn't specify any domain information. On the following screen (Figure 20.76), I configured the dial-out credentials to use the interface name of the RAS server in Atlanta (NEWYORK-ROUTER). Note also that I was given the opportunity to add the domain name for those dial-out credentials in the wizard. I assumed that a domain account would be created. So, in New York, I told the interface to use the domain account DEVTECHS\NEWYORK-ROUTER for the outbound connection to Atlanta. In Atlanta, however, the user account created in the wizard for the dial-in credentials, although it was called NEWYORK-ROUTER, was not actually created in the DEVTECHS domain. Upon closer inspection, I found that when I created the interfaces, both in New York and in Atlanta, an account was indeed created, but it was a local account. So, in the same wizard in which you can specify a domain account for the dial-out credentials, you get no opportunity to add the domain information to the dial-in account, leaving you with two different sets of credentials on each interface.

Start at one of your Windows Server 2003 boxes configured with a demand-dial interface, go to a command prompt, and ping one of the IP addresses on the distant network. You should see your demand-dial connection come online and start passing traffic. However, it is important to realize that for the type of communication you are attempting, your call setup times might take too long. For example, the ping command typically sends four ICMP echo requests, and then waits 1.5 seconds after each one for a response. All total, a test of four pings should take no longer than 6 seconds. However, if you are using analog connections, your call setup times are most likely going to be in the range of 20–30 seconds. Therefore, your connection won't come online in time to satisfy the request. For testing purposes, I would recommend using an indefinite ping by using the -t option on the command line, such as `ping -t 172.16.0.2`, which is an address in the Atlanta office in our scenario.

To solve problems like these and others, you can use some fine-tuning controls for your demand-dial connection. For example, if you are using analog lines to connect sites and the analog lines aren't billed per-minute, it might make sense to have your demand-dial connection online all the time. This is called making a *persistent* connection. From the Routing and Remote Access MMC, click the selection for Routing Interfaces in the left pane of the window. In the results pane, you should see your demand-dialed interface listed. Right-click the demand-dialed interface and select Properties to edit the properties page for this connection. You should see a four-tabbed dialog box similar to the one in Figure 20.77 (shown with the Options tab selected).

**FIGURE 20.77**

Editing router interface properties

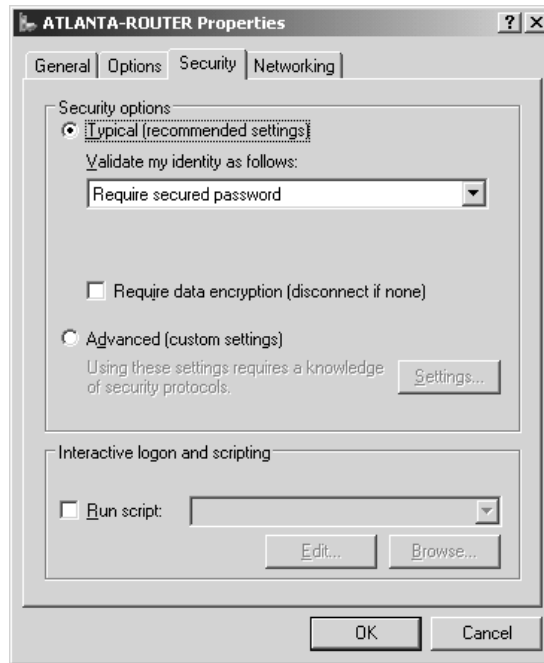

There are several settings you can control through this dialog box, but some of the most useful are listed under the Options tab shown in Figure 20.77. For example, if you are using an ISDN connection to reach your distant network and your ISDN is billed per minute, you can enter an idle time-out value in the Connection Type area of the window so your connections don't stay on any longer than necessary. Or, if the opposite is true, and you aren't billed per minute for your connections, you can select the persistent connection option to have the link stay online all the time. If, for some reason, the link fails, Windows Server 2003 will bring it right back online again. Set the options you would like to use for this interface. Now click the Security tab to view your authentication protocol and encryption options, as shown in Figure 20.78.

If you leave the default option checked for Typical (Recommended Settings) in the Security Options section of this dialog box, you are telling the RAS server to require a secured password for the connection, but you are given the opportunity to allow unsecured passwords here as well by clicking the drop-down box. The check box labeled Require Data Encryption is not a default setting, but if you want to make sure that the data that passes in and out of this interface is encrypted, select Require Data Encryption (Disconnect if None) to force the system to disallow any unencrypted communication. Otherwise, by default, the server will request encryption, but will allow nonencrypted clients to connect anyway. Dial-up connections in RAS use Microsoft Point-to-Point Encryption (MPPE). VPNs have two options for encryption. You can specify either MPPE and Point-to-Point Tunneling Protocol (PPTP), or IP Security (IPSec) encryption along with Layer 2 Tunneling Protocol (L2TP). Remote Access Policies are used to specify encryption levels, which can be set to Basic (40-bit), Strong (56-bit), or Strongest (128-bit). MPPE requires the use of the MS-CHAP (v1 or v2) or EAP-TLS authentication protocols. To set your authentication protocols for this interface,

check the box labeled Advanced (Custom Settings) and click the now-highlighted Settings button. You should see the screen shown in Figure 20.79.

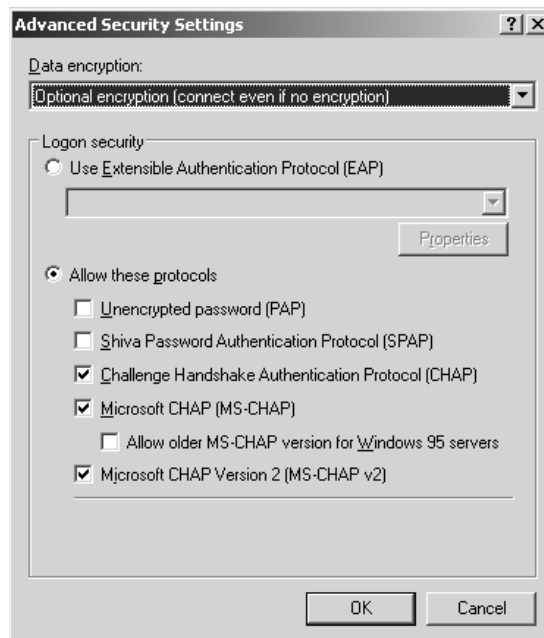

**FIGURE 20.78**

Security settings for the RAS interface

**FIGURE 20.79**

Authentication protocols for the RAS interface

Use this properties page to decide which authentication protocols to allow on the interface. You can also customize in more detail how the interface handles encryption. Rather than simply requiring encryption or asking for it and then allowing the connection anyway, you can also choose to disallow all encryption. This will disconnect any connection that tries to send encrypted data; you even have the ability to require strongest encryption without having to set this in your Remote Access Policies. If you need to create anything more customized than these settings allow, you will have to learn all about Remote Access Policies, which allow you to fine-tune exactly what your clients can do with the connection based on various attributes—for instance, the phone number that they dial in from, the type of OS they are using, group membership, or perhaps the time of day that they are calling. By using these attributes, you can create policies that will affect the way a user can connect, how long they can use the connection, IP addressing, idle times, and more. Don't forget to make sure to give the users the ability to connect by checking the Allow Access setting in their user properties. Also, remember that this interface is set up to dial another network, as well as to receive inbound calls from clients. It is, then, a client itself at times. The Networking tab allows you to adjust the client settings for this interface for the times that it is dialing in to another network, in this case, Atlanta. Click OK to save your settings and return to the RRAS MMC.

Take a look at Figure 20.80. When you right-click the demand-dial routing interface in the Routing and Remote Access MMC, there are some additional options you could set, in addition to editing the property sheets of the item itself. For instance, you can reset the credentials that this interface uses when it dials another network, in this case, our Atlanta office. Remember, though, that if you reset the username here for the dial-out credentials, you will also have to change it in the Active Directory of the remote network (it could be that both of these offices are in the *same* AD, of course) or on the local server, if the remote RAS server is not a member of a domain.

**FIGURE 20.80**

Additional interface settings

You can also manually connect or disconnect from here, which can be very useful for testing or troubleshooting. One of the more useful items listed is the ability to create IP filters for the connection. With this option, you can discriminate against certain types of traffic and allow or prohibit the

traffic through the interface. You can even specify whether the connection should be initiated at all, based on the type of traffic. If you click the Dial-Out Hours menu option, you can set the hours in which this connection can be established. If you would like to restrict the times when your demand-dial connections can be brought online, select the Dialing Hours option when you right-click the routing interface. You should end up with an hourly grid dialog box, like the one in Figure 20.81, in which you can select the hours to allow and disallow connections. By default, users can access the connection at any time of day or night.

**FIGURE 20.81**

Defining dialing hours for demand-dial connections

Once you have completed everything, you should have a functional wide area network running between locations and passing data as necessary. Through the use of this functionality, I have seen organizations that have set up completely “virtual” WANs consisting of multiple sites that all look as if they’re operating as one large network, but in reality they are each small sites which are connected to a master network over analog links. Although Windows Server 2003 isn’t designed to displace high-end routers in complex routing scenarios, it is a good solution for a lot of networking problems—some of which you may face.

## The Most Common (and Poorly Documented) RAS Problems

Microsoft’s RAS service is a great feature in Windows Server 2003—and even though they’ve made it simple to set up, under the hood a complex communication mechanism is working away to get packets from one system to another. Often, the Microsoft wizards will help you with setting up most of the settings necessary for RAS itself, but RAS depends on some other specific settings within Windows Server 2003 to function properly. In this section, we’ll take a look at some common (and poorly documented) problems that users run into when they’re trying to set up RAS.

### “I’ve connected to a RAS server from my home PC, but I can’t browse anything on the network!”

Okay, technically this doesn’t fall under a RAS problem per se—but browsing remote networks is a problem most commonly found on RAS connections. Actually, it’s the number one problem that I see posted on Usenet when people are trying to get RAS configured and running on their network.

Let's say that you gave the phone number for the RAS server to Jane in Accounting so that she can work at home. After giving her a quick lesson on how to create a dial-up networking connection, you're hoping that Jane will be able to connect to the network from her Windows 98 PC, and then navigate through the network to get to the resources that she needs.

So Jane successfully dials in over the weekend but she can't see anything in her Network Neighborhood. If she knew how to map a drive, she'd be able to do it—but she's accustomed to double-clicking things in the NetHood to find her files. So, she can't work. On Monday, she calls for help—frustrated that she's now behind in her work.

That leaves you with the unpleasant task of remotely troubleshooting a home user's PC. Who knows, maybe her 14-year-old kid messed up the TCP/IP stack? Or maybe there's some odd problem with her modem? In any case, it might seem like it's going to be a painful issue to troubleshoot since you can't easily get your hands on the PC.

Well, here's a quick tip that could save you a lot of headaches: More often than not, when a user experiences this type of problem, it's due to a misconfigured workgroup configuration on their computer.

For example, let's say that your network domain is called COMPANY (we'll stick with down-level NetBIOS names here to make it easier). Now, most retail PCs that a user might buy for their home are configured out-of-the-box with something like Workgroup for their workgroup setting. Odds are good that the company that your user bought her PC from didn't give it the same workgroup setting as the name of your domain. And that's what you need so Microsoft browsing will work properly.

The solution is to configure the workgroup name on the client's workstation to be the same as the Windows NT/2000/Server 2003 domain or workgroup to which your users are connecting. If you've run into this problem, give it a shot and see if it works.

### **“How can I keep RAS connections alive when a user logs off of their workstation?”**

By default, RAS connections (on Windows NT and 2000 clients) are automatically disconnected whenever a user logs out of their workstation. If you have a workstation setup at a remote site that multiple people use, you might not want this to be the case. In order to change this default behavior, you'll need to modify the registry on the RAS *client*—the system that is dialing in.

Look in the following key in the Registry:

```
HKEY_Local_Machine\Software\Microsoft\Windows NT\Current Version\Winlogon
```

You may see a value in that key called `KeepRasConnections`, but most likely you won't. It's not there by default. Add this value to your system as a type `REG_SZ`, and give it a value of 1 (the default behavior is indicated by a 0). This will instruct the client workstation to keep the RAS connection open, even when the user at the workstation logs out.

### **“No matter what I try, I can't seem to get a modem connection from a workstation to my RAS server.”**

If you're in this boat, you have two places to start diagnosing the problem: the server or the client. Fortunately, you might get lucky with the server diagnosis—if other users or workstations can successfully dial in to the RAS server, then it's probably not a server problem. So, the next course of action is to start troubleshooting the workstation.

The great advantage—and disadvantage—of the Windows operating system is that it hides the complexity of operating the underlying components of a system. For example, instead of knowing that to dial a modem you need to issue the command `ATDT5551212` and wait for the response, you simply need to know how to enter a phone number in the appropriate dialog box within Windows. But, what if you want to troubleshoot the dialing function? It would be helpful to see those commands as they are passed back and forth to your modem. Windows Server 2003 makes it an easy process to view the modem commands that RAS clients or RAS servers send.

By default, Windows Server 2003 will automatically log the commands that it sends to any modem. To view the log files for a particular modem, start out by selecting the Phone and Modem Options icon from the Control Panel. Click the Modems tab and then select the modem whose log file you want to view. Edit the properties for the modem, and then select the Diagnostics tab on the modem properties. You should see a View Log button on the diagnostics page—click it, and it will bring up a file named `%systemroot%\ModemLog_modemname.txt`. This file contains the history of all the commands passed back and forth between Windows Server 2003 and your modem.

Got a problem with a modem on a RAS server that never wants to answer calls? Try checking the log files to see if they're arguing over something. Got a RAS client that just can't seem to dial in, even though everything is configured correctly? Check the log and see if there's a problem with the initialization strings that Windows Server 2003 is sending. These log files can help you go far in your troubleshooting endeavors.

### **“Can I make a RAS client automatically dial in to a RAS server at a specified time?”**

Absolutely!

For example, let's say that you wanted to have an automatic routine set up for each office to call into the home server (called `HOMEbase`) every night and transmit its sales figures, back up a few key data files, etc. You'll need to create the following:

- ◆ A dial-up networking connection with the properties for the remote server (we'll call it `HOMEoffice` in our example)
- ◆ A batch file to dial the dial-up networking connection and transfer the files
- ◆ A job in Scheduled Tasks to trigger the batch file to run nightly

Now, the creation of the dial-up networking entry is pretty straightforward. We've covered that at length earlier in this chapter. The batch file that you create might look similar to the following (the important line to note is the `RASDIAL` command):

```
@ECHO OFF
CLS
ECHO Transmitting updates to HOMEbase server
RASDIAL HOMEoffice
NET USE X: \\HOMEbase\sharename
XCOPY C:\TRANSFER\*.* X: /S /E /Y
ECHO Updates to HOMEbase server completed—hanging up
RASDIAL HOMEoffice /DISCONNECT
```

**TIP** If you receive an error telling you that *RASDIAL* can't find the phonebook entry *HOMEOFFICE*, you might have to specify the path to the phonebook file (*.pbk*) in the batch file.

Now, the commands here are pretty straightforward, but the key is the *RASDIAL* command. This is a command-line utility that will automatically dial a dial-up networking entry. For this to work you will need to have cached the username and password credentials on the dial-up networking entry that is named (*HOMEOFFICE* in this case). After that, the batch file runs some standard commands to connect to a share on a server, and then copy files up to the server. After the commands are completed, the *RASDIAL* command will hang up the connection.

Test the command out to make sure that it works properly interactively—running it from the keyboard. Once you're sure that all the timing and sequence is correct for your needs, it's time to schedule the batch file to run nightly.

By default, the scheduler service is automatically installed in Windows Server 2003, so setting up a job is as simple as a few point and clicks. To create a schedule, start out by launching the Scheduled Tasks icon from the Programs/Accessories/System Tools menu. Click Add Scheduled Task to add a new task to your system, and then proceed through the wizard panels as prompted. Schedule the batch job to execute on a nightly basis, and then leave it alone as the system obeys and runs your batch file every night.

You could even get fancy with your batch file by trapping certain error levels—sending alert messages if there are errors, etc.

### **“My dial-up users aren't getting the WINS and DNS addresses that are defined on our network.”**

Due to the nature of the communications protocols used for dial-up connections versus local network connections, the rules are a little bit different when it comes to how clients get their WINS and DNS configurations.

For LAN connections, it's a pretty straightforward process: the workstations will use WINS and DNS settings that are either hard-coded into the TCP/IP stack, or whatever they receive from a DHCP server's scope properties.

So, it should work the same for dial-up connections, right? The workstation should either use its own hard-coded settings or the settings defined on a DHCP server, right? *Wrong!*

Once, this little quirk had me stumped for the better part of a day at a client's site. Here's what happens—by default, Windows Server 2003 RAS servers will offer WINS and DNS addresses to clients based not on what the DHCP scope says, but whatever is configured for the RAS server *itself*. So, if you have your network's DHCP configuration setup perfectly, but you forgot to hard-code the correct WINS or DNS configuration in the RAS server, your RAS clients will be misconfigured when they dial in.

### **“I don't want my dial-up users to get the WINS and DNS addresses that are defined on our network.”**

Okay, so let's say that you want to override the default behavior of RAS to offer its WINS and/or DNS addresses to clients that are dialing in, without removing the WINS and DNS configuration from the RAS server itself. In that circumstance, you'll need to dive into the Registry to tweak Windows Server 2003 a bit.

To prevent your RAS server from offering a WINS address to dial-in clients, look in the following key in the Registry:

```
HKEY_Local_Machine\System\CurrentControlSet\Services\  
RemoteAccess\Parameters\IP
```

You may see a value in that key called **SuppressWINSNameServers**. If you do, set the value to 1. If you don't see the value in there, add it and set it to a value of 1.

To prevent your RAS server from offering a DNS address to dial-in clients, look for a value called **SuppressDNSNameServers**. If you see that value there, set it to a 1. If you don't see the value in there, add it and set it to a value of 1.

## Chapter 21

# Novell NetWare and Windows Server

THIS CHAPTER WAS INTENDED for those of you who are working on a network that has both Server 2003 servers and NetWare. Although it is always possible to migrate all of your servers over to Windows Server, there may be some compelling reasons not to—the best reason being that Novell NetWare will run (and run well) on computers that cannot run Server 2003. To migrate, you'd have to buy new equipment. Frankly, if the NetWare servers are working, why get rid of them? Integration may be the cheapest, most convenient, and most efficient way to make the best of the resources you have. That is why this chapter will cover what is left of Windows' integration components with NetWare—and what Novell has done to compensate for Microsoft's lack of NetWare support.

In order to be sure that we're all on the same page, I am going to cover some NetWare terminology and basic concepts before actually going into integration. It helps to know what I'm talking about before I start telling you what to do. My apologies to those of you who are CNEs. I'll try to be brief.

Ever try to buy the workstation version of NetWare? You know, call your local software vendor and ask them to quote you a price on NetWare 6 workstation. You are not going to be asked if you would like the professional or home edition, that's for certain.

NetWare has always been a server product only. From the beginning, Novell was wise to keep it simple. NetWare is simply a network operating system that services clients with files, printers, and the like. A true server. No solitaire, no word processor. Heck, until relatively recently, it was menu driven. No wasted processor effort drawing windows.

And that is both its strength and its weakness. You see, NetWare is a server that services clients. Any client. DOS, Unix, Macintosh, Windows of any flavor. It was built that way, already supporting diversity out of the box. Integration is NetWare's game by definition. But the craving to just buy the workstation operating system that was designed to be a particular server's client is pretty overwhelming. Thus, Windows dominates in the networking world.

In order to get a Unix, Mac, DOS, or Windows 95 through XP workstation to access a NetWare server, you need to make them a NetWare client. To do that, you just install the appropriate client

software on the workstation of your choice. Once the software is installed, you can log in to the NetWare server and access the resources that are located there. It's the software that is the client. NetWare makes the client software available from their Web site. (It may take some searching if you actually want to use a DOS client. There is a client available from the cool solutions/cool tools page.)

Now then, why would Microsoft want to make its own NetWare integration tools? If Novell's already got it covered, then what's the point, right? Well, two things: One, Novell's client software for Windows was not necessarily without flaws. Two, Microsoft, saw an opportunity to service its customers and corner a little bit more of the market. Because of that, Microsoft added the Client for NetWare component to its operating systems (both server and workstation).

That is why Windows supports their version of Novell's IPX/SPX networking protocol, which they called NWLink. That, along with their own design of the Novell Client, made it possible for the Windows machines to access NetWare files without resorting to using anything but Microsoft products to get there.

There is one small inconvenience, of course, and that is having to install the client software (or add the Windows component) on all of the machines that will need it. You can use the Novell client, you can use the Windows client, but however you cut, client software must be on each workstation.

Thus, Gateway service for NetWare was created. This service is available on NT and 2000 but *not* Server 2003. The Gateway service made it possible for machines that do not have the NetWare client software installed to access files on the NetWare server. The Gateway service used the Windows server to handle NetWare share points as if they were located on the Windows server itself. Completely transparent to the workstations, it removed the necessity of loading the client software.

Unfortunately, Server 2003 does not have Gateway service for NetWare. Strangely enough, it can still be a NetWare client. I'm sure we all find that comforting.

Also, an interesting fact. Let's say that you want to migrate away from your NetWare servers to Windows Server. I would think that Microsoft would love the idea and would definitely have software at the ready for you to do just that. Free on the CD, and an easy download away.

I would be wrong.

Originally, Windows NT had migration software available on the Server CD. The beta version of Windows 2000 had it on the CD. But by the time Windows 2000 went retail, Directory Service Migration Tool (DSMT) and File Migration Utility (FMU) were pulled from the CD, bundled together with a few other tools for about \$200 (give or take, check with your vendor) and called "Services for NetWare." Thus, quite possibly making migrating to Windows not entirely cost effective.

If you are turned off by the idea of having to install Client for NetWare on all of your workstations and servers to access the NetWare files, don't be. Novell has come up with a way to centrally manage client access from the NetWare server, avoiding client software altogether. They created Native File Access (NFA), so Windows clients can access the servers as if they were Server 2003 servers. And, being as broad minded as they are, Novell also has native file access for Unix and Macintosh too. (Not that we are going to need them here, I just thought I'd mention it.) Make note, NFA is relatively new, and because of that it works only with NetWare 5.1 (with Service Pack 3 and higher) and 6 (straight out of the box). I think it goes without saying that it will probably be available on all new versions of the NOS as well.

## NetWare 101: The Basics

Although I don't intend to use this chapter to prepare you for Novell certification, I am going to briefly explain two concepts that I think will help you understand why NetWare uses the terminology it does, when it does. These two concepts are NetWare's Directory Service and the way it handles its filesystem.

### Directory Service

In 2000, Microsoft came out with its own directory service, Active Directory. NetWare has had had its own Novell Directory Service (NDS) for quite a while. It has been upgraded with newer versions of NetWare and is now called eDirectory but, for our purposes, any version does what we need it to do, so I will refer to Novell's Directory Services, new or old, as NDS. This directory service is suspiciously similar to Active Directory but has been around much longer (you can make your own assumptions). There are trees, containers such as organizations and organizational units (OUs), users, computers, and other objects.

As in AD, designing the NetWare tree takes some planning. It is a bit different though. With an NDS tree, you define the tree name, and then you choose the container that the server or servers will reside in. These large containers can be called country, organization, or domain. There are several large container types to choose from because some businesses are structured geographically while others are structured organizationally. Recently, Novell added the domain type of container for administrators who are partial to domain models. All the containers function in basically the same way: they organize groups of servers, user accounts, and other resources for management and logical convenience. And, just like domains in a tree in AD, there can be more than one of these large containers in a NetWare tree, any of which can contain any number of organizational units and other objects.

NDS tends to think of users as an object essentially equal to servers and not "contained" in them per se. They can be in the same organization as the server, or they can be located in an OU within that organization (and they are generally organized by OU, just as they are in AD). Because of this, NetWare users may need to specify the "context" or container their account is in explicitly, not just their tree and organization. Generally, when you log in to a NetWare server, you are really logging in to the container where your user account resides. You will typically be using a login dialog box that has a field in which to specify the tree, a field for the big container, and a field for the username. To further specify where the user account really is, you will need to add the context of the exact container in which the user account is located by adding it to the username itself. The syntax for entering a username with context on one line is *username.container*. Just like a domain name, there has to be a period between the username and the container name. If the container (probably an OU) is nested within another container, the context will be nested as well, from small to big: for example, *username.subOU.OU*.

In your network environment, your NetWare administrators may have set up their Novell servers and clients to allow for Contextless Login. This can require NetWare to scan the NDS tree for all users regardless of what OU they are in (especially if the NetWare admin has not set up a catalog on the server of containers for the users). If there are several John Smiths and one of them is trying to log in, a list will pop up to allow him to choose the right one (you hope), then enter his password.

## Filesystem

Because NetWare likes to keep it simple, doesn't fix what isn't broken, and has been around for a long time, it uses DOS. DR DOS to be precise, but DOS nonetheless. As a matter of fact, the boot partition of the NetWare server's hard drive is a DOS partition. That also brings us to another NetWare naming convention. The NetWare partitions are not given a new drive letter and a name, as they are in Windows. They are volumes, so they are given volume names. In NetWare, the first partition is usually called SYS, and additional volumes are inevitably named, vol1, vol2, vol3, and so on. Not particularly creative or intuitive, I know. This is probably because, being rooted in DOS, the administrators instinctively keep names short (especially since many patches and support packs are DOS based). Mind you, this does not mean that NetWare cannot handle long filenames.

In order to access files on a Server 2003 server, the user must have a valid account and password. That account must have the right to access the folders and use files. That helps secure the resources on the network. I guess it comes as no surprise that NetWare also requires any user accessing its filesystem to have a valid user account and password. Although it is redundant (and therefore must be managed at both servers), it is logical.

I can almost hear you groaning about the extra work necessary to create and manage dual user accounts. Chances are that the NetWare server already has user accounts for all users who access files there, but even if they haven't been created already, there are several handy tools that the NetWare administrator can use to import users into NetWare from AD. All you need is a valid username and password. There is no need, on the NetWare side, to do anything else but give the users rights to folders, so no fussing with home directories or login scripts unless you want to.

***TIP** Native File Access (NFA) has a User Import Utility that will pull user account names and passwords from the authenticating domain controller and create simple NetWare accounts with them. Just make sure NFA is set to Domain Mode so it can find the correct Domain Controller to pull from.*

Now that I've covered the particulars of NetWare, specifying a user context during login and browsing through volumes on the server should make more sense. That said, it's time to delve into the mysteries of the NetWare client.

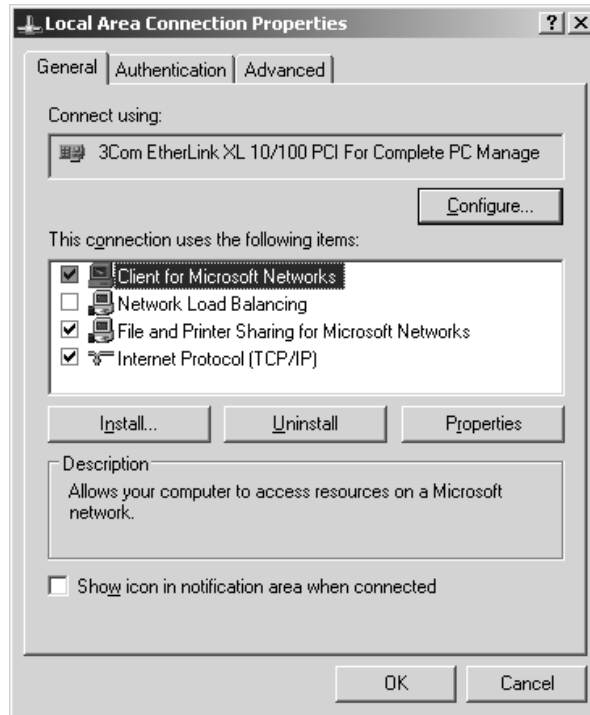

## CSNW (Client Service for NetWare)

Client Service for NetWare (CSNW) hasn't changed much over the years. It requires NWLink IPX/SPX and NetBIOS over IPX/SPX to communicate with the NetWare servers, so it installs these protocols during its install process. It uses the username and password that is being utilized to log in to the workstation to authenticate to the NetWare server. Obviously that inhibits logging in to the Server 2003 network as one person and logging in to the NetWare network as another. It's important to make sure the NetWare user account matches the user account on the Server 2003 domain controller for everyone who will be using CSNW. Once CSNW is installed, it runs pretty much invisibly.

To add the CSNW to the Server 2003 server (or to an XP workstation, for that matter), you will need to access the Local Area Connection properties page. On an XP Workstation, right-click Network Places on the Start menu and choose Properties. Alternatively, go to the Control Panel and select Internet and Network Connections, choose Network Connections, right-click the Local Area Connection icon, and select Properties from the drop-down menu. On a Server 2003 server, choose Control Panel from the Start menu, go to Network Connections, and select Local Area Connection (see Figure 21.1).

**FIGURE 21.1**

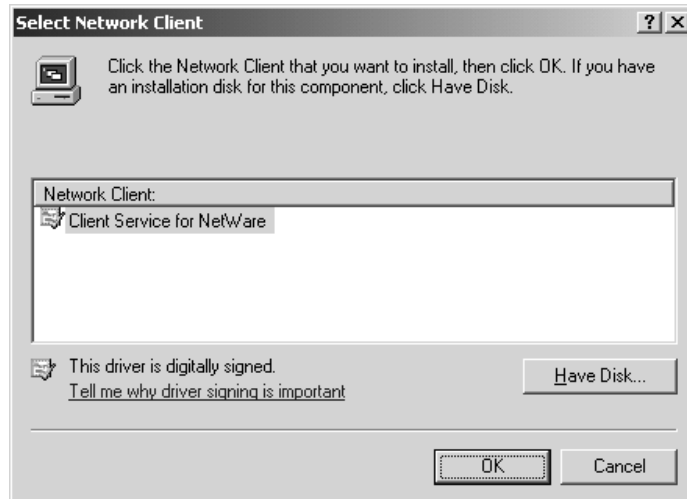

Local Area  
Connection  
properties page

Click Install. It will bring up a dialog box that will list the type of component you could install. Select Client and click Add. In the Select Network Client dialog box (see Figure 21.2), choose Client Service for NetWare (it may be your only choice) and click OK.

**FIGURE 21.2**

Installing Client  
Service for NetWare

In a moment or two, you will be prompted to reboot the computer. Because, by definition, the Client Service for NetWare is intended for clients, it does require a reboot. This, of course, is not generally something that an administrator wants to do with a Server 2003 server during business hours—unless they actually enjoy talking to a large number of irate users.

Once the computer has rebooted and you log back in, you will be prompted to enter either the name of the NetWare server you prefer to use, or the tree and context (container) in which your NetWare account is located (see Figure 21.3). This second option is useful if there is more than one server in the organization (or country or domain) your account belongs to.

**FIGURE 21.3**

Logging in to  
NetWare Network

**TIP** The choices you make in the Select NetWare Logon dialog box will be saved to the local drive and used when you log in again. If you want to change your preferred server or context, you will need to go to the Control Panel, change to Classic View, and double-click the CSNW icon.

Once the Desktop comes up, it will appear as if nothing has changed. To see if CSNW did in fact install NWLink IPX/SPX-compatible protocol and NWLink NetBIOS, go to the Local Area Connection properties page (see Figure 21.4). They should be listed.

**NOTE** If you are having a problem getting CSNW to work, remember that it uses IPX/SPX. Early versions of NetWare used the nonstandard Ethernet frame type 802.3; all newer NetWare servers use 802.2. It is possible for the auto-detect feature of NWLink to choose the wrong one. Pretty unlikely, but possible. You can fix this problem by selecting the NWLink IPX/SPX/NetBIOS Compatible Transport Protocol, then clicking the Properties button. In the properties page, you can choose to manually add the appropriate frame type.

To access the newly available NetWare servers, simply browse to your network through My Network Places (or whatever way suits your fancy). You will notice that there is a new NetWare or Compatible Network icon (see Figure 21.5).

If you double-click the NetWare network icon (or select it in the Folders list, as I did in Figure 21.6), you will be presented with the icons for the tree and/or server(s) that fit your context (if you've ever played with Windows' pre-existing icons and wondered what the tree was for, now you know).

**FIGURE 21.4**

Making sure  
NetWare-  
compatible  
protocols are  
installed

**FIGURE 21.5**

New NetWare  
Network icon

If you double-click a server, it will display the volumes available (see Figure 21.7). You may not have the right to access them all, but they are there. You can map a drive letter to a volume or directory just like any other network drive.

If you were to open up one of those volumes (assuming you have the rights to), you would see that the filesystem (as shown in Figure 21.8), complete with long names, is just like that of Windows.

**FIGURE 21.6**

NetWare resource icons

**FIGURE 21.7**

NetWare volumes

Windows' Client Service for NetWare is pretty straightforward. It integrates well with Windows software (for obvious reasons). Also, since it is not a separate software package, you don't have to worry about installing upgrades, patches, or service packs.

CSNW does have some limitations, one of which is the fact that your Windows login has to match your NetWare login. If this is a problem and you would like to monitor your connections or have additional functionality other than logging in and that's it, installing Novell's Client may be the right

thing for you. Be aware that this product is not supported by Microsoft (since it's made by Novell), so it may not play nice with some software packages, and it may be difficult to uninstall. I suggest you test it before you install it on a production machine. And, just to be safe, never load it on a Server 2003 server that's in production (to avoid any software fighting on the server during work).

**FIGURE 21.8**

List of folders on the NetWare server

On the other hand, the Novell Client is really convenient to use. Once you've had it installed for a while, you'll wonder how you got along without it. It is especially useful for and designed to support administering NetWare servers and services from the client (by someone with the correct rights of course).

## Novell's Client for Windows (Client32)

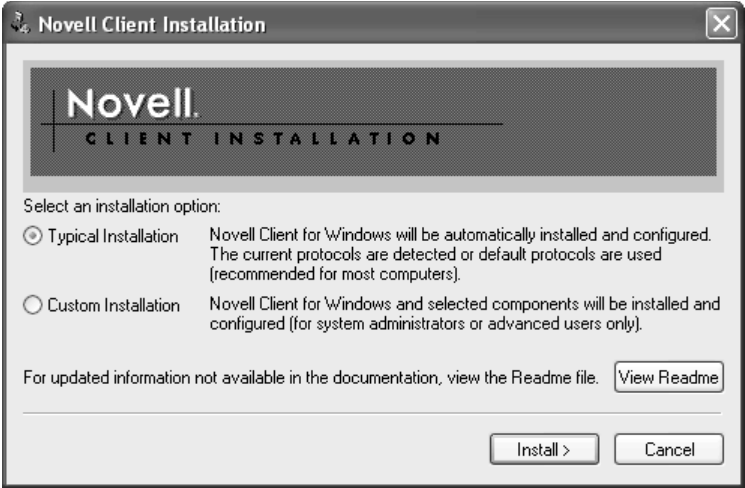

To install the Novell Client for Windows, affectionately known as Client32, you first need to download it from Novell's Web site. It will be easy to find, even if Novell makes changes to their site.

Once you have downloaded the client software, unzip it to a location of your choice (preferably a network share, if you are going to be using it elsewhere in the future). In that location, it will unzip to a folder called WINNT.

Open WINNT, open the subfolder called i386, and scroll to the setupnw file. Double-click setupnw to launch the Novell Client Installation program (see Figure 21.9). For a typical client, perform the typical install. If you are going to be administering any NetWare servers, you may want to do a custom install and add additional components.

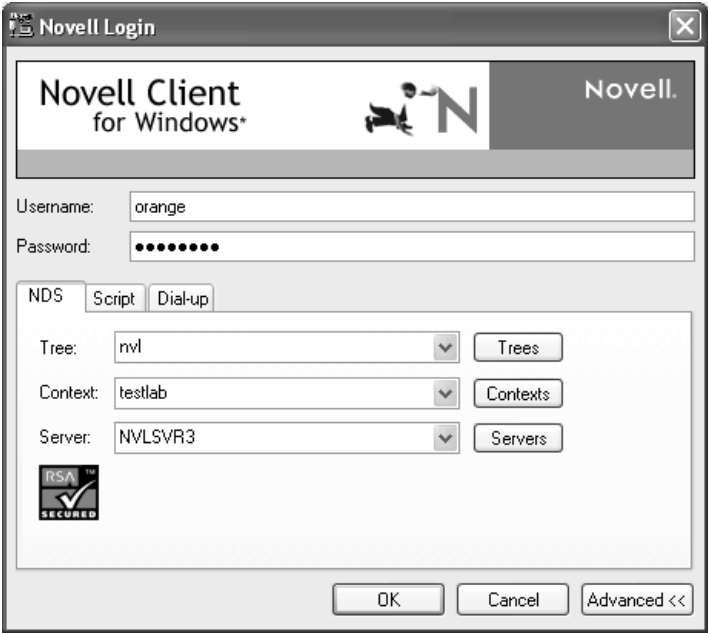

**WARNING** *If you have Microsoft's Client Services for NetWare running, it will be uninstalled during the Novell Client installation process, otherwise it will cause conflicts as to which software package controls NetWare server access. You will be prompted to allow the installer to remove CSNW. You really don't have any choice; the install will abort if you don't allow the removal of CSNW to happen.*

**FIGURE 21.9**  
NetWare Client  
Installation program

After the installation is complete, you'll be prompted to reboot. The first thing you'll notice after rebooting is that the Windows Welcome screen has been replaced by a Novell Client box with a picture of three big Ctrl, Alt, and Del buttons on it (and the words "to login" next to them). If you press Ctrl+Alt+Del, the Novell Login dialog box displays (see Figure 21.10).

**FIGURE 21.10**  
Novell Login  
dialog box

This dialog box obviously has more going on than CSNW did. It can have separate tabs (if you click the Advanced button during login, as shown in Figure 21.10) for things like logging in with different NetWare and Windows accounts and displaying login scripts. If the NetWare server needs to be accessed via dial-up, dial-up settings can be managed here. At the very least, the Novell Client gives the user the opportunity to log in to Windows as one user and NetWare as another if they need to. This can be very useful if you need to log in using an administrative account on the Windows machine, and you need to log in as an administrator on the NetWare server. These two accounts will usually be different, if only for the sake of security. There are separate tabs for NetWare and Windows.

Once you've logged in, you may notice that there is a red *N* next to the clock in the system tray on the taskbar. Right-click the *N* and you will get a menu with a plethora of extra options for managing your client connection, mapping network drives, and configuring your client login (see Figure 21.11).

**FIGURE 21.11**  
Novell Client menu

### TO WHOM IT MAY CONCERN: CONTEXTLESS LOGINS

To save time, especially if there is no one else on the NetWare server with your username, the Novell Client can be set up to do contextless logins. (The NetWare server(s) may need to be first prepped by your NetWare admin to handle logins without context, depending on which version they are running, so check first.) Select Novell Client Properties from the red *N* pop-up menu and go to the Contextless Login tab to enable a contextless login (see Figure 21.12). Be sure to specify the user's tree and, if there is one, the catalog of OUs to search for users in this dialog box. If you don't do this, NetWare will browse every container in the tree looking for any account that matches your username. That will slow down the login process and possibly bring up that list of matching names (like John Smith) to choose from.

*Continued on next page*

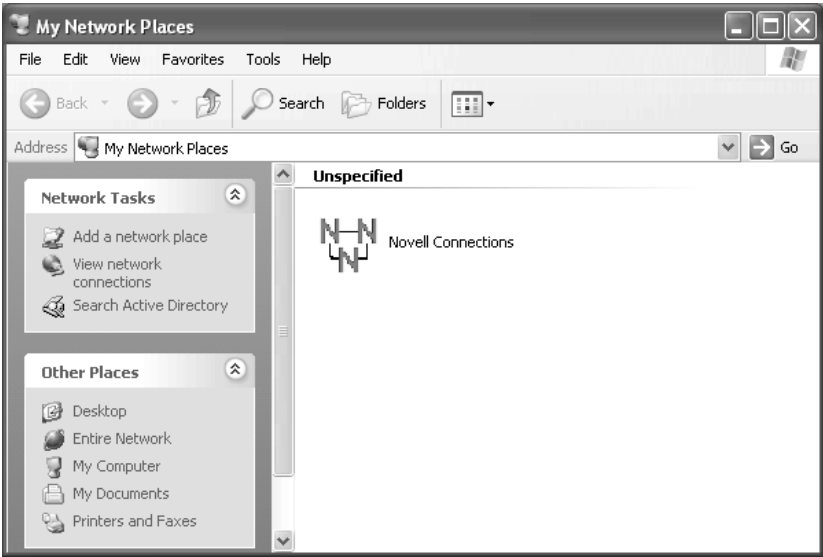

**TO WHOM IT MAY CONCERN: CONTEXTLESS LOGINS (continued)**

**FIGURE 21.12**  
Novell Client  
Configuration,  
Contextless Login

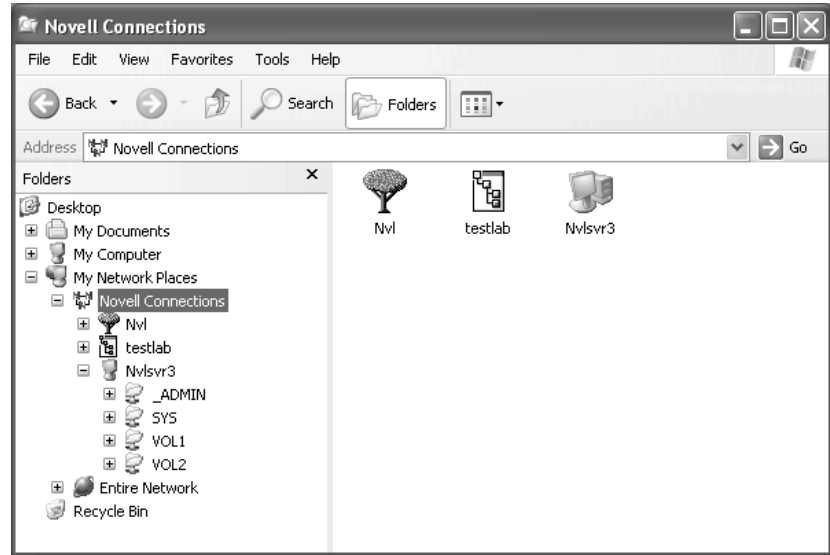

As far as file access is concerned, that has also changed a bit with the installation of the Novell Client. In My Network Places, there is now an icon consisting of a circle of red Ns that denotes a NetWare client's Novell NetWare connection (see Figure 21.13) and there is a new NetWare Services icon under Entire Network.

**FIGURE 21.13**  
New Novell  
Connections icon

Double-click the red Ns to access the NetWare resources (see Figure 21.14).

**FIGURE 21.14**  
NetWare resources

Up until this point, I have focused on managing the client's access to the NetWare network from the workstation point of view. If you do not want to install and support client software on every client machine just to access files on the NetWare servers, then you are in luck. Novell has created Native File Access (NFA) for Windows just for you... Well, maybe not you exactly, but people just like you.

## Native File Access for Windows

Available as part of the Native File Access Pack (NFAP) from Novell, NFA for Windows is a NetWare server-based software package that makes client-side opening, saving, and working with NetWare stored files possible, without installing any NetWare client software. In many cases you can take a new Windows workstation, configure TCP/IP and, as long as there is a valid NetWare user account (and license), immediately start using it to access files on the NetWare servers.

NFA for Windows uses CIFS (Common Internet File System) over TCP/IP to give Windows clients the impression that they are browsing a Windows server. Like SMB (Small Machine Block) protocol, it is easily recognized by Windows clients as a filesystem it can use to share files.

CIFS file shares, and the display name for the server to the Windows clients, can be set in the CIFS properties page during install or under the properties of the NetWare server. If no file shares are specified, CIFS should display all volumes. (This is another good reason for the NetWare administrator to take user rights to files and folders seriously.)

To use CIFS, the Windows clients need to authenticate somewhere to be given access to the volumes on the NetWare servers. To this end, Novell offers two different authentication methods: Local and Domain.

Local authentication means that the Windows user has a user account on the NetWare server that has a simple password. The name is misleading though. It doesn't mean the password is insecure or needs

to be short and easy to crack. Novell's eDirectory Service password uses a one-way hashed algorithm. Microsoft clients cannot do one-way hash. Thus, the simple password was created as a work-around. It allows Windows clients to have NetWare passwords that they can understand, while allowing the password to be encrypted enough to be secure. This means, however, that either the user updates their NetWare password every time they change their Windows password (which means administrators have to make sure that every NetWare user account has a simple password that matches their Windows account), or they end up with two passwords. Although inconvenient, using simple passwords with local authentication is the method preferred by Novell and is extremely stable and easy to use.

**NOTE** *An NDS password and a simple password are not the same thing. They can and should match, but a NetWare account can have both.*

Domain authentication means that the users utilize their Windows username and password to get to the files on the NetWare servers. The NetWare server gets the user information and passes it on to the domain controller, which accepts it if it's valid and passes the acceptance back to the NetWare server, which then lets the user access whatever files they have rights to. Mind you, there still needs to be a user account on the NetWare server that matches the Windows account because it is something to apply rights and restrictions to. Using Domain authentication allows Windows clients to only have one password. If their Windows password changes, that's okay because they don't have a simple password on the NetWare server to update.

Domain authentication is more complicated to implement and, if something goes wrong, it's harder to troubleshoot. However, it is a great way to limit the administrative load while giving users NetWare file access.

**NOTE** *NetWare 6 installs NFAP during its setup. The administrator can choose at that time to initiate the Local or Domain login method. They can change the method after installation, but they may have to stop and start CIFS in order for it to take hold properly.*

**TIP** *NetWare 5.1 does not set up NFAP during installation (since it was released to CD before NFAP came out), but it can be added after the fact. The administrator needs to be sure that Service Pack 3 and any necessary patches have been installed before installing NFAP.*

NetWare does not use fully qualified domain names to find Windows servers. Because of that, a WINS server needs to be up and accessible to the NetWare server if it is supposed to handle Domain logins. NetWare communicates with the Server 2003 server by way of NetBIOS over TCP/IP (NBT), especially while negotiating Domain authentication, so the Server 2003 server needs to be sure that it is accepting NBT over TCP/IP at all times. By default, Server 2003 enables NBT if the address from which it is receiving NetBIOS broadcasts is a static address, but it is best to manually set the Server 2003 server to explicitly accept NetBIOS over TCP/IP.

To check if NBT is enabled, go to the Local Area Connection properties page. Select Internet Protocol (TCP/IP) and click Properties. Click Advanced and turn to the WINS tab (see Figure 21.15). Make certain that Enable NetBIOS over TCP/IP is selected.

There are a few other preparations you can make on the Server 2003 server to prepare it to perform domain logins with NetWare. The NetWare server will need to have a computer account in the Server 2003 domain. When creating the computer account, make sure that you check the Assign This Computer Account as a Pre-Windows 2000 Computer. This will help Server 2003 realize that it uses NetBIOS.

**FIGURE 21.15**

Enabling NetBIOS over TCP/IP

**TIP** If authentication is set to Local, once there are user accounts in the NetWare tree, the NetWare administrator can use NFAP Security in the Remote Manager to generate simple passwords for every user it finds.

To use files stored on a NetWare server from the Windows client side, just browse to it in My Network Places (or however you generally like to get to network resources). Once you select the server you would like to access, a dialog box will pop up requiring a username and password (see Figure 21.16).

**FIGURE 21.16**

Connecting to a NetWare server with NFA

**NOTE** Remember that you may need to use the syntax `username.context` in the Username field if CIFS is set for Local authentication.

Authentication will take place (it may take a few moments), and then the contents available for CIFS sharing will appear in the window (see Figure 21.17). It's that easy. Notice that the NetWare server (I gave mine the name "netshare," otherwise known as `nvlsvr3w`) shows up under Microsoft Networks looking just like a Windows server.

**FIGURE 21.17**

Native file access to NetWare resources

Integration seems to be a word that many network administrators avoid. I'll admit that it may be easier to handle a homogenous environment, where every server is just like every other one, and workstations are identical. But in the real world, operating systems (and hardware) can vary greatly. Things come and go over time, directions change. And, just like the people who use them, these different networks can work together. It may take some effort, but it's worth it. Or maybe, just maybe, you might not have any choice. Sometimes you just have to make it work.

I hope that, instead of giving up on your NetWare resources, you have learned from this chapter how easy it is to give Server 2003 network users access to the NetWare servers, despite their differences.
